- Cardiac MRI: up to 76% Se, 96% Sp for myocarditis or infiltrative disease (*JACC Imaging* 2014;7:254); nontransmural delayed gadolinium enhancement in *noncoronary* distribution suggestive of DCM; extent of midwall fibrosis correlated w/ mortality in NICM (*JAMA* 2013;309:896)

- Laboratory evaluation: TFTs, iron studies, HIV, SPEP, ANA; others per clinical suspicion; viral serologies *not* recommended (*JACC* 2012;59:779)
- Stress test: useful to r/o ischemia (low false ⊖ rate), high false ⊕ rate, even w/ imaging
- Coronary angiography to r/o CAD if risk factors, h/o angina, Qw MI on ECG, equivocal ETT; consider CT angiography (*JACC* 2007;49:2044)
- ? Endomyocardial biopsy (*JACC* 2007;50:1914)

  yield 10%: of these, 75% myocarditis (for which no proven Rx) & 25% systemic disease

  40% false ⊖ rate (patchy dis.) & false ⊕ (necrosis → inflammation)

  ∴ biopsy if: acute & hemodynamic or electrical compromise (r/o GCM, ANEM); arrhythmia or RCMP features (r/o infiltrative); or suspect toxic, allergic, tumor
- Family hx & genetic testing (*JAMA* 2009;302:2471; *Circ* 2013;128:e240)

  family hx for ≥3 generations; incomplete penetrance and variable expression make dx of familial CMP challenging

  sequencing of DCM gene panels now available; typically test most clearly affected person

  if specific mutation identified, then can screen family using genetic testing

  if no mutation identified, consider cascade clinical screening (ECG, echo) of 1° relatives every ~3-5 years

Treatment (see "Heart Failure" for standard HF Rx)

- Implantation of devices may be tempered by possibility of reversibility of CMP
- Immunosuppression: for giant cell myocarditis (prednisone + AZA + cyclosporine), collagen vasc disease, peripartum (? IVIg), & eosinophilic; no proven benefit for viral myocarditis
- Prognosis differs by etiology (*NEJM* 2000;342:1077): postpartum (best), ischemic/GCM (worst)
- Abstain from EtOH (for alcoholic CMP and reasonable for others)
- Consider ACEI and/or βB if genotype ⊕ but currently phenotype ⊖

HYPERTROPHIC CARDIOMYOPATHY (HCM)

Definition and epidemiology

- LV (usually ≥15 mm) and/or RV hypertrophy disproportionate to hemodynamic load
- Prevalence: 1/500; 50% sporadic, 50% familial, most asymptomatic
- Autosomal-dominant mutations (> 1500) in cardiac sarcomere genes most common genes involved: β-myosin heavy chain (*MYH7,* ~40%), myosin-binding protein C (*MYBPC3,* ~40%), cardiac troponin T (*TNNT2,* ~5%) and I (*TNNI3,* ~5%) no clear correlation between genotype and clinical course
- Noonan syndrome: HCM, pulmonic stenosis, ASD, short stature, pectus, webbed neck
- Ddx: LVH 2° to HTN, AS, elite athletes (wall usually <13 mm & symmetric and nl/↑ rates of tissue Doppler diastolic relaxation; LV cavity large; no late gadolinium enhancement on MRI; *Circ* 2011;123:2723), Fabry dis. (↑ Cr, skin findings)

Pathology

- Myocardial fiber disarray with hypertrophy, which creates arrhythmogenic substrate
- Morphologic hypertrophy variants: asymmetric septal; concentric; midcavity; apical
- LVH evolves over time, typically manifests in adolescence

Pathophysiology

- Subaortic outflow obstruction: narrowed tract 2° hypertrophied septum + systolic anterior motion (SAM) of ant. MV leaflet (may be fixed, variable or nonexistent) and papillary muscle displacement. Gradient (▽) worse w/ ↑ contractility (digoxin, β-agonists, exercise, PVCs), ↓ preload or ↓ afterload.

P.1-32

- Mitral regurgitation: due to SAM (mid-to-late, post.-directed regurg. jet) and/or abnl mitral leaflets and papillary muscles (pansystolic, ant.-directed regurg. jet)
- Diastolic dysfunction: ↑ chamber stiffness + impaired relaxation
- Ischemia: small vessel dis., perforating artery compression (bridging), ↓ coronary perfusion
- Syncope: Δs in load-dependent CO, arrhythmias

Clinical manifestations (70% asymptomatic at dx)

- **Dyspnea** (90%): due to ↑ LVEDP, MR, and diastolic dysfunction
- **Angina** (25%) even w/o epicardial CAD; microvasc. dysfxn (*NEJM* 2003;349:1027)
- **Arrhythmias** (AF in 20-25%; VT/VF) → palpitations, syncope, sudden cardiac death

Physical exam

- Sustained PMI, S_2 paradoxically split if severe outflow obstruction, ⊕ S_4 (occ. palpable)
- **Systolic murmur:** crescendo-decrescendo; LLSB; ↑ **w/ Valsalva** & standing (↓ preload)
- ± mid-to-late or holosystolic murmur of MR at apex
- Bifid carotid pulse (brisk rise, decline, then 2nd rise); JVP w/ prominent *a* wave
- Contrast to AS, which has murmur that ↓ w/ Valsalva and ↓ carotid pulses

Diagnostic studies

- CXR: cardiomegaly (LV and LA)
- ECG: LVH, anterolateral and inferior pseudo-Qw, ± apical giant TWI (apical variant)
- Echo: no absolute cutoffs for degree of LVH but septum/post. wall ≥1.3 suggestive, as is septum >15 mm; other findings include dynamic outflow obstruction, SAM, MR
- MRI: hypertrophy + patchy delayed enhancement (useful for dx & prog) (*Circ* 2015;132:292)
- Cardiac cath: subaortic pressure ▽ *Brockenbrough sign* = ↓ pulse pressure post-PVC (in contrast to AS, in which pulse pressure ↑ post-PVC)
- ? Genotyping for family screening, but pathogenic mutation ID'd in <½ (*Circ* 2011;124:2761)

Treatment (*Circ* 2011;124:e783 & 2012;125:1432; *Lancet* 2013;381:242; *EHJ* 2014;35:2733)

- Heart failure

  ⊖ **inotropes/chronotropes:** nonvasodilating βBs, CCB (verapamil), disopyramide

  Careful use of diuretics, as may further ↓ preload. Vasodilators only if systolic dysfxn. Avoid digoxin.

  If sx refractory to drug Rx + *obstructive* physiology (▽ >50 mmHg):

  (a) Surgical myectomy: long-term ↓ symptoms in 90% (*Circ* 2014;130:1617)

  (b) Alcohol septal ablation (*Circ* CV *Interv* 2011;4;256; *JACC* 2011;58:2322): gradient ↓ by ˜80%, only 5-20% remain w/ NYHA III-IV sx; 14% require repeat ablation or myectomy. Good alternative for older Pts, multiple comorbidities. Complic: transient (& occ. delayed) 3° AVB w/ 10-20% req. PPM; VT due to scar formation.

  No clear benefit of dual-chamber pacing (*JACC* 1997;29:435; *Circ* 1999;99:2927)

  If refractory to drug therapy and there is *nonobstructive* pathophysiology: transplant
- Acute HF: can be precip. by dehydration or tachycardia; Rx w/ fluids, βB, phenylephrine
- AF: rate control with βB, maintain SR with disopyramide, amiodarone; low threshold to anticoagulate
- SCD: ICD (*JACC* 2003;42:1687). Risk factors: h/o VT/VF, ⊕ FHx SCD, unexplained syncope, NSVT, ↓ SBP or rel HoTN (↑ SBP <20 mmHg) w/ exercise, LV wall ≥30 mm, extensive MRI delayed enhancement. EPS *not* useful. Risk 11%/y if h/o VT/VF, 4%/y if highrisk w/o h/o VT/VF (*JAMA* 2007;298:405).
- Counsel to avoid dehydration, competitive sports & extreme exertion
- Endocarditis prophylaxis not recommended (*Circ* 2007;16:1736)
- First-degree relatives: periodic screening w/ echo, ECG (as timing of HCM onset variable). Genetic testing if known mutation. ? CCB for preclinical HCM (*JACC* HF 2015;3:180).

RESTRICTIVE CARDIOMYOPATHIES (RCM)

Definition (*Circ* 2006;113:1807)

- Impaired ventricular filling with ↓ compliance in nonhypertrophied, nondilated ventricles; normal or ↓ diastolic volumes, normal or near-normal EF; must r/o pericardial disease

Amyloidosis (*Circ* 2011;124:1079 & 2012:126:1286)

- Extracellular deposition of misfolded proteins in a variety of organs (eg, heart, kidney, liver, autonomic nervous system; deposition leads to morbidity & mortality)
- Age at presentation ˜60 y; ♂: ♀ 3:2
- AL (primary; MM, light-chain, MGUS, WM): multiorgan disease (˜50% cardiac)
- ATTR (familial; mutation in transthyretin, TTR; *Circ* 2012;126:1286)

  V122I variant → 2.6× ↑ HF risk; 10% carriage in blacks >65 y w/ HF (*JACC* 2006:47:1724)

  V30M variant seen in European & Japanese

  T60R variant in Europeans, autonomic + peripheral neuropathy common

- SSA (senile; normal TTR): typically presents at age >70 y, prevalence >5% beyond age 80, ♂ >> ♀ (50:1), heart-only

- Workup

  ECG: ↓ QRS amplitude in AL (50%), pseudoinfarct pattern (Qw), AVB (10-20%), hemiblock (20%), BBB (5-20%)

  Echo: biventricular wall thickening (*yet* w/ *low voltage on* ECG), granular sparkling texture (30%), biatrial enlargement (40%), thickened atrial septum, valve thickening (65%), diastolic dysfxn, small effusions

  Normal voltage & septal thickness has NPV ˜*90%*

  Lab: SPEP, UPEP, serum free light chain ratio (<0.25 or >1.65 κ-to-λ ratio) 91% Se for AL amyloid (*Clin Chem* 2005;51:878)

  MRI: diffuse subendo late gado enhance, ˜90% Se/Sp vs bx (*JACC* 2008;51:1022)

  (99m)Tc-pyrophosphate PET: ↑ tracer retention in ATTR >> AL differentiates cardiac amyloid subtypes (*Circ Imaging* 2013;6:195)

  Cardiac bx: gold standard (˜100% Se due to widespread amyloid distrib) and permits subtyping of precursor protein. Abd fat pad bx 70% sensitivity for AL.

- Treatment: judicious loop diuretics often only tolerated Rx avoid digoxin (↑ toxicity w/ binding fibrils) and CCB (⊖ inotrope)

  βB or ACEI often poorly tolerated b/c of HoTN

  cardiac tx usually contraindic. b/c extracardiac involvement, but isolated cardiac AL amyloid combined heart/auto stem cell tx yields survival ≈ other RCM (*JHLT* 2014;33:149)

  LVADs not appropriate b/c small restricted LV and frequent RV dysfunction

- Prognosis (median survival after HF dx): AL <12 mo, ATTR ˜30 mo, SSA ˜60 mo

Sarcoidosis

- Noncaseating, granulomatous disorder that can involve any organ
- Recognized cardiac disease in ˜5% of those w/ systemic sarcoid, but imaging & autopsy data show myocardial involvement in >50%
- LV dysfxn (DCM ≥ RCM); MR can be due to involvement of papillary muscles
- ECG: AVB (75%), can be high grade; RBBB (20-60%); atrial & vent. arrhythmias
- Cardiac MRI: T2-imaging and early gadolinium detect acute inflammation (edema), nontransmural patchy delayed gado enhancement, particularly in basal and/or midventricular septum detects fibrosis/scar from chronic disease and predicts prognosis (⊕ LGE → 31× risk for adverse cardiac events; *JACC Imaging* 2013;6:501)
- Echo: regional WMA (particularly basal septum) with thinning or mild hypertrophy
- Nuclear imaging: thallium perfusion defects in a noncoronary distribution; gallium uptake in areas of active inflammation can guide steroid Rx; PET: ↑ FDG uptake in areas of active inflammation
- Cardiac bx w/ low yield as granulomas patchy
- Treatment: steroids are standard although have not been evaluated in RCTs; 47% of Pts w/ AV conduction disease improved w/ steroids (*Can J Cardiol* 2013;29:1034) and retrospective studies suggest ↓ mortality. For steroid-sparing or intolerance, consider MTX, AZA, chloroquine or anti-TNF drugs. Low threshold for PPM-ICD.

Hemochromatosis

- In middle-aged men (espec Northern European)
- 15% p/w cardiac sx, typically HF and conduction disturbances
- Cardiac MRI: myocardial T2* is reduced (<20 ms) in iron overload disorders and enables tracking of response to Rx
- Treatment w/ phlebotomy or, in one report, chelation has been associated with reversal of LV dysfunction (*JACC* 1986;8:436)

Other etiologies (*Circ* 2005;112:2047 & *JACC* 2010;55:1769)

- **Myocardial processes**

  Autoimmune (scleroderma, polymyositis-dermatomyositis)

  Infiltrative diseases (see primary entries for extracardiac manifestations, Dx, Rx)

  Storage diseases: Gaucher's, Fabry, Hurler's, glycogen storage diseases

  Diabetes mellitus

- **Endomyocardial processes**

  Chronic eosinophilic: Löffler's endocarditis (temperate climates; ↑ eos; mural thrombi that embolize); endomyocardial fibrosis (tropical climates; var. eos; mural thrombi; *NEJM* 2008;359:43); treat for heart failure, steroids early, anticoagulation for thrombus

  Toxins: radiation (also p/w constrictive pericarditis, valvular dis, ostial CAD), anthracyclines

  Serotonin: carcinoid, serotonin agonists, ergot alkaloids

  Metastatic cancer

Pathology & pathophysiology

- Path: normal or ↑ wall thickness ± infiltration or abnormal deposition
- ↓ myocardial compliance → nl EDV but ↑ EDP → ↑ systemic & pulm. venous pressures
- ↓ ventricular cavity size → ↓ SV and ↓ CO

Clinical manifestations (*Circ* 2000;101:2490)

- **Right-sided > left-sided heart failure** w/ peripheral edema ± ascites > pulmonary edema
- **Diuretic "refractoriness"**
- **Thromboembolic events**
- Poorly tolerated tachyarrhythmias; VT → syncope/sudden cardiac death

Physical exam

- ↑ JVP, ± Kussmaul's sign (JVP ↑ w/ inspiration, classically seen in *constrictive pericarditis*)
- Cardiac: ± S_3 and S_4 (usually absent in amyloid b/c atrial dysfxn), ± murmurs of MR and TR

- Congestive hepatomegaly, ± ascites and jaundice, peripheral edema

Diagnostic studies

- CXR: normal ventricular chamber size, enlarged atria, ± pulmonary congestion
- ECG: low voltage, pseudoinfarction pattern (Qw), ± arrhythmias
- Echo: ± symmetric wall thickening, biatrial enlarge., ± mural thrombi, ± cavity oblit. w/ diast dysfxn: ↑ early diast (E) and ↓ late atrial (A) filling, ↑ E/A ratio, ↓ decel. time
- Cardiac MRI/PET: may reveal inflammation or evidence of infiltration (but nonspecific)
- Initials labs: SPEP, UPEP & serum free light chains, Fe studies (transferrin sat, HFE mutation), BNP (typically higher in RCM than in constrictive pericarditis)
- Cardiac catheterization: atria: **M's** or **W's** (prominent *x* and y descents)

  Ventricles: **dip & plateau** (rapid ↓ pressure at onset of diastole, rapid ↑ to early plateau)

  Concordance of LV and RV pressure peaks during respiratory cycle (vs discordance in constrictive pericarditis; *Circ* 1996;93:2007)
- Endomyocardial biopsy if suspect infiltrative process; fat pad bx for amyloid
- Restrictive cardiomyopathy vs constrictive pericarditis: see "Pericardial Disease"

Treatment (in addition to Rx'ing underlying disease)

- Gentle diuresis. May not tolerate CCB or other vasodilators. Avoid digoxin in amyloid.
- Control HR (but can ↓ CO); maintain SR (helps filling). Digoxin ↑ arrhythmias in amyloid.
- Inotropes may have limited efficacy due to small ventricular cavity & preserved systolic fxn
- Anticoagulation (particularly with AF or low CO)
- Transplantation for refractory cases

OTHER CARDIOMYOPATHIES

Arrhythmogenic (right ventricular) cardiomyopathy (ACM, formerly ARVC)

- RV or biventricular (˜50%) or isolated LV (rare) dysfxn due to fatty infiltration and fibrous replacement (small amount of former normal variant) (*Lancet* 2009;373:1289)
- Due to mutations in desmosome (cell-cell coupling): eg, plakophilin 2, desmoglein, desmo-plakin; abnl Wnt signaling leads to myocytes → adipocytes
- Naxos syndrome (mutation in plakoglobin): wooly hair, palmar & plantar keratoses, ACM
- Clinical phases (*Circ* CV *Gen* 2015;8:437): (1) subclinical w/ nl imaging, but ↑ risk of SCD;

  (2) abnl ventricular fxn on imaging, sx ventricular arrhythmias (VT w/ LBBB morphology w/ superior axis), but no HF; (3) RV failure; (4) ? LV failure
- ECG: ± RBBB, TWI V_1-V_3, ε wave 
- Dx w/ MRI

- Avoid bx as septum usually *not* involved (∴ high false ⊖ rate) and risk of perforation w/ free wall bx
- Major dx criteria (*EHJ* 2010;31:806): (1) regional RV akinesia/dyskinesia and ↑ RVEDV;

  (2) fibrous replacement of RV free wall; (3) TWI V_1-V_3, (4) ε wave
- Treatment (*Circ* 2015;132:441): usual HF Rx; EP study & ICD; VT ablation as needed

Ion channelopathies (CMP despite lack of structural abnl; *Circ* 2006;113:1807)

- Defective ionic channel proteins lead to abnl cell membrane transit of Na and K ions
- Disorders include: LQTS, short-QT syndrome (SQTS), Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia (CPVT)

LV noncompaction (LVNC; *JACC* 2015;66:578)

- Prominent trabeculae w/ deep intertrabecular recesses due to intrauterine arrest of compaction of loose interwoven myocardial meshwork
- Debated whether distinct genetic CMP vs morphological trait of other CMPs
- Clinical: HF, atrial and/or vent arrhythmias, cardioembolic events
- Dx w/ MRI > echo; >2:1 ratio of noncompacted to compacted myocardium at end-systole, thickened LV wall and prominent deep trabeculae
- Usual HF Rx; low threshold to anticoagulate

VALVULAR HEART DISEASE

AORTIC STENOSIS (AS)

Etiology

- **Calcific:** predominant cause in Pts >70 y; risk factors include HTN, ↑ chol., ESRD
- **Congenital** (ie, bicuspid AoV w/ premature calcification): cause in 50% of Pts <70 y
- **Rheumatic heart disease** (AS usually accompanied by AR and MV disease)
- AS mimickers: subvalvular (HCMP subAo membrane) or supravalvular stenosis

Clinical manifestations (usually indicates AVA <1 cm^2 or concomitant CAD)

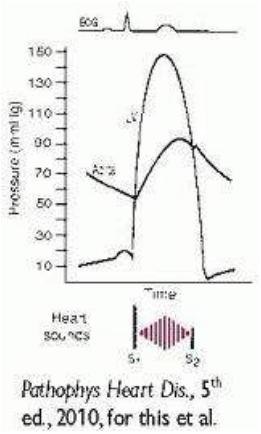
- **Angina:** ↑ O_2 demand (hypertrophy) + ↓ O_2 supply (↓ cor perfusion pressure) ± CAD
- **Syncope** (*exertional*): peripheral vasodil. w/ fixed CO → ↓ MAP → ↓ cerebral perfusion
- **Heart failure:** outflow obstruct + diastolic dysfxn → pulm. edema; espec If ↑ HR/AF (↓ LV fill.)
- Acquired vWF disease (~20% of sev. AS): destruction of vWF; GI angiodysplasia
- Natural hx: usually slowly progressive (AVA ↓ ~0.1 cm^2/y, but varies; *Circ* 1997;95:2262), until sx develop; mean survival based on sx: angina = 5 y; syncope = 3 y; CHF = 2 y

Physical exam

- **Midsystolic crescendo-decrescendo** murmur at **RUSB**, harsh, high-pitched, radiates to carotids, apex (holo-systolic = Gallavardin effect), ↑ w/ passive leg raise, ↓ w/ standing & Valsalva. In contrast, dynamic

outflow obstruction (HCM) ↓ w/ leg raise, ↑ w/ standing, Valsalva.

- Ejection click after S_1 sometimes heard with *bicuspid* AoV
- Signs of severity: *late-peaking* murmur, paradoxically split S_2 or inaudible A_2, small and delayed carotid pulse ("*pulsus parvus et tardus*"), LV heave, ⊕ S4 (occasionally palpable)



Pathophys Heart Dis., 5th ed., 2010, for this et al.

Diagnostic studies

- ECG: may see LVH, LAE, LBBB, AF (in late disease)
- CXR: cardiomegaly, AoV calcification, poststenotic dilation of ascending Ao, pulmonary congestion
- **Echo:** valve morphology, jet velocity, estim pressure gradient (∇) & calculate AVA, LVEF if concom severe AR: vel & ∇ may be ↑ than typical b/c of ↑ flow, but AVA calc valid if concom severe MR: vel & ∇ may be ↓ than typical b/c of ↓ flow, but AVA calc valid
- **Cardiac cath:** usually to r/o CAD (in ~½ of calcific AS); for hemodyn. if disparity between exam & echo: ✓ pressure gradient (∇) across AoV, calc AVA (underestim. if mod/sev AR)
- **Dobutamine challenge:** in cases with low flow, low ∇, and low LVEF, repeating echo (or cath) during low-dose dobutamine can differentiate:

Condition	Comment	SV	Jet Vel	∇	AVA
Afterload mismatch	Low EF 2° to severe AS; EF should ↑ post-AVR	≥20% ↑	↑	↑	no Δ
Pseudostenosis	Low AVA *artifact* of LV dysfxn	≥20% ↑	no Δ	no Δ	↑
Lack contractile reserve	EF prob. will *not* ↑ w/ AVR	no Δ	no Δ	no Δ	no Δ

Classification of Aortic Stenosis (*Circ* 2014;129:e521)

Stage	Sx	Severity	Max Jet Vel ($^m/_s$)	Mean Grad (mmHg)	AVA (cm^2)[a]	LVEF
n/a	N	Normal	1	0	3-4	nl
A	N	At risk	<2	<10	3-4	nl
B	N	Mild	2-2.9	<20	>1.5	nl
		Moderate	3-3.9	20-39	1-1.5	nl
C1		Severe	≥4	≥40	≤1.0	nl
	N	Very severe	≥5	≥60	≤0.8	nl
C2		Severe + ↓ EF	≥4	≥40	≤1.0	↓
D1		Severe	≥4	≥40	≤1.0	nl
D2	Y	Severe + low flow/∇ + ↓ EF[b]	<4	<40	≤1.0	↓
D3		Severe + low flow/∇ + nl EF[c]	<4	<40	≤1.0	nl

[a]AVA indexed to BSA <0.6 cm^2/m^2 also severe;

[b]DSE → max jet vel ≥4 & AVA ≤1.0;

[c]small LV w/ ↓ stroke vol.

Treatment (*Circ* 2014;129:e521 & *NEJM* 2014;371:744)

- Management decisions based on *symptoms*: once they develop AVR is needed. If asx, HTN can be cautiously Rx'd (probably best w/ ACEI/ARB rather than diuretics). Statins have not been proven to ↓ progression.
- **AVR**

  Indicated in: **sx severe AS** (ie, stage D1); **asx severe AS + EF <50%** (stage C2); or asx severe (stage C1) *and* undergoing other cardiac surgery.

  Reasonable if:

asx severe AS (stage C1) *but* either **sx or ↓ BP w/ exercise** (can *carefully* exercise asx AS to uncover sx, do *not* exercise sx AS) or **very severe**

sx severe w/ low flow/▽ w/ low EF & response to dobuta (stage D2) or normal EF but AS felt to be cause of sx (stage D3)

asx moderate AS (stage B) *and* undergoing cardiac surgery

- Transcatheter AoV replacement (TAVR, see below) indicated if surgical risk prohibitive or as reasonable alternative to surgery if high operative risk (STS predicted mortality 8-15%)
- Medical (if not AVR candidate or to temporize): careful diuresis prn, control HTN, maintain SR; digoxin if ↓ EF & HF or if AF; *avoid* venodilators (nitrates) & ⊖ inotropes (βB/CCB) if severe; avoid vigorous physical exertion once AS mod-severe; ? nitroprusside if p/w CHF w/ sev. AS, EF <35%, CI <2.2, & nl BP (*NEJM* 2003;348:1756)
- IABP: stabilization, bridge to surgery
- Balloon AoV valvotomy (BAV): 50% ↑ AVA & ↓ peak ▽, *but* 50% restenosis by 6-12 mo & ↑ risk of peri-PAV stroke/AR (*NEJM* 1988;319:125), ∴ bridge to AVR or palliation

TAVR (transcatheter AoV replacement)

- Catheter-based technique for replacing diseased AoV with bioprosthetic valve
- Valves: balloon-expandable (Edwards SAPIEN) or self-expanding (Medtronic CoreValve); balloon-expandable w/ less AR, less redo, less need for PPM (*JAMA* 2014;311:1503)
- Approaches: primarily retrograde via percutaneous transfemoral access; also retrograde via axillary artery or ascending aorta (via small sternotomy & aortotomy); alternatively transapical via direct LV apical puncture and antegrade implantation through small thoracotomy (if severe PAD or heavily calcified ascending Ao & arch)
- Periprocedural: local anesthesia w/ conscious sedation or general anesthesia; RV pacing (to decrease SV during deployment); TEE to guide placement
- Peri- & postprocedural complications: low CO, annular rupture or coronary occlusion (both rare), local vascular complications, paravalvular leaks & heart block (see below)
- ASA lifelong + clopidogrel × 6 mo
- Outcomes

  in nonoperative Pts vs med Rx: 44% ↓ mortality, but still ~20% annual mortality in TAVR group illustrating comorbidities in this population (*NEJM* 2012;366:1696; *JACC* 2014;63:1972)

  high-risk operative Pts vs surg AVR (*NEJM* 2012;366:1686 & 2014;370:1790) postop ≈ sx & hemodynamics mortality ≈ (balloon-expandable) or 26% ↓ (self-expanding) w/ TAVR vs surgery ↑ vasc complic; ↑ early risk of stroke/TIA w/ balloon-expandable heart block requiring PPM in ~20% w/ self-expanding; paravalvular leaks in ~7% prelim data in low-risk Pts shows lower mortality & stroke with TAVR (*JACC* 2015;65:2184)

AORTIC REGURGITATION (AR)

Etiology (*Circ* 2006;114:422)

- **Valve disease** (43%)

  rheumatic heart disease (usually mixed AS/AR and concomitant MV disease)

  bicuspid AoV: natural hx: ⅓→ normal, ⅓ → AS, 1/6 → AR, 1/6 → endocarditis → AR **infective endocarditis**

valvulitis: RA, SLE; anorectics (fen/phen) & other serotoninergics (*NEJM* 2007;356:29,39), XRT

- **Root disease** (57%)

  HTN

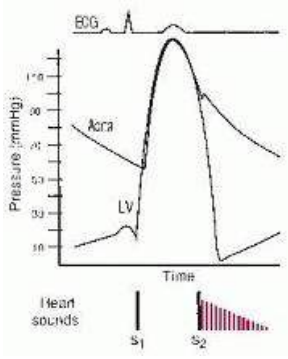
  aortic aneurysm or dissection, annuloaortic ectasia, Marfan syndrome

  aortic inflammation: giant cell, Takayasu's, ankylosing spond., reactive arthritis, syphilis

Clinical manifestations

- Acute: sudden ↓ forward SV and ↑ LVEDP (noncompliant ventricle) → pulmonary edema ± hypotension and cardiogenic shock
- Chronic: clinically silent while LV dilates (to ↑ compliance to keep LVEDP low) more than it hypertrophies → chronic volume overload → LV decompensation → CHF
- Natural hx: *variable* progression (unlike AS, can be fast or slow); once decompensation begins, prognosis poor w/o AVR (mortality ~10%/y)

Physical exam



- **Early diastolic decrescendo murmur at LUSB** (RUSB if dilated Ao root); ↑ w/ sitting forward, expir, handgrip; severity of AR ∝ duration of murmur (except in acute and severe late); *Austin Flint murmur:* mid-to-late diastolic rumble at apex (AR jet interfering w/ mitral inflow)
- **Wide pulse pressure** due to ↑ stroke volume, hyper-dynamic pulse → many of classic signs (see table); pulse pressure narrows in late AR with ↓ LV fxn; bisferiens (twice-beating) arterial pulse
- PMI diffuse and laterally displaced; soft S_1 (early closure of MV); ± S_3 (≠ ↓ EF but rather just volume overload in AR)

Classic Eponymous Signs in Chronic AR (*South Med J* 1981;74:459)

Sign	Description
Corrigan's pulse	“water hammer” pulse (ie, rapid rise/fall or distention/collapse)
Hill's sign	(popliteal SBP - brachial SBP) >60 mmHg
Duroziez's sign	to-and-fro murmur heard over femoral artery w/ light compression

Pistol shot sounds	pistol shot sound heard over femoral artery
Traube's sound	double sound heard over femoral artery when compressed distally
de Musset's sign	head-bobbing with each heartbeat (low Se)
Müller's sign	systolic pulsations of the uvula
Quincke's pulses	subungual capillary pulsations (low Sp)

Diagnostic studies

- ECG: can see LVH, LAD, abnl repol; CXR: cardiomegaly ± ascending Ao dilatation
- **Echo:** severity of AR (in addition to parameters below, severe AR requires holodia-stolic flow reversal in proximal abdominal Ao); LV size & fxn (chronic severe AR requires LV dilatation; LV dysfxn = EF <50% or LV end-syst. diam. [LVESD] >50 mm)
- Cardiac MR if TTE not sufficiently informative

Classification of Aortic Regurgitation

Severity	Regurg. fraction (%)	Jet width (% of LVOT)	ERO (cm^2)	Angio*
Mild	<30	<25	<0.1	1+
Moderate	30-49	25-64	0.1-0.29	2+
Severe	≥50	≥65	≥0.3	3/4+

*1+ = incomplete LV opac.; 2+ = opac. <Ao root & clears 1 beat; 3+ = LV = Ao root opac.; LV > Ao root opac.

Treatment (*Circ* 2014;129:e521)

- Acute decompensation (consider ischemia and endocarditis as possible precipitants):
  surgery usually urgently needed for acute severe AR, which is poorly tolerated by LV IV afterload reduction (nitroprusside) and inotropic support (dobutamine) ± chronotropic support (↑ HR → ↓ diastole → ↓ time for regurgitation) pure vasoconstrictors and IABP contraindicated
- In chronic AR, management decisions based on LV *size and fxn* (and before sx occur)
- **Surgery** (AVR, replacement or repair if possible):
  severe and **sx** (if equivocal, consider stress test)
  asx *and* either **EF ≤50%** or **LV dilation** (LVESD >50 mm) or undergoing cardiac surg
- Transcatheter AoV replacement (TAVR) being explored (*JACC* 2013;61:1577)

- Medical therapy: **vasodilators** (nifedipine, ACEI/ARB, hydralazine) if severe AR w/ sx or LV dysfxn & Pt not operative candidate or to improve hemodynamics before AVR; no clear benefit on clinical outcomes or LV fxn when used to try to prolong compensation in asx severe AR w/ mild LV dilation & nl LV fxn (*NEJM* 2005;353:1342)

MITRAL REGURGITATION (MR)

Etiology (*Lancet* 2009;373:1382; *NEJM* 2010;363:156)

- **Primary** (degeneration of valve apparatus)

  leaflet abnl*:* myxomatous (MVP), endocarditis, calcific RHD, valvulitis (collagen-vascular disease), congenital, anorectic drugs, XRT

  chordae tendineae rupture: myxomatous, endocarditis, spontaneous, trauma

  papillary muscle dysfxn b/c of ischemia or *rupture* during MI [usu. posteromedial papillary m. (supplied by PDA only) vs anterolateral (suppl. by diags & OMs)]

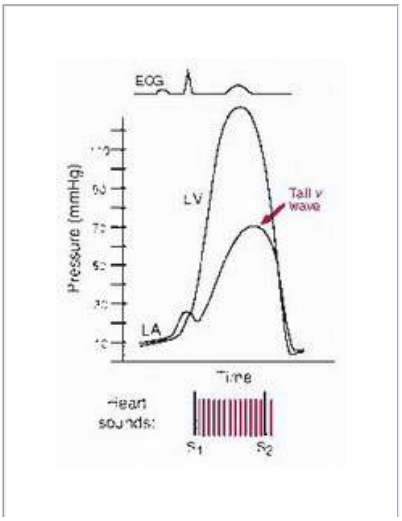
- **Secondary (functional):** inferoapical papillary muscle displacement due to ischemic LV remodeling or other causes of DCM (*JACC* 2015;65:1231)

Clinical manifestations

- Acute: **pulmonary edema**, hypotension, cardiogenic shock (*NEJM* 2004;351:1627)
- Chronic: typically asx for yrs, then as LV fails → progressive DOE, fatigue, AF, PHT
- Prognosis: 5-y survival w/ medical therapy is 80% if asx, but only 45% if sx

Physical exam

- **High-pitched, blowing, holosystolic murmur at apex;** radiates to axilla; ± thrill; ↑ w/ handgrip (Se 68%, Sp 92%), ↓ w/ Valsalva (Se 93%) (*NEJM* 1988;318:1572) ant. leaflet abnl → post. jet heard at spine post. leaflet abnl → ant. jet heard at sternum
- ± diastolic rumble b/c ↑ flow across valve
- Lat. displ. hyperdynamic PMI, obscured S_1, widely split S_2 (A_2 early b/c ↓ LV afterload, P_2 late if PHT); ± S_3
- Carotid upstroke brisk (vs diminished and delayed in AS)



Diagnostic studies (*NEJM* 2005;352:875)

- ECG: may see LAE, LVH, ± atrial fibrillation
- CXR: dilated LA, dilated LV, ± pulmonary congestion
- **Echo:** MV anatomy (ie, etiol); MR severity: jet area (can underestimate eccentric jets), jet width at origin (vena contracta) or effective regurgitant orifice (ERO; predicts survival); LV fxn (EF should be *supranormal* if compensated, [EF <60% w/ sev. MR = LV dysfxn); TEE if TTE inconclusive or pre/intraop to guide repair vs replace
- Cardiac MR if TTE not sufficiently informative
- **Cardiac cath:** prominent PCWP *c-v* waves (not spec. for MR), LVgram for MR severity & EF

Classification of Primary Mitral Regurgitation

Severity	**Regurg. fraction**	**Jet area** (% of LA)	**Jet width** (cm)	**ERO** (cm^2)	**Angio***
Mild	<30%	<20	<0.3	<0.2	1+
Moderate	30-49%	20-40	0.3-0.69	0.2-0.39	2+
Severe†	≥50%	>40	≥0.70	≥0.40	3/4+

*1+ = LA clears w/ each beat; 2+ = LA does not clear, faintly opac. after several beats; 3+ = LA & LV opac. equal.

†For secondary MR, because ERO underestimated & likely progressive LV dysfxn, ERO ≥0.20 is severe

Treatment (*Circ* 2014;129:e521)

- Acute decompensation (consider ischemia and endocarditis as precipitants) IV afterload reduction (nitroprusside), ± inotropes (dobuta), IABP, avoid vasoconstrictors *surgery* usually needed for acute severe MR as prognosis poor w/o (*JAMA* 2013;310:609)
- **Surgery** (repair [preferred if feasible] vs replacement w/ preservation of mitral apparatus)

  for **severe** *primary* MR indicated if **sx & EF >30%** or if **asx & either EF 30-60% or LV sys. diam. ≥40 mm** MV *repair* reasonable if asx & either EF >60% + LVESD <40 mm or new AF or PHT if AF, maze procedure or pulm vein isolation → ↓ AF recurrence, Ø Δ stroke; consider for sx cntl or if planning no anticoag (*NEJM* 2015;372:1399)

  for **severe** *secondary* MR*:* consider if NYHA III-IV; replacement results in more durable correction than repair but no difference in clinical outcomes (*NEJM* 2014;370:23)
- In Pts undergoing CABG w/ mod-sev fxnal MR, annuloplasty ↓ MR but longer surgery, ↑ neurologic events, & no impact on fxnal status or mortality (*NEJM* 2014;371:2178)
- Percut. MV repair (*Circ* 2014;130:1712): edge-to-edge clip less effective than surgery but consider for

sev. sx nonoperative Pt (*NEJM* 2011;364:1395); perc valve under study (*JACC* 2014;64:1814)

- Medical: Ø clinical benefit in asx Pts; βB preserve LV fxn (*JACC* 2012;60:833); if sx but not operative candidate ↓ preload (↓ HF and MR by ↓ MV orifice): diuretics, nitrates (espec if ischemic/fxnal MR); if LV dysfxn: ACEI, βB, ± BiV pacing; maintain SR

MITRAL STENOSIS (MS)

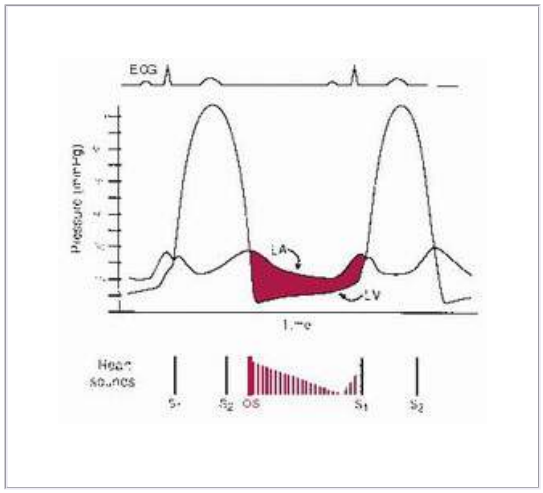
Etiology (*Lancet* 2012;379:953)

- **Rheumatic heart disease** (RHD): *fusion of commissures* → "fish-mouth" valve from autoimmune rxn to β strep infxn; seen largely in developing world today
- **Mitral annular calcification** (MAC): encroachment upon leaflets → functional MS
- Congenital, infectious endocarditis w/ large lesion, myxoma near MV, thrombus
- Valvulitis (eg, SLE, amyloid, carcinoid) or infiltration (eg, mucopolysaccharidoses)

Clinical manifestations (*Lancet* 2009;374:1271)

- **Dyspnea and pulmonary edema** (if due to RHD, sx usually begin in 30s) precipitants: exercise, fever, anemia, volume overload (incl. pregnancy), tachycardia, AF
- **Atrial fibrillation:** onset often precipitates heart failure in Pts w/ MS
- **Embolic events:** commonly cerebral, espec in AF or endocarditis

- Pulmonary: hemoptysis, frequent bronchitis (due to congestion), PHT, RV failure
- Ortner's syndrome: hoarseness from LA compression of recurrent laryngeal nerve



Physical exam

- **Low-pitched mid-diastolic rumble at apex** w/ presystolic accentuation (if not in AF); best heard in L lat decubitus position during expiration, ↑ w/ exercise; severity proportional to *duration* (not intensity) of murmur
- **Opening snap** (high-pitched early diastolic sound at apex) from fused leaflet tips; MVA proportional to S_2-OS interval (tighter valve → ↑ LA pressure → shorter interval)
- Loud S_1 (unless MV calcified)

Diagnostic studies

- ECG: **LAE** ("P mitrale"), ± AF, ± RVH
- CXR: **dilated LA** (straightening of left heart border, double density on right, left mainstem bronchus elevation)
- **Echo:** estimate pressure gradient (▽), RVSP, valve area, valve echo score (0-16, based on leaflet mobility & thick., subvalvular thick., Ca^{++}); exer. TTE (to assess Δ RVSP and ▽) if sx & severity of MS at rest discrepant; TEE to assess for LA thrombus before PMV
- **Cardiac cath:** ▽ from simultaneous PCWP & LV pressures, calculated MVA; LA pressure tall *a* wave and blunted y descent; ↑ PA pressures

Classification of Mitral Stenosis

Stage	Mean ▽ (mmHg)	Pressure ½ time	MV area (cm^2)	PA systolic (mmHg)
Normal	0		4-6	<25
Mild-Mod	<5	100-149	1.6-2	<30
Severe	5-9	150-219	1.1-1.5	30-50
Very severe	≥10	≥220	≤1	>50

Treatment (*Circ* 2014;129:e521)

- Medical: Na restriction, cautious diuresis, βB, sx-limited physical stress
- Antibiotic Ppx recommended if h/o RHD w/ valvular disease for 10 y or until age 40
- Anticoag if: AF; prior embolism; LA thrombus; ? LA >55 mm or lg LA w/ spont contrast
- Mechanical intervention indicated if **heart failure sx w/ MVA ≥1.5;**
  reasonable if asx but very severe (MVA ≤1) and morphology favorable for PMBC; may consider PMBC if MVA >1.5 but hemodyn signif w/ exercise, or if asx but MVA ≤1.5 and new-onset AF
- **Percutaneous mitral balloon commissurotomy** (PMBC): preferred Rx if RHD; MVA doubles, ▽ ↓ by 50%; ≈ MVR *if* valve score <8, ≤ mild MR, Ø AF or LA clot
- Surgical (MV repair if possible, o/w replacement): consider in sx Pts w/ MVA ≤1.5 if PMV unavailable/contraindicated (mod. MR, LA clot), or valve morphology unsuitable
- Pregnancy: if NYHA class III/IV → PMV, o/w medical Rx w/ low-dose diuretic & βB

MITRAL VALVE PROLAPSE (MVP)

Definition and Etiology

- Billowing of MV leaflet ≥2 mm above mitral annulus in parasternal long axis echo view
- Leaflet redundancy from myxomatous proliferation of spongiosa of MV apparatus

- Idiopathic, familial and a/w connective tissue diseases (eg, Marfan's, Ehlers-Danlos)
- Prevalence 1-2.5% of gen. population, ♀ > ♂ (*NEJM* 1999;341:1), most common cause of MR

Clinical manifestations (usually asymptomatic)

- MR (from leaflet prolapse or ruptured chordae); infective endocarditis; embolic events
- Arrhythmias, rarely sudden cardiac death

Physical exam

- High-pitched, midsystolic click ± mid-to-late systolic murmur
- ↓ LV volume (standing) → click earlier; ↑ LV volume or afterload → click later, softer

Treatment

- Endocarditis prophylaxis no longer recommended (*Circ* 2007:116:1736)
- Aspirin or anticoagulation if prior neurologic event or atrial fibrillation

TRICUSPID REGURGITATION

- Primary etiol: rheumatic, CTD, radiation, IE, Ebstein's anomaly, carcinoid, tumors
- Fxnal etiol: RV and/or pulm HTN (may be 2° to L-sided dis.), RV dilation and/or infarct

- Assess based on severity TR, annular dilation, leaflet coaptation (*JACC* 2015;65:2331)
- Consider repair, annuloplasty or replacement for sx and severe TR (eg, ERO ≥ 0.40 cm^2)

PROSTHETIC HEART VALVES

Mechanical (60%)

- Bileaflet (eg, St. Jude Medical); tilting disk; caged-ball
- Very durable (20-30 y), but thrombogenic and ∴ require anticoagulation consider if age <˜60 y or if anticoagulation already indicated (*JACC* 2010;55:2413)

Bioprosthetic (40%)

- Bovine pericardial or porcine heterograft (eg, Carpentier-Edwards), homograft
- Less durable, but min. thrombogenic; consider if >˜70 y, lifespan <20 y or Ø anticoag
- If 50-69 y, 2× reop but ½ bleeding or stroke vs mech (*JAMA* 2014;312:1323 & 2015;313:1435)

Physical exam

- Normal: **crisp sounds**, ± soft murmur during forward flow (normal to have small ▽)
- Abnormal: regurgitant murmurs, absent mechanical valve closure sounds

Anticoagulation & antiplatelet therapy (*Circ* 2014;129:e521)

- Assess for *high-risk features:* prior thromboembolism, AF, EF<30-35%, hypercoagulable

- **Warfarin:** low-risk mech AVR: INR 2-3

  mech MVR or high-risk mech AVR: INR 2.5-3.5

  high-risk bioprosthetic: INR 2-3; for 1st 3 mo, reasonable in low-risk MVR, consider in low-risk AVR
- **ASA** (75-100 mg) for all prosthetic valves; avoid adding to warfarin if h/o GIB, uncontrolled HTN, erratic INR or >80 y
- If thrombosis, ↑ intensity (eg, INR 2-3 → 2.5-3.5; 2.5-3.5 → 3.5-4.5; add ASA if not on)

Periprocedural "Bridging" of Anticoagulation in Pts with Mechanical Valve(s)

AVR w/o risk factors	d/c warfarin 2-4 before surg; restart 12-24 h after surg
MVR or AVR w/ risk factors	Preop: d/c warfarin, start UFH when INR <2 4-6 h preop: d/c UFH; postop: restart UFH & warfarin ASAP

Procedures include noncardiac surgery, invasive procedures, and major dental work

Correction of overanticoagulation (*Circ* 2014;129:e521)

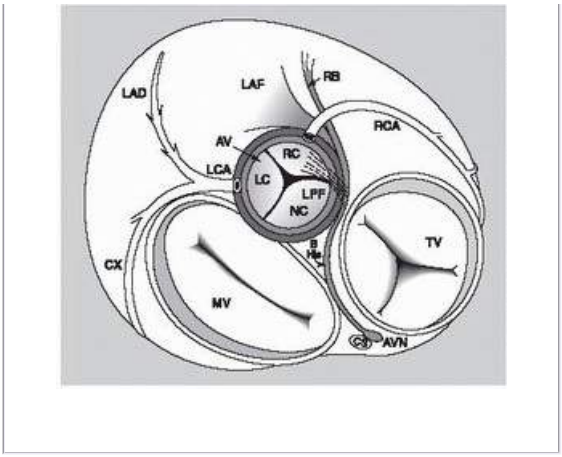
- Risk from major bleeding must be weighed against risk of valve thrombosis
- Not bleeding: if INR 5-10, withhold warfarin; if INR > 10 also give vit K 1-2.5 mg PO
- Bleeding: FFP or PCC ± low-dose (1 mg) vit K IV

Endocarditis prophylaxis: for all prosthetic valves (see "Endocarditis") Complications

- Structural failure (r/o endocarditis); mechanical valves: rare except for Bjork-Shiley; bioprosth: up to 30% rate w/in 10-15 y, mitral > aortic; consider TAVR (*JAMA* 2014;312:162)
- Paravalvular leak (r/o endocarditis); small *central* jet of regurg is normal in mech. valves
- Obstruction from thrombosis or pannus ingrowth: ✓ TTE, TEE, and/or fluoroscopy if ? clot significantly sx *pannus* ingrowth: remove w/ surgery

  thrombosis: surgery if L-sided valve & either severe sx or lg (? ≥0.8 cm) thrombus; lytic often *ineffective* for L-sided thrombosis & 12-15% risk of stroke; consider UFH ± lytic (? low-dose tPA via slow infusion, *JACC CV Imaging* 2013;6:206) if mild sx & small clot burden or poor surg candidate; lytic reasonable for R-sided
- Infective endocarditis ± valvular abscess and conduction system dis. (see "Endocarditis")
- Embolization (r/o endocarditis); risk ~ 1%/y w/ warfarin (vs 2% w/ ASA, or 4% w/o meds) mech MVR 2× risk of embolic events vs mech AVR (*Circ* 1994;89:635)
- Bleeding (from anticoag), hemolysis (espec w/ caged-ball valves or paravalvular leak)

HEART VALVES (superior view, *JAMA* 1976;235:1603)



AV = aortic valve

AVN = AV node

B His = bundle of His

CS = coronary sinus

Cx = circumflex artery

LAD = left anterior descending artery

LAF = left anterior fascicle

LCA = left coronary artery

LPF = left posterior fascicle

MV = mitral valve

RB = right bundle

RC/LC/NC = right/left/noncoronary cusp

RCA = right coronary artery

TV = tricuspid valve

CARDIOPULMONARY EXERCISE TESTING

Background, rationale, and measurements performed (*Circ* 2010;122:191)

- In exercise, to meet metabolic demands of active cells, need to ↑ effective ventilation, ↑ cardiac output, and ↓ pulmonary & systemic vascular resistance, ↑ O_2 extraction
- Dyspnea due to insufficient supply to or impaired uptake of O2 by skeletal muscle
- Ddx of dyspnea:

  impaired external respiration (ventilation & pulmonary gas exchange)

  impaired circulatory system (transport of O_2 and CO_2)

  impaired internal respiration (peripheral capillary gas exchange and O_2 utilization)
- Cardiorespiratory fitness predicts morbidity & mortality
- CPET is an individualized incremental exercise test that combines traditional cardiac stress test parameters: ECG, heart rate, BP quantification of O2 consumption ([V with dot above]O_2), CO_2 production ([V with dot

above]O_2), minute ventilation (V_E) if invasive (radial artery & PA cath): RAP, PAP, & PCWP; arterial & mixed venous sats can be coupled with cardiac imaging (eg, radionuclide ventriculography, TTE)

- Well tolerated even w/ advanced disease, 0.16% adverse event rate (*Circ* 2012:126:2465)

Indications for CPET

- Diagnose etiology of exercise intolerance or dyspnea by defining organ system limiting gas exchange (heart, pulm mechanical, pulm vasculature, muscles/mitochondria)
- Grade severity of advanced heart and lung diseases and predict prognosis

  Prioritize Pts for heart/lung transplantation, mechanical support:

  Heart transplant candidacy: peak [V with dot above]O_2 <14 ml/kg/min, <12 on βB, ± <50% predicted LVAD candidacy <12 ml/kg/min (*NEJM* 2001;345:1445)

  Determine whether to intervene on valvular disease, shunts/congenital heart disease
- To objectively measure responses to interventions (clinical trials, disability, rehabilitation)

Clinical relevance of measurement patterns

- RER (respiratory exchange ratio) = [V with dot above]CO_2/[V with dot above]O_2, indicator of volitional effort independent of chronotropic response (goal > 1.05)
- V_E/MVV (max voluntary vent): >70-80% indicates encroachment on pulm mechanical limit
- Peak [V with dot above]O_2: max aerobic capacity at peak exercise; indicator of cardiorespiratory fitness measured with metabolic cart but also represented by the Fick equation:

  [V with dot above]O_2 = (heart rate × stroke volume) × [(arterial - mixed venous) O_2 content]
- VAT (ventilatory anaerobic threshold): % of peak predicted [V with dot above]O_2 at which O_2 supply inadequate → anaerobic metabolism (normal value >40%); indep. of volitional effort, highly reproducible, and occurs at activity levels often assoc. w/ daily living. Low VAT reflects impaired O_2 delivery ± utilization but does not localize organ system responsible. In HFrEF, VAT<11 ml/kg/min assoc w/ 5× ↑ in 6-mo mortality (*Circ* 2002;106:3079).
- V_E/VCO_2 slope: ventilation required to exchange 1 L/min of CO_2 in addition, V_E/VCO_2 slope = constant / [P_aCO_2 × (1 - V_d/V_t)] high level (>36) especially seen in pulm vascular and/or RV dysfunction, where V/Q mismatch & ↓ pulm perfusion → ↑ V_d/V_t, and ↑ ventilatory drive → ↓ P_aCO_2

  high levels also indicate poor prognosis (*Circ* 2007;115:2410; *Circ* HF 2008;1:227)
- Exercise oscillatory vent: periodic breathing that reflects circul. delay (ie, low CO) relative to metab needs during exercise; assoc w/ 3× ↑ mort (*JACC* 2010;55:1814; *Circ* 2011;124:1442)
- mPAP/CO slope (serial measurements during exercise define the pulm artery pressure response to increased blood flow through the pulmonary circulation during exercise): mPAP = TPG + LAP mPAP/CO slope >3 indicates *either* abnl pulm vascular response to exercise *or* upstream transmission of high LAP (*Circ* 2013;128:1470), with TPG/CO (ie, PVR) that fails to fall and remains > 1.5 indicative of pulmonary vascular dysfunction and

  PCWP/CO slope >2 indicative of left-sided failure

- DPG (diastolic pulmonary gradient) = PAD - LAP; DPG >5-7 indicates pulm vasc disease and may be preferable to TPG (mPAP - LAP) for pulm vasc disease diagnosis b/c it is not significantly influenced by ΔLAP and CO (*Chest* 2013;143:758)

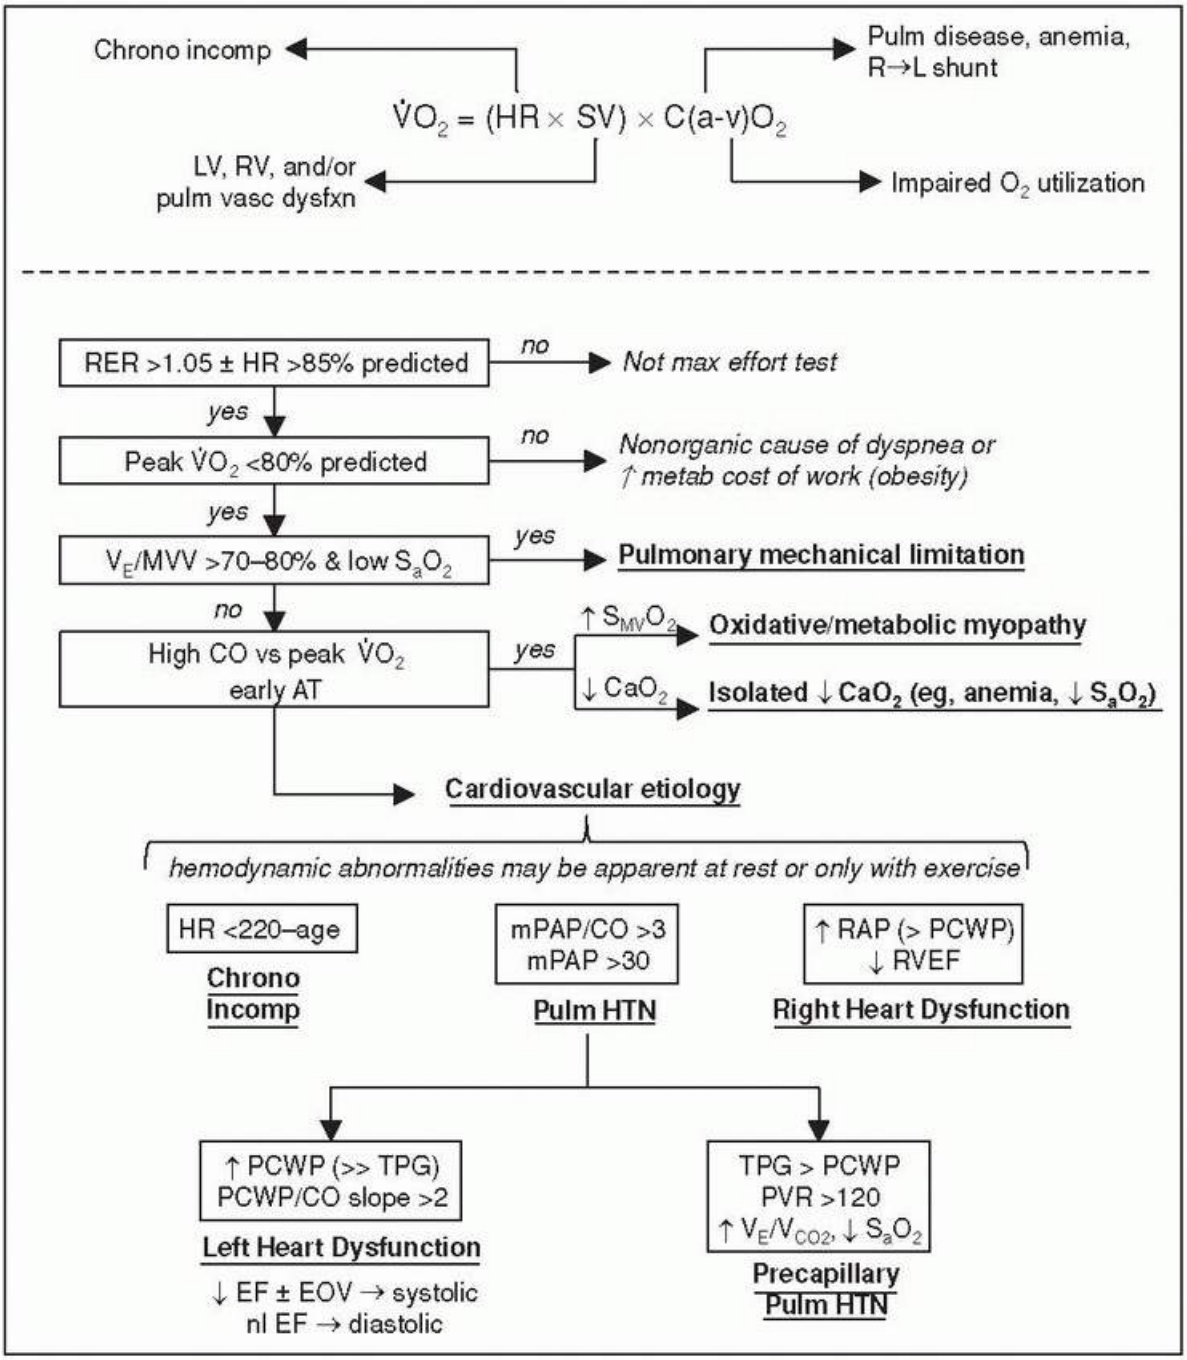


Figure 1-4 Approach to CPET

PERICARDIAL DISEASE

GENERAL PRINCIPLES

Anatomy

- 2-layered (parietal & visceral) tissue sac surrounding heart & proximal great vessels

Disease states

- Inflammation (w/ or w/o fluid accumulation) → pericarditis
- Fluid accumulation → effusion ± tamponade
- Decrease in compliance (sequela of inflammation) → constrictive pericarditis
- Tamponade and constriction characterized by increased ventricular interdependence

PERICARDITIS AND PERICARDIAL EFFUSION

Etiologies of Acute Pericarditis (*Lancet* 2004;363:717; *Curr Probl Cardiol* 2012;37:75)

Idiopathic (~90%)	Most presumed to be undiagnosed viral etiologies
Infectious (<5% can be confirmed infectious)	Viral: Coxsackie, echo, adeno, EBV, VZV, HIV, influenza Bacterial (from endocarditis, pneumonia or s/p cardiac surgery): *S. pneumococcus, N. meningitidis, S. aureus, Borrelia* (Lyme); TB Fungal: *Histo, Coccidio, Candida;* Parasitic: *Entamoeba, Echino*
Neoplastic (<10%)	*Common:* metastatic (lung, breast, lymphoma, leukemia, RCC) *Rare:* primary cardiac & serosal tumors (mesothelioma)
Autoimmune	Connective tissue diseases: SLE, RA, scleroderma, Sjögren's Vasculitides: PAN, Churg-Strauss, Wegener's Drug-induced: procainamide, hydralazine, INH, CsA
Uremia	~5-13% of Pts prior to HD; ~20% occurrence in chronic HD Pts
Cardiovascular	Acute STEMI, late post-MI (Dressler's syndrome), but both rare in modern era; proximal AoD; chest trauma/postpericardiotomy
Radiation	>40 Gy to mediastinum; acute or delayed; may be transudative
Effusions w/o pericarditis	HF, cirrhosis, nephrotic syndrome, hypothyroidism, amyloidosis Transudative

Clinical manifestations (*NEJM* 2014;371:2410)

- **Pericarditis:** retrosternal chest pain that is pleuritic, positional (↓ by sitting forward), radiates to trapezius; may be *absent* in TB, neoplastic, post-XRT and uremic pericarditis; ± fever; ± s/s of systemic etiologies
- **Effusion:** ranges from asx to tamponade (see below)

Physical exam

- **Pericarditis:** multiphasic **friction rub** best heard at LLSB w/ diaphragm of stethoscope. Notoriously variable and evanescent leathery sound w/ up to 3 components: atrial contraction, ventricular contraction, ventricular relaxation (*NEJM* 2012;367:e20).
- **Effusion:** distant heart sounds, dullness over left posterior lung field due to compressive atelectasis from

pericardial effusion (Ewart's sign)

Diagnostic studies (*EHJ* 2004;25:587; *Circ* 2006;113:1622 & 2010;121:916)

- ECG: may show diffuse STE (*concave up*) & PR depression (except in aVR: ST ↓ & PR ↑), TWI; classically and in contrast to STEMI, TWI do not occur until STs normalize Stages: (I) STE & PR ↓ ; (II) ST & PR normalize; (III) diffuse TWI; (IV) Tw normalize ECG may show evidence of large effusion w/ low voltage & electrical alternans (beat-to-beat Δ in QRS amplitude and/or axis due to swinging heart)
- CXR: if large effusion (>250 mL of fluid) → ↑ cardiac silhouette w/ "water-bottle" heart and epicardial halo
- **Echocardiogram:** presence, size, & location of *effusion;* presence of *tamponade physiology;* pericarditis itself w/o spec. abnl (∴ echo can be nl), although can see pericardial stranding (fibrin or tumor); can also detect LV/RV dysfxn (myocarditis ?)
- CT will reveal pericardial effusions, often appearing larger than on echocardiography
- CK-MB or troponin (⊕ in ~30%, *JACC* 2003;42:2144) if myopericarditis. Consider CRP/ESR.

Workup for effusion

- r/o infxn: usually apparent from Hx & CXR; ? value of ✓ acute and convalescent serologies
- r/o noninfectious etiologies: BUN, Cr, ANA, RF, HIV, screen for common malignancies
- Pericardiocentesis if suspect infxn or malignancy or large effusion (>2 cm) or recurrent ✓cell counts, TP, LDH, glc, Gram stain & Cx, AFB, cytology ADA, PCR for MTb, and specific tumor markers as indicated by clinical suspicion "exudate" criteria: TP >3 g/dL, TP_{eff}/TP_{serum} >0.5, LDH_{eff}/LDH_{serum} >0.6 or glc <60 mg/dL high Se (~90%) but *very low* Sp (~20%); overall low utility (*Chest* 1997;111:1213)
- Pericardial bx if suspicion remains for malignancy or TB

Treatment of pericarditis (*Circ* 2013;127:1723)

- High-dose **NSAID** (eg, ibuprofen 600-800 mg tid) or ASA (eg, 650-1000 mg tid) × 7-14 d then taper over wks; ASA preferred over NSAID in acute MI; consider PPI to ↓ risk of GIB
- Add **colchicine** 0.5 mg bid (qd if ≤70 kg) × 3 mo; ↓ risk of refractory or recurrent pericarditis by 50% (*NEJM* 2013;369:1522)
- Steroids (usually systemic; occ. intrapericardial) only for systemic rheum or autoimmune disorder, uremic, preg., contraindication to NSAID, or refractory idiopathic dis. Systemic steroids appear to ↑ rate of pericarditis recurrence (*Circ* 2008;118:667).
- Avoid anticoagulants (although no convincing data that ↑ risk of hemorrhage/tamponade)
- Infectious effusion → pericardial drainage (preferably surgically) + systemic antibiotics
- Acute idiopathic effusion self-limited in 70-90% of cases
- Recurrent pericarditis (*Circ* 2007;115:2739)

  risk factors: subacute, lg effusion/tamponade, T >38°C, lack of NSAID response after 7 d treatment: colchicine 0.5 mg bid × 6 mo (*Annals* 2011;155:409 & *Lancet* 2014;383:2232)
- Recurrent effusion: consider pericardial window (percutaneous vs surgical)

PERICARDIAL TAMPONADE

Etiology

- Any cause of pericarditis but espec **malignancy**, **uremia**, **idiopathic**, proximal aortic dissection with rupture, myocardial rupture
- Rapidly accumulating effusions most likely to cause tamponade as no time for pericardium to stretch (eg, to ↑ compliance) and accommodate ↑ intrapericardial fluid volume

Pathophysiology (*NEJM* 2003;349:684)

- ↑ intrapericardial pressure, compression of heart chambers, ↓ venous return → ↓ CO
- Diastolic pressures ↑ & equalize in all cardiac chambers → minimal flow of blood from RA to RV when TV opens → blunted y descent
- ↑ ventricular interdependence → pulsus paradoxus (pathologic exaggeration of nl physio) Inspiration → ↓ intrapericardial & RA pressures → ↑ venous return → ↑ RV size → septal shift to left. Also, ↑ pulmonary vascular compliance → ↓ pulm venous return. Result is ↓ LV filling → ↓ **LV stroke volume** & blood pressure.

Clinical manifestations

- **Cardiogenic shock** (hypotension, fatigue) **without pulmonary edema**
- Dyspnea (seen in ~85%) may be due to ↑ respiratory drive to augment venous return

Physical exam (*JAMA* 2007;297:1810)

- **Beck's triad** (present in minority of cases): **distant heart sounds**, ↑ **JVP**, **hypotension**
- ↑ JVP (76%) w/ blunted y descent
- Reflex tachycardia (77%), hypotension (26%; occasionally hypertensive), cool extremities
- **Pulsus paradoxus** (Se 82%, Sp 70%) = ↓ SBP ≥10 mmHg during inspiration

  ⊕ LR 3.3 (5.9 if pulsus >12), ⊖ LR 0.03

  Ddx = PE, hypovolemia, severe COPD, constriction (~⅓), RV infarct

  Can be absent if pre-existing ↑ LVEDP, arrhythmia, severe AI, ASD, regional tamponade
- Distant heart sounds (28%), ± pericardial friction rub (30%)
- Tachypnea but clear lungs

Diagnostic studies

- ECG: ↓ voltage (seen in 42%), electrical alternans (20%), ± signs of pericarditis
- CXR: ↑ cardiac silhouette (89%)
- **Echocardiogram:** ⊕ **effusion,** IVC plethora, **septal shift** with inspiration **diastolic collapse** of RA (Se 85%, Sp 80%) and/or RV (Se <80%, Sp 90%) **respirophasic** Δ's **in transvalvular velocities** (↑ across TV & ↓ across MV w/ inspir.) postsurgical tamponade may be localized and not easily visible
- Cardiac cath (right heart and pericardial): elevation (15-30 mmHg) and equalization of intrapericardial and

diastolic pressures (RA, RV, PCWP), blunted y descent in RA ↑ in stroke volume postpericardiocentesis = ultimate proof of tamponade if RA pressure remains elevated after drainage, may have effusive-constrictive disease (*NEJM* 2004;350:469) or myocardial dysfxn (eg, from concomitant myocarditis)

Treatment

- Volume (but be careful as overfilling can worsen tamponade) and ⊕ inotropes (avoid βB)
- Avoid vasoconstrictors as will ↓ stroke volume & potentially ↓ HR
- **Pericardiocentesis** (except if due to aortic or myocardial rupture, in which case consider removing just enough fluid to reverse PEA en route to emergent surgery)

CONSTRICTIVE PERICARDITIS

Etiology (*Circ* 2011;124:1270)

- Any cause of pericarditis (~1-2% incidence overall after acute pericarditis)
- Highest risk w/ **TB**, **bacterial**, **neoplastic**, connective tissue, postcardiac surgery
- **Viral/idiopathic**, as most common cause of pericarditis, also account for signif proportion

Pathophysiology

- Adhesion of visceral and parietal pericardial layers → rigid pericardium that limits diastolic filling of ventricles → ↑ systemic venous pressures
- Venous return is limited only after early rapid filling phase; ∴ rapid ↓ in RA pressure with atrial relaxation and opening of tricuspid valve and *prominent x and* y *descents*
- Kussmaul sign: JVP does not decrease with inspiration (↑ venous return with inspiration, but negative intrathoracic pressure not transmitted to heart because of rigid pericardium)

Clinical manifestations (*NEJM* 2011;364:1350)

- Right-sided > left-sided heart failure (systemic congestion > pulmonary congestion)

Physical exam

- ↑ **JVP** with **prominent y descent,** ⊕ **Kussmaul sign** (Ddx: tricuspid stenosis, acute cor pulmonale, RV failure and RV infarct, RCMP
- Hepatosplenomegaly, ascites, peripheral edema. Consider on Ddx of idiopathic cirrhosis.
- PMI usually not palpable, **pericardial knock**, usually no pulsus paradoxus

Diagnostic studies

- ECG: nonspecific, AF common (up to 33%) in advanced cases
- CXR: calcification (MTb most common), espec in lateral view (although not specific)
- Echocardiogram: ± thickened pericardium, "**septal bounce**" = abrupt displacement of septum during rapid filling in early diastole

- Cardiac catheterization: atria w/ **Ms** or **Ws** (prominent *x* and y descents) ventricles: **dip-and-plateau** or **square-root sign** (rapid ↓ pressure at onset of diastole, rapid ↑ to early plateau)

  discordance between LV & RV pressure peaks during respiratory cycle (*Circ* 1996;93:2007)

- CT or **MRI:** thickened pericardium (>4 mm; Se ~80%) w/ tethering (*Circ* 2011;123:e418)

Treatment

- Diuresis for intravascular volume overload; surgical pericardiectomy in advanced cases
- ? MRI able to predict reversibility with anti-inflammatory agents (*Circ* 2011;124:1830)

Constrictive Pericarditis vs Restrictive Cardiomyopathy

Evaluation	Constrictive pericarditis	Restrictive cardiomyopathy
Physical exam	⊕ Kussmaul sign Absent PMI ⊕ Pericardial knock	± Kussmaul sign Powerful PMI, ± S_3 and S_4 ± Murmurs of MR, TR
ECG	± Low voltage	Low voltage if infiltrative myopathy ± Conduction abnormalities
Echocardiogram	Respirophasic variation (25-40%): inspir. → ↑ flow across TV and ↓ flow across MV E′ (tissue velocity) nl/↑ (> 12) Expir. hepatic vein flow reversal Septal bounce during early diastole Normal wall thickness	<10% respirophasic variation Slower peak filling rate Longer time to peak filling rate E′ ↓ (<8 cm/sec) Inspir. hepatic vein flow reversal Biatrial enlargement ± ↑ wall thickness
CT/MRI	Thickened pericardium	Normal pericardium
NT-proBNP	Variable	Typically ↑ /↑ ↑ (*JACC* 2005;45:1900)
	Prominent *x* and *y* descents Dip-and-plateau sign	
Cardiac catheterization	LVEDP = RVEDP RVSP <55 mmHg (Se 90%, Sp 29%) RVEDP > ⅓ RVSP (Se 93%, Sp 46%) Discordance of LV & RV pressure peaks during respiratory cycle Systolic area index (ratio of RV to LV pressure-time area in inspir vs expir) >1.1 (Se 97%, Sp 100%)	LVEDP > RVEDP (esp. w/ vol.) RVSP >55 mmHg RVEDP <⅓ RVSP Concordance of LV & RV pressure peaks during respiratory cycle Systolic area index ≤1.1 (*JACC* 2008;51:315)

Endomyocardial biopsy	Usually normal	± Specific etiology of RCMP (fibrosis, infiltration, hypertrophy)

Vascular Disease

HYPERTENSION

Classification

Category	Systolic (mmHg)	Diastolic (mmHg)
Normal	<120	<80
Pre-HTN	120-139	80-89
Stage 1 HTN	140-159	90-99
Stage 2 HTN	≥160	≥100

Average ≥2 measurements >1-2 min apart. Confirm stage 1 w/in 1-4 wk; can Rx stage 2 immediately. ✓ q2y (if nl) or yearly (if pre-HTN). (*J Clin HTN* 2014;16:14)

Ambulatory Thresholds

Setting	Systolic (mmHg)	Diastolic (mmHg)
24-hr average	135	85
Day* (awake)	140	90
Night (asleep)	125	75

*Threshold of hypertension for home readings should be same as daytime ambulatory

Epidemiology (*Circulation* 2012;125:e2)

- Prevalence 33.5% in U.S. adults; >75 million affected (prevalence equal for men and women, highest in African American adults at 44%)
- ↑ Age → ↓ arterial compliance → systolic HTN
- Only 48% of patients with dx of HTN have adequate BP control

Etiologies

- **Essential** (95%): onset 25-55 y; ⊕ FHx. Unclear mechanism but ? additive microvasc renal injury over time w/

contribution of hyperactive sympathetics (*NEJM* 2002;346:913). Both genetic (*Nature* 2011;478:103) & environmental risk factors (Na, obesity, inactivity) Blacks more likely to be salt sensitive and have less activation of renin-angiotensin system, explaining preference for thiazides & CCB over ACEI or ARB

- **Secondary:** Consider if Pt <20 or >50 y or if sudden onset, severe, refractory HTN

Secondary Causes of Hypertension

Diseases		Suggestive findings	Initial workup
RENAL	**Renal parenchymal** (2-3%)	h/o DM, polycystic kidney disease, glomerulonephritis	CrCl, albuminuria See "Renal Failure"
	Renovascular (1-2%, qv) Athero (90%) FMD (10%, women) PAN, scleroderma	ARF induced by ACEI/ARB Recurrent flash pulm edema Renal bruit; hypokalemia (*NEJM* 2009;361:1972)	MRA (>90% Se & Sp, less for FMD), CTA, duplex U/S, angio, plasma renin (low Sp)
ENDO	**Hyperaldo or Cushing's** (1-5%)	Hypokalemia Metabolic alkalosis	See "Adrenal Disorders"
	Pheochromocytoma (<1%)	Paroxysmal HTN, H/A, palp.	
	Myxedema (<1%)	See "Thyroid Disorders"	TFTs
	Hypercalcemia (<1%)	Polyuria, dehydration, Δ MS	iCa
OTHER	**Obstructive sleep apnea** (qv)		
	Medications: OCP, steroids, licorice; NSAIDs (espec COX-2); Epo; cyclosporine		
	Aortic coarctation: ↓ LE pulses, systolic murmur, radial-femoral delay; abnl TTE, CXR		
	Polycythemia vera: ↑ Hct		

Standard workup (*J Clin HTN* 2014;16:14)

- Goals: (1) identify CV risk factors or other diseases that would modify prognosis or Rx;

  (2) reveal 2° causes of hypertension; (3) assess for target-organ damage
- History: CAD, HF, TIA/CVA, PAD, DM, renal insufficiency, sleep apnea, preeclampsia; ⊕ FHx for HTN; diet, Na intake, smoking, alcohol, prescription and OTC meds, OCP
- Physical exam: ✓ **BP in both arms**; funduscopic exam; BMI & waist circumference; cardiac (LVH, murmurs) including signs of HF, vascular (bruits, radial-femoral delay); abdominal (masses or bruits); neuro exam

- Testing: K, BUN, Cr, Ca, glc, Hct, U/A, lipids, TSH, urinary albumin:creatinine (if ↑ Cr, DM, or peripheral edema), ? renin, ECG (for LVH), CXR, TTE (eval for valve abnl, LVH)
- Ambulatory BP monitoring (ABPM): predictive of CV risk and ↑ Se & Sp for dx of HTN vs office BP (HTN 2005;46:156). Consider for suspected episodic or white coat HTN, resistant HTN, HoTN sx on meds, or suspected autonomic dysfxn. Rec by some guidelines to confirm HTN dx, so utilization may expand (*BMJ* 2011;342:d3621 & 343:d4891).

Complications of HTN

- *Each ↑ 20 mmHg* SBP *or 10 mmHg* DBP *→ 2× → CV complications* (*Lancet* 2002;360:1903)
- Neurologic: **TIA/CVA**, ruptured aneurysms, vascular dementia

- Retinopathy: stage I = arteriolar narrowing; II = copper wiring, AV nicking; III = hemorrhages and exudates; IV = papilledema
- Cardiac: **CAD**, **LVH**, **HF**, **AF**
- Vascular: aortic dissection, aortic aneurysm (HTN = key risk factor for aneurysms)
- Renal: proteinuria, **renal failure**

Treatment (*JAMA* 2014;311:507; *J Clin HTN* 2014;16:14; *JACC* 2015;65:1998)

- Goal: in general, <**140/90 mmHg**

  In elderly: data sparser, but benefit, albeit w/ less strict BP target (*NEJM* 2008;358:1887); thus, consider <150/90 mmHg if either (a) ≥80 y and w/o DM or CKD (ASH/ISH rec), or (b) ≥60 y (but no need to downtitrate if <140/90 & tolerating meds) (JNC 8 rec)

  In Pts w/ prior MI or stroke: reasonable to consider <130/80 (HTN 2015;65:1372)

  In Pts w/ DM and/or CKD: prior targets of <130/80 not supported by data (and harm if target <120; *NEJM* 2010;362:1575), but may consider if CKD & albuminuria for renal protection (ASH/ISH rec based on *NEJM* 1994;330:877)
- *Treatment results in 50% ↓ HF, 40% ↓ stroke, 20-25% ↓ MI* (*Lancet* 2014;384:591)
- **Lifestyle modifications** (each ↓ SBP ~5 mmHg) weight loss: goal BMI 18.5-24.9; aerobic exercise: ≥30 min exercise/d, ≥5 d/wk diet: rich in fruits & vegetables, low in saturated & total fat (DASH, *NEJM* 2001;344:3) sodium restriction: ≤2.4 g/d and ideally ≤1.5 g/d (*NEJM* 2010;362:2102) maintain adequate potassium intake through diet counseling (~120 mEq of dietary potassium) if no predisposition to hyperkalemia (*NEJM* 2007;356:1966)

  limit alcohol consumption: ≤2 drinks/d in ♂; ≤1 drink/d in ♀ & lighter-wt Pts avoid exacerbating exposures (eg, NSAID use)
- **Pharmacologic options** for HTN or pre-HTN w/ comorbidity (nb, pre-HTN w/o DM, CKD, CV disease, or other end organ dysfunction treated w/ lifestyle alone) **Pre-HTN:** ARB prevents onset of HTN, no ↑ in clinical events (*NEJM* 2006;354:1685) **HTN:** *choice of therapy controversial, concomitant disease and stage may help guide* Rx **uncomplicated:** CCB, ARB or ACEI, or thiazide (chlorthalidone preferred) are 1st line (*NEJM* 2009;361:2153); βB not 1st line (*Lancet* 2005;366:1545).

  For non-black Pts <60 y: reasonable to start w/ ARB or ACEI, then add CCB or thiazide if needed, and then add remaining class if still needed

  For black, elderly, and ? obese Pts (all of whom more likely to be salt sensitive): reasonable to start with

CCB or thiazide, then add either the other 1st choice class or ARB or ACEI if needed, and then all 3 classes if still needed

+CAD (*Circ* 2015;131:e435): ACEI or ARB (*NEJM* 2008;358:1547); ACEI+CCB superior to ACEI+thiazide (*NEJM* 2008;359:2417) or βB+diuretic (*Lancet* 2005;366:895); may require βB and/or nitrates for anginal relief; if h/o MI, βB ± ACEI/ARB ± aldo antag (see "ACS")

+HF: ACEI/ARB, βB, diuretics, aldosterone antagonist (see "Heart Failure")

+2° stroke prevention: ACEI (*Lancet* 2001;358:1033); ? ARB (*NEJM* 2008;359:1225)

+diabetes mellitus: ACEI or ARB; can also consider thiazide or CCB

+chronic kidney disease: ACEI or ARB (*NEJM* 1993;329:1456 & 2001;345:851 & 861)

- **Tailoring therapy**

  lifestyle Δs typically complementary rather than alternative to drug Rx [although if low risk (stage 1, no end-organ damage or risk factors), could start with lifestyle]

  if stage 1, start w/ monoRx; if stage 2, consider starting w/ combo (eg, ACEI + CCB; *NEJM* 2008;359:2417), as most will require ≥2 drugs

  typically start drug at ½ maximal dose; after 2-3 wk either titrate up or add new drug

Resistant hypertension (*JAMA* 2014;311:2216)

- BP > goal on ≥3 drugs incl diuretic, ~12-13% of hypertensive population (HTN 2011;57:1105)
- Differentiate between true & *pseudoresistance,* w/ latter due to: inaccurate measurement or use of wrong cuff size poor dietary compliance (Na/K intake, can assess w/ 24-hr urine for Na, K and Cr) suboptimal med dosing (eg, <50% of max dose) or poor med compliance volume expansion (inadequate diuretic dosing) white coat HTN (consider ABPM) 2° causes or external drivers (eg, OSA, steroids, NSAIDS, alcohol) (*Lancet* 2010;376:1903)
- True resistance = uncontrolled BP confirmed by ABPM despite compliance w/ optim. doses
- Treatment considerations:

  Persistent ↑ volume may contribute even if on standard HCTZ (*Archives* 2008;168:1159).

  Effective diuretic dosing required for most to achieve control (HTN 2002;39:982).

  Chlorthalidone over HCTZ (if renal function preserved). Loop diuretic favored over thiazide for initial Rx if eGFR <30; however, adding thiazide to loop can ↑ diuresis if insufficient response to loop alone.

  Adding aldosterone antagonist (if renal function preserved) (*PATHWAY-2, ESC* 2015)

  Adding β-blocker (particularly vasodilating ones such as labetalol, carvedilol, or nebivolol), centrally acting agent, α-blocker, or direct vasodilator

  Other Rx under investigation: renal denervation (see below); carotid baroreceptor stimulation; central AV anastomosis ↑ SBP by ~23 mmHg (*Lancet* 2015;385:1634)

- **Renal denervation:** catheter-based RF ablation of renal nerves modifying sympathetic outflow. Had appeared beneficial in unblinded and/or uncontrolled studies, but no effect on BP in controlled trial, so not currently an option in routine care (*NEJM* 2014;370:1393).

Special situations

- **Secondary causes**

  Renovascular (qv)

  Renal parenchymal disease: salt and fluid restriction, ± diuretics

  Endocrine etiologies: see "Adrenal Disorders"

- **Pregnancy:** methyldopa, labetalol, nifedipine, hydralazine; avoid diuretics; Ø ACEI/ARB

HYPERTENSIVE CRISES

- **Hypertensive emergency:** ↑ BP → acute target-organ ischemia and damage

  neurologic: encephalopathy (insidious onset of headache, nausea, vomiting, confusion), hemorrhagic or ischemic stroke, papilledema

  cardiac: ACS, HF/pulmonary edema, aortic dissection

  renal: proteinuria, hematuria, acute renal failure; scleroderma renal crisis

  microangiopathic hemolytic anemia; preeclampsia-eclampsia

- **Hypertensive urgency (severe asymptomatic HTN):** SBP >180 or DBP >120 (?110) w/ minimal or no target-organ damage

Precipitants

- Progression of essential HTN ± medical noncompliance (espec clonidine) or Δ in diet
- Progression of renovascular disease; acute glomerulonephritis; scleroderma; preeclampsia
- Endocrine: pheochromocytoma, Cushing's
- Sympathomimetics: cocaine, amphetamines, MAO inhibitors + foods rich in tyramine
- Cerebral injury: do *not* treat HTN in acute ischemic stroke unless Pt getting lysed, extreme BP (>220/120), Ao dissection, active ischemia or HF (*Stroke* 2003;34:1056)

Treatment (*Chest* 2007;131:1949)

- Tailor goals to clinical context (eg, more rapid lowering for Ao dissection)
- Emergency: ↓ MAP by ˜25% in mins *to 2* h w/ IV agents (may need arterial line for monitoring); goal DBP <110 w/in 2-6 h, as tolerated
- Urgency: ↓ BP to ≤160/100 in *hrs* using PO agents; goal normal BP in ˜1-2 d
- Watch UOP, Cr, mental status: may indicate a lower BP is not tolerated

Drugs for Hypertensive Crises

IV	Nitroprusside* 0.25-10 mcg/kg/min	Nitroglycerin 5-1000 mcg/min
	Labetalol 20-80 mg IVB q10min or 0.5-2 mg/min	Esmolol 0.5 mg/kg load → 0.05-0.2 mg/kg/min
	Fenoldopam 0.1-1.6 mcg/kg/min	Hydralazine 10-20 mg q20-30 min

	Nicardipine 5-15 mg/h	Clevidipine 1-16 mg/h
	Phentolamine 5-15 mg bolus q5-15min	Enalaprilat 1.25 mg
	Captopril 12.5-100 mg tid	Labetalol 200-800 mg tid
PO	Clonidine 0.2 mg load → 0.1 mg qh	Hydralazine 10-75 mg qid

*Metabolized to cyanide → Δ MS, lactic acidosis, death. Limit use of very high doses (8-10 mcg/kg/min) to <10 min. Monitor thiocyanate levels. Hydroxocobalamin or sodium thiosulfate infusion for treatment of cyanide toxicity.

Treatment Considerations for Specific Clinical Settings

Clinical	Setting Note	Treatment
Acute stroke	BP ↓ must be balanced w/ risk of worsening ischemia	Consult stroke team
Aortic dissection (qv)	✓ BP in both arms and treat higher value	βB first, then add vasodilator (eg, nitroprusside) if needed
Acute pulm edema	Avoid ⊖ inotropes (eg, βB) if LV dysfxn, unless ischemia	Vasodilator (eg, NTG) and loop diuretic
Antihypertensive withdrawal	Suspect if abrupt d/c of symp. blocker (eg, clonidine)	Restart d/c'd drug or consider labetalol or nitroprusside
Sympathetic activity (pheo, auton dysfxn, cocaine, MAO + tyramine-containing foods)	Avoid βB as could → unopposed α in vasculature → vasconstriction and further ↑ BP	Phentolamine (pheochromocytoma), nitroprusside

RENOVASCULAR DISEASE

Pathophysiology

- ↑ renal perfusion → activation of RAA system → vasoconstriction, ↑ aldo & vasopressin, ↑ sympathetic activity → volume retention & HTN → progressive renal dysfxn and CV risk

- Unilateral stenosis ↑ HTN
- Bilateral (or unilat involving solitary functioning kidney) → HTN & progressive renal insuffic

Etiologies

- **Atherosclerosis** (˜90%): usually involving ostial or prox segments. Often incidental finding as common in Pts w/ established athero (eg, CAD, PAD) but uncommon cause of HTN.
- **Fibromusclar dysplasia** (FMD, ˜10%): nonathero medial fibroplasia usually mid/distal female-predominant (85-90%); mean age 52 y (*Circ* 2012;125:3182) characteristic “string of beads” appearance (or concentric smooth stenosis) on angio usually > 1 territory involved (eg, carotid in ˜65%), explaining sx of HA, dizziness, tinnitus
- Other (uncommon): vasculitis (Takayasu's, GCA, PAN or eosinophilic granulomatosis w/ polyangiitis) often w/ ↑ inflammatory markers, systemic s/s; scleroderma; local aneurysm or dissection; embolism; retroperitoneal fibrosis

Diagnosis

- Consider testing if any of the following *and* if finding would modify treatment:

  Clinical picture consistent w/ secondary HTN w/ no other compelling etiology Severe HTN (SBP ≥180 and/or DBP ≥120 mmHg) and/or flash pulm edema/CHF Progressive renal insufficiency w/ bland sediment, unilateral small kidney (≤9 cm), renal asymmetry > 1.5 cm, or acute sustained Cr ↑ by ≥30% w/in 1 wk of starting ACEI/ARB

Testing for Renovascular Disease (*Am Fam Physician* 2009;80:273)

Modality	Se	Sp	Notes
Duplex Doppler US	85%	92%	Pt habitus & operator dependent. May be preferred if renal dysfxn. Allows quantification of resistive index.*
CTA	88-96%	97%	Less sensitive (˜30%) for distal disease such as FMD Contrast agent nephrotoxic
MRA	88-100%	>95%	Less sensitive (˜30%) for distal disease such as FMD Risk of nephrogenic systemic fibrosis if mod-sev CKD
Angiography (DSA)	gold standard		Allows measurement of gradients Invasive, contrast agent nephrotoxic
Plasma Renin Activity (PRA)	50-80%	low	Not 1st line. Can ↑ Se by measuring 1 hr after capto administration
Captopril Renal Scan	75-100%	n/a	Not 1st line, but can determine hemodynamic signif of stenosis. Not reliable in bilateral RAS or poor renal fxn.

*Resistive index = [(peak syst vel - end diast vel) / peak syst vel].

- Monitoring: for athero, repeat imaging only necessary if Δ in clinical status that would lead to intervention; for FMD image q6-12mo to assess for progression

Treatment

- If due to atherosclerosis, risk factor modification: quit smoking, ↓ chol
- Antihypertensive Rx effective for most Pts: diuretic + ACEI/ARB (watch for ↑ Cr) or CCB
- Revascularization (typically percutaneous w/ stenting):

  Had considered if refractory HTN, recurrent flash pulm edema, worsening CKD

  However, clinical trials enrolling stable Pts w/ mod stenosis (50-70%) and HTN on ≥2 agents showed no benefit on # of BP meds, renal fxn or CV outcomes (*NEJM* 2000;342:1007; 2009;361:1953; 2014;370:13). Unknown if beneficial in more severe stenoses or in higher-risk Pts (eg, recent CHF, >3 meds).

  Resistive index >80 on U/S implies intrinsic renal damage and thus less likely to benefit from revasc, so may predict outcome after intervention (*NEJM* 2001;344:410). Operator dependent and some studies have not replicated findings, so not utilized broadly.

  Renal vein renin measurements, PRA, captopril renogram may provide supportive evidence as to hemodynamic significance of RAS, but limited utility due to low Se

  For FMD (usually more distal lesions): PTA ± bailout stenting
- Surgery (very rare): resection of pressor kidney
- Bilateral RAS: 20-46% of Pts w/ RAS. Associated w/ higher creatinine and worse CV outcomes. In addition to anti-HTN Rx, consider revasc if likely to benefit (failure of meds, recurrent pulmonary edema, progressive renal failure). Trials including Pts w/ bilateral RAS did not show benefit but included moderate stenoses.

AORTIC ANEURYSMS

Definitions

- **True** aneurysm (≥50% dilation of all 3 layers of aorta; <50% called ectasia) vs **false or pseudoaneurysm** (rupture contained by adventitia)
- **Location:** root (annuloaortic ectasia), thoracic aortic aneurysm (TAA), thoracoabdominal aortic aneurysm (TAAA), abdominal aortic aneurysm (AAA)
- **Type:** fusiform (circumferential dilation) vs saccular (localized dilation of aortic wall)

Epidemiology (*Circ* 2010;121:e266, 2011;124:2020 & 2013;127:e6; *Nat Rev Cardiol* 2011;8:92)

- In U.S., ~15,000 deaths/y from aortic ruptures; overall ~50,000 deaths/y from Ao disease
- **TAA:** 10/100,000 Pt-yrs, ♂:♀ 2:1; ~60% root/ascending; 40% descending

- **AAA:** ~4-8% prev in those >60 y (although may be ↓ ; *Circ* 2011;124:1118); 4-6× more common in ♂ vs ♀; mostly infrarenal
- Arch & TAAA rarer

Pathophysiology (*NEJM* 2009;361:1114; *Nat Med* 2009;15:649)

- Medial degeneration and/or ↑ wall stress

  Medial degeneration = muscle apoptosis, elastin fiber weakening, mucoid infiltration

  Wall stress ∝ [(ΔP × r) / (wall thickness)], LaPlace's law
- **TAA:** most commonly medial degeneration; seen w/ connective tissue disorders & aortitis
- **AAA:** most commonly long-standing HTN + athero/inflammation → medial weakening

Risk factors

- Classic: **HTN**, **atherosclerosis**, **smoking**, **age**, **male sex**
- **Marfan syndrome** (mutations in fibrillin-1, *FBN*-1): cardinal features are Ao root aneurysm & ectopia lentis. Other suggestive signs include: tall stature; arachnodactyly w/ *thumb sign* (entire distal phalanx of adduct. thumb extends beyond ulnar border of palm) and/or *wrist sign* (tip of thumb covers 5th finger fingernail when wrapped around contralat wrist); pectus deformities; scoliosis; dural ectasia; spontaneous PTX; MVP.
- **Loeys-Dietz syndrome** (mutation in TGF-β receptors 1 or 2, *TGFBR1/2*): triad of arterial tortuosity & aneurysms, widely spaced eyes, bifid uvula or cleft palate. Also w/ velvety & hyperlucent skin and bluish sclera.
- Vascular **Ehlers-Danlos syndrome** (mutation in type III procollagen, *COL3A1*): easy bruising; thin, translucent skin w/ visible veins (but not excessively stretchable); acrogeria (aged appearance of hands & feet); flexible digits; uterine or intestinal rupture; distinctive facial features (protruding eyes, thin nose & lips, sunken cheeks, small chin)
- Other genetic disorders: **bicuspid AoV**; Turner syndrome (45X; short stature, ovarian failure, Ao coarctation); other familial aortopathies (mutations in smooth muscle myosin & actin genes including MYH11 and ACTA2)
- **Aortitis:** Takayasu's, GCA, spondyloarthritis, IgG4-related disease
- **Infection** (ie, mycotic aneurysm): salmonella, TB, syphilis

Screening (*Circ* 2010;121:e266 & 2011;124:2020; *Annals* 2014;161:281; *JAMA* 2015;313:1156)

- **TAA:** if bicuspid AoV or 1° relative w/: (a) TAA or bicuspid valve, (b) Marfan, Loeys-Dietz, Turner; known relevant genetic mutation (see above)
- **AAA:** ✓ for pulsatile abd mass; U/S ♂ >60 y w/ FHx of AAA & ♂ 65-75 y w/ prior tobacco

Diagnostic studies (*Circ* 2010;121:e266 & 2011;124:2020)

- **Contrast CT:** quick, noninvasive, high Se & Sp for all aortic aneurysms
- **TTE/TEE:** TTE most useful for root and proximal Ao; TEE can visualize other sites of TAA
- **MRI:** preferred over CT for aortic root imaging for TAA; also useful in AAA but time-consuming; noncontrast “black blood” MR to assess aortic wall

- **Abdominal U/S:** screening and surveillance test of choice for infrarenal AAA

Treatment principles (*Circ* 2006;113:e463; 2008;117:1883; 2010;121:1544 & e266)

- Goal is to prevent rupture (50% mortality prior to hospital) by modifying risk factors
- **Smoking cessation:** smoking associated w/ ↑ rate of expansion (*Circ* 2004;110:16)
- **Statin** (to achieve LDL-C <70 mg/dL): ↓ death and stroke & possibly ↓ rate of expansion (*Eur J Vasc Endovasc Surg* 2006;32:21)
- **BP control: βB** (↓ dP/dt) ↓ aneurysm growth (*NEJM* 1994;330:1335)

  ACEI a/w ↓ risk of rupture (*Lancet* 2006;368:659)

  ARB may ↓ rate of aortic root growth in Marfan (*NEJM* 2008;358:2787)

  βB and ARB similar ↓ rate of Ao root growth in children and young adults w/ Marfan (*NEJM* 2014;371:2061)

- Moderate cardiovascular exercise okay, but no burst activity/exercise requiring Valsalva maneuvers (eg, heavy lifting)
- **Indications for intervention** (surgery/endovascular repair)

  Individualize based on FHx, body size, gender, anatomy, surgical risk

  TAA (*Circ* 2010;121:1544 & e266) symptoms

  ascending Ao ≥5.5 cm (4-5 cm if Marfan, bicuspid AoV, Loeys-Dietz, vascular EDS, or other genetic/familial disorder)

  descending >6 cm ↑ >0.5 cm/y

  aneurysm >4.5 cm and planned AoV surgery

  AAA (*NEJM* 2002;346:1437 & 2014;371:2101) symptoms infrarenal ≥5.5 cm, but consider ≥5.0 cm in ♀ ↑ >0.5 cm/y; inflam/infxn

Surgery (*Circ* 2010;121:e266; *EHJ* 2014;25:2873)

- Ascending aorta

  No root involvement: resection & replacement w/ Dacron tube graft

  Root involvement: need to address AoV integrity; depending on AoV itself: modified Bentall: Dacron Ao root + prosthetic AoV, reattach coronaries valve-sparing: reimplant native AoV in Dacron Ao graft; reattach coronaries

- Arch: high-risk, complex surgery because of the arch branches; variety of combinations of partial/complete resection, stent graft & bypass of arch vessels
- Descending thoracic aorta: resection & grafting vs endovascular repair (qv)

Endovascular repair (EVAR) (*NEJM* 2008;358:494; *Circ* 2011;124:2020 & 2015;131:1291)

- Depends on favorable aortic anatomy
- TEVAR (thoracic EVAR) for descending TAA ≥5.5 cm may ↑ periop morbidity and possibly mortality (*Circ* 2010;121:2780; *JACC* 2010;55:986; *J Thorac CV Surg* 2010;140:1001 & 2012;144:604)
- AAA

Guidelines support open repair or EVAR for infrarenal AAA in good surg candidates ↓ short-term mort., bleeding, LOS; but long-term graft complic. (3-4%/y; endoleak, need for reintervention, rupture) necessitate periodic surveillance, with no proven Δ in overall mortality in trials, except ? in those <70 y (*NEJM* 2010;362:1863, 1881 & 2012;367:1988)

In observational data, EVAR assoc w/ ↑ survival over 1st 3 y, after which survival similar. Rates of rupture over 8 y 5.4% w/ EVAR vs 1.4% w/ surgery (*NEJM* 2015;373:328)

In Pts unfit for surgery or high periop risks: ↓ aneurysm-related mortality but no Δ in overall mortality over medical Rx (*NEJM* 2010;362:1872). EVAR noninferior (? superior) to open repair in ruptured AAA w/ favorable anatomy (*Ann Surg* 2009;250:818).

- Pt selection for endovascular includes requirement to comply with long-term surveillance

Complications (*Circ* 2010;121:e266; *Nat Rev Cardiol* 2011;8:92)

- **Pain:** gnawing chest, back or abdominal pain; new or worse pain may signal rupture
- **Rupture:** risk ↑ w/ diameter, ♀, current smoking, HTN

  TAA: ~2.5%/y if <6 cm vs 7%/y if >6 cm

  AAA: ~1%/y if <5 cm vs 6.5%/y if 5-5.9 cm rupture p/w severe constant pain and hemorrhagic shock; ~80% mortality at 24 h
- **Aortic insufficiency (TAA)** and **CHF**
- **Acute aortic syndromes** (qv)
- **Thromboembolic ischemic events** (eg, to CNS, viscera, extremities)
- **Compression of adjacent structures** (eg, SVC, trachea, esophagus, laryngeal nerve)

Follow-up (*Circ* 2010;121:1544 & e266; *Nat Rev Cardiol* 2011;8:92; *JAMA* 2013;309:806)

- Expansion rate ~0.1 cm/y for TAA, ~0.3-0.4 cm/y for AAA
- AAA: <4 cm q2-3 yrs; 4-5.4 cm q6-12 mos; more frequent if rate of expansion >0.5 cm in 6 mo
- TAA: 6 mo after dx to ensure stable, and if stable, then annually (*Circ* 2005;111:816)
- Screen for CAD, PAD and aneurysms elsewhere, espec popliteal. About 25% of Pts w/ TAA will also have AAA, and 25% of AAA Pts will have a TAA: consider pan-Ao imaging.
- Patients with endovascular repair require long-term surveillance for endoleak & to document stability of aneurysm

ACUTE AORTIC SYNDROMES

Definitions (*Circ* 2005,112:3802 & 2010;121:e266; *Eur Heart J* 2012;33:26)

- **Aortic dissection** (AoD): intimal tear → blood extravasates into Ao media (creates false lumen). Rate 3-16/100,000 Pt-yrs. False lumen acts as "wind sock," ↑ in size and compressing true lumen (patency of false lumen associated with outcome).
- **Intramural hematoma** (IMH): vasa vasorum rupture → medial hemorrhage that does not communicate with aortic lumen; 6% of aortic syndromes; clinically managed as AoD

- **Penetrating ulcer** (PAU): atherosclerotic plaque penetrates elastic lamina → medial hemorrhage. PAU in setting of IMH assoc. w/ similar outcomes as AoD. Outcomes for isolated PAU less well defined but considered AAS. Rx depends on clinical context.

Classification (proximal twice as common as distal)

- **Proximal:** involves ascending Ao, regardless of origin (= Stanford A, DeBakey I & II)
- **Distal:** involves descending Ao only, distal to L subclavian art. (= Stanford B, DeBakey III)
- **Other Considerations:** isolated to arch generally treated as proximal; distal with involvement of subclavian depends on overall clinical picture.

Risk factors

- **Classic** (in older Pts): **hypertension** (h/o HTN in >70% of dissections); **age** (60s-70s), **male sex** (~70% ♂); **smoking**
- **Genetic or acquired predisposition** (may present younger; see "Aortic Aneurysms"):

  Connective tissue disease/congenital anomaly: Marfan, Loeys-Dietz, vascular Ehlers-Danlos, bicuspid AoV, coarctation (eg, in Turner's), other familial aortopathies, PCKD

  Aortitis: Takayasu's, GCA, Behçet's, syphilis

  Pregnancy: typically 3rd trimester
- Other environmental factors:

  Trauma: blunt, deceleration injury

  Cardiovascular procedures: IABP, cardiac or aortic surgery, cardiac catheterization

  Acute ↑ BP: cocaine, Valsalva (eg, weightlifting)

Clinical Manifestations and Physical Exam* (*JAMA* 2000;283:897)

Feature	Proximal	Distal
"Aortic" pain (abrupt, severe, tearing or ripping quality, *maximal at onset* [vs crescendo for ACS])	**94%** (chest, back)	**98%** (back, chest, abd)
Syncope (often due to tamponade)	**13%**	4%
HF (usually due to acute AI)	**9%**	3%
CVA	**6%**	2%
HTN	36%	**70%**
HoTN or shock (tamponade, AI, MI, rupture)	**25%**	4%

Pulse deficit (if involves carotid, subclavian, fem)	**19%**	**9%**
AI murmur	**44%**	12%

*S/S correlate w/ affected branch vessels & distal organs; may Δ as dissection progresses.

Initial evaluation (*Circ* 2010;121:e266)

- H&P, including bilateral BP and radial pulses for symmetry

  High-risk conditions: Marfan, CTD, FHx AoD, recent Ao manip., AoV dis., Ao aneurysm

  High-risk pain features: chest, back or abd pain described as [both (abrupt onset or severe intensity) and (ripping, tearing, sharp or stabbing) (absence ⊖ LR 0.3)]

  High-risk exam features:

  perfusion deficit [pulse deficit (⊕ LR 5.7), systolic BP differential (>20 mmHg), or focal neuro deficit + pain (⊕ LR >6)], or

  murmur of AI (new or not known to be old and in conjunction w/ pain), or hypotension or shock
- 12-lead ECG: often abnl but non-dx; may show STE if prox AoD involving coronary
- CXR: abnl in 60-90% [↑ mediast. (absence ⊖ LR 0.3), L pl effusion] but *cannot* r/o AoD
- *Obtain expedited Ao imaging if:* ≥2 high-risk features, 1 high-risk feature w/o clear alternative dx, or 0 features but unexplained HoTN or widened mediastinum on CXR

Diagnostic studies (*Circ* 2010;121:e266; *JACC CV Img* 2014;7:406)

- **CT:** quick, noninvasive, readily available, Se ≥93% & Sp 98%; however, if ⊖ & high clin. suspicion → additional studies (⅔ w/ AoD have ≥2 studies; *AJC* 2002;89:1235)
- **MRI:** Se & Sp >98%, but time-consuming test & not readily available
- Axial studies (CT, MRI) should be gated to ECG to evaluate Ao root; if high index of suspicion, study should include entire aorta (chest, abd, & pelvis)

- Echo

  TTE: low Se (∴ not dx study) but can show effusion, AI, & dissection flap (if proximal)

  TEE: Se >95% prox, 80% for distal; can assess cors/peric/AI; "blind spot" behind trachea
- **Aortography:** Se ~90%, time-consuming, cannot detect IMH; can assess branch vessels
- **D-dimer:** Se/NPV ~97%; ? <500 ng/mL to r/o dissec (*Circ* 2009;119:2702) but not in Pts at high clinical risk (doi:10.1016/j.annemergmed.2015.02.013); does not r/o IMH

Initial medical treatment (*Lancet* 2008;372:55; *Circ* 2010;121:1544; *JACC* 2013;61:1661)

- ↓ **dP/dt** targeting HR <60 & central BP <120 (or lowest that preserves perfusion; r/o pseudohypotension, eg, arm BP ↑ due to subclavian dissection; use highest BP reading)

- ***First* with IV βB** (eg, esmolol, labetalol) to blunt reflex ↑ HR & inotropy that would occur in response to vasodilators; verap/dilt if βB contraindic.
- ***Then* ↓ SBP with IV vasodilators** (eg, nitroprusside)
- HTN control may require multiple agents (median of 4 in one study; *J Hum Hypertens* 2005;19:227). If unable to control readily: 1st evaluate for complication (eg, visceral ischemia); Rx pain w/ MSO_4; if no complication, then consider other drivers (eg, EtOH withdrawal).
- **If HoTN:** urgent surgical consultation, IVF to achieve euvolemia, pressors to keep MAP 70 mmHg; r/o complication (eg, tamponade, contained rupture, severe AI)

Treatment of proximal AoD (*Circ* 2010;121:1544; *Lancet* 2015;385:800)

- *Acute:* all cases should be considered for emergent surgery

  root replacement; valve sparing unless bicuspid or valve involvement

  acute stroke should not necessarily dissuade from surgery (mortality w/o surgery ~100%, *Circ* 2013;128:S175)

  prior AoV surgery postulated to be protective from complications, but most would operate

  need for preop coronary angio debatable as procedure nontrivial in setting of dissection and likelihood of performing concomitant CABG low
- *Chronic:* consider surgery if complicated by progression, AI or aneurysm

Treatment of distal AoD (*Circ* 2010;121:1544; *JACC* 2013;61:1661; *Lancet* 2015;385:800)

- Intervention warranted if complication (see below)
- Endovascular intervention (fenestrate flap to decompress false lumen, open occluded branch, stent entry tear) may be preferred over surgery due to possible ↑ mort. (*JACC* 2013;61:1661 & *Circ* 2015;131:1291)
- Stent graft for *uncomplicated* cases may ↓ risk of aorta-related complications and adverse remodeling (*Circ Cardiovasc Interven* 2013;6:407)

Complications (occur in ~20%; *Circ* 2003;108:II-312 & 2010;121:e266)

- *Monitor all Pts w/ frequent assessment (sx, BP, UOP), pulse exam, labs (Cr, Hb, lactic acid), imaging (~7 d or sooner if sx or significant lab Δ)*
- *Uncontrolled BP despite intensive IV Rx or continued or → pain may indicate complication*
- **Progression:** propagation of dissection, ↑ aneurysm size, ↑ false lumen size
- **Rupture:** pericardial sac → tamponade (avoid pericardiocentesis unless PEA); blood in pleural space, mediast., retroperitoneum; ↑ in hematoma on imaging portends rupture
- **Malperfusion** (partial or complete obstruction of branch artery) can be *static* (avulsed/thrombosed) or *dynamic* (Δs in pressure in true vs false lumen) coronary → MI (usually RCA → IMI, since dissection often along outer Ao curvature) innominate/carotid → CVA, Horner intercostal/lumbar → spinal cord ischemia/paraplegia innominate/subclavian → upper extremity ischemia; iliac → lower extremity ischemia celiac/mesenteric → bowel ischemia (can be subtle w/ nonspecific GI sx, anorexia, pain) renal → acute renal failure or gradually ↑ Cr, refractory HTN
- **AI:** due to annular dilatation or disruption or displacement of leaflet by false lumen
- Mortality (*Circ* 2013;127:2031; *JACC* 2015;66:350)

~50% prior to hospital

historically ~1%/h × 48 h for acute prox AoD who survive to hospital w/ 47% subseq mort at 30 d; more recent data w/ 22% in-hospital mortality

13% at 30 d for acute distal overall but 25% if complications mortality similar for proximal and distal that survive to discharge: ~85% at 5 y

Long-term monitoring

- Major concern is progression to aneurysm or recurrent dissection
- Treat BP, risk factors aggressively
- **Serial imaging for all** (CT or MRI, latter may be preferred to lower cumulative radiation exposure) at 1, 3, and 6 mo, and then annually (18 mo, 30 mo, etc.)
- Pts treated endovascularly need close follow-up to monitor for complication (eg, endoleak)
- Partial thrombosis of false lumen associated with worse outcomes/mortality (*NEJM* 2007;357:349)
- In patients who present at young age or other indications of predisposing factor, consider genetic evaluation and screening of family members

PERIPHERAL ARTERY DISEASE (PAD)

Epidemiology and risk Factors

- Prev. ↑ w/ age: <1% if <40 y, ~15% if ≥70 y; risk factors incl. **smoking**, **DM**, HTN, chol
- More frequent in Pts w/ other symptomatic atherosclerotic disease (eg, coronary, carotid)
- Associated w/ ↑ risk of CV events (*JAMA* 2007;297:1197)
- If sx, 3-y risk of stroke ~3%, acute limb ischemia ~4%, periph revasc ~22% (*Circ* 2013;112:679)

Clinical Features

- **Asymptomatic** (~35%) or **atypical** sx (~40%): often undertreated in terms of risk factor modifying therapy (*Circ* 2011;124;17)
- **Claudication** (~25%): dull ache, often in calves precip by walking & relieved by stopping (vs spinal stenosis, qv)

  Leriche syndrome (aortoiliac occlusive disease): buttock & thigh claudication, ↑ or ø femoral pulses, & erectile dysfxn
- **Critical limb ischemia** (CLI, 1-2%): 1 or more of the following 3 manifestations

  rest pain: ↑ w/ elevation b/c ↓ perfusion

  ulcer: typically at pressure foci, often dry (in contrast, venous ulcers are more often at medial malleolus, wet, and with hemosiderin deposition)

  gangrene: more typically “dry” (ie, distal limb, dry shrunken and dark red, lack of pus) as a manifestation of ischemia due to impaired blood flow rather than “wet” (ie, infected, pus present, fetid smell), which may occur in the setting of infection or injury may be chronic (ie, sx >2-wk duration) vs acute limb ischemia, which is a

vascular emergency (see below)

a/w poor outcome: 45% amputation & 20% mortality at 6 mo (*J Vasc Surg* 2000;31:S1)

- Blue toe syndrome: most likely atheroembolic disease with occlusion of digital arteries

PAD Clinical Symptom Classification

Rutherford		Fontaine		Typical ABI*
Stage	**Definition**	**Stage**	**Definition**	
0	Asx	1	Asx	0.9-1.0
1	Mild claudication	2a	Sx at distance >650 ft	0.4-0.9
2	Mod claudication			
3	Severe claudication	2b	Sx at distance <650 ft	
4	Rest pain	3	Nocturnal or rest pain	<0.4
5	Ischemic ulceration not exceeding ulcer on digits of foot	4	Necrosis (death of tissue) and/or gangrene of limb	
6	Severe ischemic ulcers or frank gangrene			

*ABI is generally, but not absolutely correlated w/ clinical measures of lower extremity fxn & sx

Diagnosis

- Ddx includes

  nonvascular:

  neurogenic claudication (spinal stenosis): pain w/ standing, relieved by sitting, lying, or forward flexion; a/w neurologic abnl (weakness, sensory Δs, h/o deg. disc disease)

  musculoskeletal/arthritis: joint pain, morning stiffness, associated joint pathology or instability, crepitus or effusion

  Baker's cyst: posterior knee pain, knee stiffness, mass behind knee, discomfort w/ prolonged standing, impairment of bending

  non-athero vascular:

  venous claudication (uncommon): pain w/ walking in setting of proximal venous obstruction & no arterial obstruction

  dissection, embolism, aneurysm, or vasculitis

popliteal artery entrapment (exercise-induced lower leg pain)

- Physical exam: ↓ peripheral pulses ± femoral bruits if severe: pallor of feet w/ elevation, dependent rubor, cyanosis other signs of chronic PAD: hair loss/shiny or cool skin, skin atrophy, nail hypertrophy

Testing

- **Ankle:brachial index (ABI):** nl 1-1.4; borderline 0.91-0.99; abnl ≤0.90; if > 1.4, non-dx, likely due to calcified/noncompressible vessel
- **Toe:brachial index (TBI)** helpful if noncompressible (toe artery less likely to calcify); but ranges different than ABI (>0.7 nml, 0.5-0.7 mild, 0.35-0.5 mod, <0.35 mod-severe, severe if toe pressure <30 mmHg)

- **Segmental pressures** to determine level of disease (20 mmHg gradient between segments indicates stenosis)
- **Pulse volume recording (PVR)** done w/ segmental pressures: determine site and severity of disease. Abnormal waveform can indicate disease in noncompressible vessel, but pressures used over waveform if vessels are compressible.
- If ⊕ sx but nl ABI: ✓ **exercise ABI** (some consider even in asx Pt w/ risk factors for PAD if will modify therapy)
- Treadmill study (or 6-min walk test) to quantify magnitude of functional limitation
- **Imaging** (Duplex arterial U/S; CTA w/ distal run-off; MRA or angio) if dx in question or considering intervention. Some do routine Duplex U/S to monitor graft/stent patency.

Medical treatment (*JACC* 2013;61:1555; *JAMA* 2013;309:453; *Circ Res* 2015;116:1579)

- **Treat risk factors:** smoking cessation, high-intensity statin, control HTN & DM, smoking cessation (*JACC* 2010;56:2105). βB OK if indicated for another reason (eg, CAD, AF).
- **Antiplatelet Rx:** benefit shown primarily for ↑ CV risk (*BMJ* 2002;324;71)

  If asx: benefit of antiplt Rx unclear espec if ABI only borderline (*JAMA* 2010;303;9)

  If sx: ASA or clopidogrel

  ASA: 23% ↓ risk of major CV events seen in meta-analysis of older studies (mostly ASA but also other antiplatelet Rx) (*BMJ* 2002;324:71)

  Clopidogrel: superior to ASA, but single, older study (*Lancet* 1996;348:1333)

  ASA+clopi may be better than ASA alone, but only posthoc data (*EHJ* 2009;30:1992)

  Vorapaxar (PAR-1 antag.) further ↓ risk on top of ASA or clopidogrel (*Circ* 2013;112:679)
- Anticoagulation w/ warfarin not beneficial (*NEJM* 2007;357:217)
- **ACEI/ARB** to ↓ CV risk (*NEJM* 2000;342:145)
- **Improve claudication**

  Supervised exercise: sx-limited, ≥3×/wk, ≥30-45 min/session, ↑ as tolerated; beneficial including ↑ walking time 50-200% (*Cochrane* 2014;7:CD990); structured exercise more effective than home-based, but home-based still effective (*JAMA* 2013;310:57)

  ACEI & statins may ↓ sx (*Circ* 2003;108:1481)

  Cilostazol (nb, interacts w/ diltiazem & omeprazole; may cause headache or diarrhea; do not use in Pts w/

CHF); pentoxifylline likely less effective

- **Limb preservation:** foot exams for ulcers/wounds, revasc (qv), vorapaxar (PAR-1 antag) ↓ acute limb ischemia (*Circ* 2013;112:679), statin use assoc. w/ ↓ amput (*EHJ* 2014;35:2864)

Revascularization

- Consider if limiting sx despite exercise/medical Rx or if CLI; also consider as 1st-line Rx for isolated aortoiliac disease given high rate of long-term patency (*Circ* 2013;128:2704)
- **Endovascular** (angioplasty or stenting) usually favored over **surgical** (bypass or endarterectomy), but depends on lesion complexity & location (aortoiliac or "inflow" vs infrainguinal or "outflow") and Pt comorbidities
- Decision for stent vs angioplasty alone depends on lesion length & complexity, location (eg, over joints) (*J Vasc Surg* 2007;33:S1)
- Angioplasty w/ paclitaxel-coated balloon associated with ↑ primary patency vs regular balloon for femoropopliteal disease (*NEJM* 2015;373:145)
- Durability of endovascular revascularization depends in part on location, with greater longterm patency for iliac vs femoral interventions (*JACC* 2006;47:e1)
- Dual antiplatelet (DAPT, ASA + clopidogrel) commonly prescribed after endovascular intervention for 1-3 mo, but no prospective data. DAPT after bypass surgery not beneficial overall but possibly in subgroup w/ prosthetic grafts (*J Vasc Surg* 2010;52:825).
- Anticoagulation with warfarin does not improve patency (*NEJM* 2007;357:217), but may be indicated in subgroups with high thrombotic risk
- Stents not ferromagnetic, so MRI safe, but both MRI & CT may have artifact. Duplex U/S useful to assess stent patency and is used by some for serial routine monitoring of stent or graft patency, even in asx Pts.
- If coronary angiography needed, avoid access through CFA stent or femoral bypass

Acute limb ischemia (ALI)

- Sudden decrement in limb perfusion that threatens viability; *viable* (no immed threat of tissue loss): audible art. Doppler signals, sensory & motor OK *threatened* (salvage requires prompt Rx): loss of arterial Doppler signal, sensory or motor
- Etiologies: embolism > acute thrombosis (eg, athero, APLA, HITT), trauma to artery
- Clinical manifestations (**6 Ps**): pain (distal to proximal, ↑ in severity), poikilothermia, pallor, pulselessness, paresthesias, paralysis
- Testing: thorough pulse & neuro exam; arterial Doppler; angiography, either CT w/ bilateral run-off through feet or arteriography
- Urgent consultation w/ vascular medicine and/or vascular surgery
- Treatment: immediate anticoagulation ± intra-arterial lytic; angioplasty or surgery

CEREBROVASCULAR DISEASE

EXTRACRANIAL DISEASE

Pathobiology

- Involving portions of carotid or vertebral arteries outside skull. Most commonly at carotid bifurcation but may involve common (CCA), internal (ICA), or external carotid (ECA).
- Most common etiology is athero; others include FMD, vasculitis, dissection, & radiation
- Associated w/ ↑ risk of systemic CV events including ipsilateral TIA/stroke
- Progressive narrowing, thrombosis or unstable plaque in CCA or ICA → embolization and/or ↑ distal perfusion → ischemia → TIA/stroke
- Asx *chronically occluded* vessel associated w/ low risk, as no embolization and Circle of Willis provides collateral flow

Diagnosis (*Circ* 2011;124:354)

- Stenosis defined as % lumen diameter at most severe stenosis relative to either ICA, probable lumen diameter at site of stenosis, or proximal common carotid (*J Neuroimaging* 1994;4:222). Significant stenosis is >50%.
- Carotid bruit suggestive but not sensitive
- **Duplex U/S:** Se >80%, Sp ~85%; 1st-line test

  Peak systolic velocity (PSV) for severity

  ↑ end diastolic velocity (EDV), spectral broadening, carotid index (ratio of PSV in ICA vs CCA) and echolucent plaque each associated w/ ↑ risk

  PSV >200 cm/s + EDV > 140 cm/s + carotid index > 4.5 has Se 96% for significant stenosis (*Stroke* 1996;27:1965; *Mayo Clin Proc* 2000;75:1133)
- Transcranial Doppler (TCD) as adjunct to U/S may show severe stenosis, evidence of occlusion (collateral flow), or microemboli by high-intensity signal transients (HITS)
- If significant but nonsevere stenosis, repeat study at 6 mo to determine if stable and then annually thereafter
- If stenosis appears severe (≥70%) or requires further characterization, then either CT angio (Se ~90%, Sp ≥95%) or MRA (Se ~95%, Sp ≥95%). Caution with contrast & risk of either renal dysfxn (CTA) or nephrogenic systemic fibrosis (MRA).
- Angiography gold standard but invasive and assoc w/ risk of stroke

Asx carotid stenosis (*Curr Treat Opt CV Med* 2013;252:63; *Expert Rev CV Ther* 2014;12:437)

- Cause of <15% of strokes and risk <1% annually in Pts on standard med Rx (see below)
- General management

  lifestyle intervention (smoking cessation, diet modification, exercise)

  antiplatelet therapy: ASA 75-325 mg/d or clopidogrel 75 mg/d if ASA allergic (*Circ* 2011;124:354)

  high-intensity statin (see "Lipids") and **BP control** (see "HTN")
- **Revascularization** (see options below) for selected Pts w/ ≥70% stenosis

  older trials have shown ↓ stroke risk vs med Rx alone, but not compared to modern med Rx (*NEJM*

1993;328:221; *JAMA* 1995;273:1421; *Lancet* 2004;363:1491)

due to low rate of associated stroke, absolute risk reduction likely small and benefit of intervention debated

consider Pt preference, risk of procedure, overall life expectancy (eg, ≥5 y), gender (benefit less certain in women), lesion characteristics of ↑ stroke risk (eg, echolucent plaque, TCD evidence of microemboli)

Symptomatic carotid stenosis (*NEJM* 2013;369:12)

- Symptomatic stenosis indicative of severe/unstable plaque and associated w/ ↑ risk of stroke. ∴ determination of sx important regarding treatment plan.
- Defined as recent (<6 mo) focal neurologic sx, sudden in onset, referable to carotid distribution. May include TIA or minor stroke [incl amaurosis fugax (transient monocular blindness)]. Vertigo & syncope unlikely related and generally not considered sx.
- For acute treatment for stroke, see “Stroke”
- All Pts w/ sx stenosis should receive med Rx as above
- Revascularization (*NEJM* 1991;325:445; *Lancet* 2004;363:915)

  recommended for 70-99% stenosis, generally w/in 2 wk unless severe comorbidity w/ limited lifespan, severe ipsilateral stroke w/ persistent deficit, occluded carotid, or high operative risk (≥6%)

  consider for 50-69% stenosis, depending on Pt-specific factors

  not indicated if <50% stenosis

Revascularization options

- **Carotid endarterectomy** (CEA): gold standard. Risk of procedural stroke or death <3% for asymptomatic disease and <6% for sx disease in experienced centers.
- Carotid artery stenting (CAS; *JACC* 2014;64:722): compared w/ CEA, periprocedural risk of stroke ↑ (espec in elderly) & MI ↑ (although many asx), subsequent rates of stroke similar (*NEJM* 2010;363:11; *Lancet* 2010;376:1062). Consider if not surgical candidate (anatomy or comorbidities). Generally requires DAPT (ASA + clopidogrel) for 30 d.

INTRACRANIAL DISEASE

- Cerebral and basilar arteries and distal branches thereof
- Most common etiology is athero & assoc w/ traditional athero risk factors (*Circ* 2014;1407:14); others include: dissection, FMD, vasoconstriction, vasculitis, moyamoya
- Estimated to cause 5-10% of ischemic strokes and more prevalent among blacks, Hispanics and Asians (*Stroke* 1995;26:14)
- Diagnosis: MRA, CTA, or TCD vs angio (see above); duplex U/S not useful
- Medical treatment similar as in extracranial; however, consider ASA+clopidogrel for sx disease for 90 d (*NEJM* 2011;365:993)
- Stenting and intracranial bypass not shown to be beneficial and not routinely recommended (*NEJM* 2011;365:993; *JAMA* 2015;313:1240)

PHARMACOLOGIC SECONDARY STROKE PREVENTION

Antiplatelet therapy (*NEJM* 2012;366:1914)

- In general monotherapy preferred to multiagent therapy for long-term prevention due to ↑ ICH risk w/ multiagent therapy
- **ASA:** ↓ death & repeat stroke; equal to warfarin in nonembolic stroke (*NEJM* 2001;345:1444)
- **Clopidogrel:** marginally superior to ASA, slightly ↑ ICH (*Lancet* 1996:348:1329)
- **Multiagent antiplatelet therapy:**

  ASA + clopi: not more effective than ASA alone and ↑ bleeding & ICH (*Lancet* 2004;364:331; *NEJM* 2012;367:817). In *minor stroke/*TIA, ASA + clopi × 21 d → clopi monoRx vs ASA monoRx resulted in ↓ stroke w/o ↑ ICH (*NEJM* 2013;369:11).

  ASA + dipyrimadole: superior to ASA (*Lancet* 2006;367:1665), but ↑ ICH and poor compliance

  Addition of vorapaxar to ASA or ASA+clopi ↑ first stroke in Pts w/ athero, but contra-indicated in patients w/ prior stroke due to ICH risk (*NEJM* 2012;366:1404; *Stroke* 2013;691:8)

Anticoagulation

- Not routinely indicated. Anticoag if cardiac/paradoxical emboli (except bacterial endocarditis) or hypercoag state. See "AF" and "VTE" for details.
- **Hold off on anticoag** in large strokes for ~2-4 wk given risk of hemorrhagic conversion.

Risk factor management

- BP (see "HTN"): long-term SBP target 120-139 mmHg (*JAMA* 2011;306:2137)
- LDL: high-intensity statin therapy (*Circ* 2014;129(*Suppl* 2):S1)

OTHER CEREBROVASCULAR DISEASES

Cervical artery dissection

- May involve intracranial or extracranial arteries. Manifests as luminal stenosis, thrombo-embolism or aneurysm. ~20% of ischemic strokes in young Pts (primarily embolic).
- Etiologies: trauma, physical activity, ? neck manip.; can be spontaneous (if assoc cond.)
- FMD most common assoc. condition (seen in 15-20%). Others infrequent: vascular EDS, Marfan, osteogenesis imperfect, homocystinuria, PKD, α_1-AT.
- Most (>60%) report HA or neck pain, Horner's in ~25%, tinnitus, rarely eye pain
- Imaging may show "crescent sign" of hematoma, string sign, tapering stenosis, flap or dissected aneurysm. Duplex U/S can be initial screen but lower Se (68-95%) and limited utility at skull base. CTA & MRA w/ similar Se & Sp; angio if inconclusive noninvasive imaging.
- Treatment: if stroke, see "Stroke." In general, thrombolysis should not be withheld if indicated. If SAH, manage accordingly.
- Antithrombotic therapy: either anticoagulation (AC) or antiplatelet Rx may be considered for extracranial dissection; however, large meta-analysis showed no benefit of AC over antiplatelet

  Rx (*Neurology* 2012;79:686). If AC chosen, typically for 3-6 mo, then Δ to antiplatelet. Intracranial dissection treated with antiplatelet monotherapy and not AC.

- Endovascular therapy or surgery considered for selected Pts, particularly if recurrent ischemia; however, no trials to demonstrate benefit.

Patent foramen ovale (PFO; in ˜27% of population) (*NEJM* 2005;353:2361)

- ↑ stroke risk: ≥4-mm separation, R → L shunting at rest, ↑ septal mobility, atrial septal aneurysm
- If PFO & stroke/TIA: no benefit of warfarin over ASA (*Circ* 2002;105:2625), but consider if at high risk for or has DVT/PE. No sig benefit shown for PFO closure so far, albeit studies small & w/ favorable trends (*NEJM* 2012;366:991; 2013:1083 & 1092).

Intracranial aneurysm (*Stroke* 2015;46:2368)

- Prevalence of saccular aneurysms 3.2%, w/ equal sex ratio (*Lancet Neurol* 2011;10:626); 20-30% having > 1 aneurysm
- Associated with family hx, hereditary syndromes (eg, EDS, polycystic kidney), smoking, HTN, aortic coarctation, ? estrogen deficiency (female preponderance after menopause) (*Stroke* 2001;32:606)
- Clinical presentations: most commonly incidental finding on brain imaging may be found in those presenting with SAH, which typically presents as “worst headache of my life,” ± syncope, nausea, vomiting, meningismus (*Neurology* 1986;36:1445) rarely unruptured aneurysms become symptomatic (eg, headache, visual change, cranial neuropathy, facial pain)
- Diagnosis: CTA or MRA
- Instruct Pt to avoid smoking, heavy EtOH use, illicit drugs, straining/Valsalva
- Treatment requires consideration of size, location, Pt age and comorbidities. In general: if sx or SAH → repair if no sx/SAH and ≥7-10 mm, consider repair if <7 mm observe (CTA or MRA q6mo and every 2-3 y once showing no Δ) endovascular coiling ↑ periprocedural morbidity & mortality vs surgical clipping, but ↑ risk of recurrence

Extracranial aneurysm

- Rare (<1% of arterial aneurysms) (*Surgery* 1983;93:319)
- True aneurysm may be associated with athero, trauma, dissection (qv), infection, vasculitis or radiation. Male:female predominance (2:1).
- Infected pseudoaneurysm may occur at site of prior carotid intervention.
- Clinical presentation: TIA/stroke; less likely mass effect or rupture
- Diagnosis: see approach for carotid disease above
- Instruct Pt to avoid smoking, heavy EtOH use, illicit drugs, straining/Valsalva
- Treatment: sx disease should be repaired; consider repair if asx and >2 cm, w/ thrombus, or ≤2 cm but ↑ 'ing. Surgical and endovascular options depending on anatomy & Pt risk.

Cerebral venous thrombosis (CVT) (*Circ* 2012;125:1709)

- Uncommon (<2/100,000/yr); female predominance (3× more common)
- >85% w/ risk factor including: hypercoagulable state, OCP, pregnancy, malignancy, infection, prior trauma, vasculitis, other inflammatory states (eg, IBD), hematologic disorders, nephrotic syndrome

- Clinical presentation variable and includes HA (˜90%), seizure, focal deficits, encephalopathy, sx of isolated intracranial hypertension (HA ± vomiting, papilledema, visual problems) may occur if hemorrhage or edema
- Diagnose w/ MR venography or CT venography (traditional head CT normal in ˜30% of CVT). D-dimer may be elevated but does not reliably exclude.
- Acute treatment

  treat elevated ICP

  consider antiseizure Rx if seizure on presentation or otherwise high risk

  anticoagulation (UFH or LMWH; see VTE for dosing) if no contraindication (nb, presence of ICH not absolute contraindication)

  consider endovascular venous recanalization with direct thrombolysis if progressive neurologic worsening despite anticoagulation
- Chronic treatment

  anticoagulation w/ VKA w/ INR 2-3 for 3-6 mo if provoked or 6-12 if unprovoked

  consider indefinite duration if recurrent, complicated by DVT or PE, or severe thrombophilia

  if occurred in setting of OCP, change to nonestrogen-based contraception
- Monitoring: imaging at 3-6 mo after dx to assess for recanalization

VENOUS THROMBOEMBOLISM (VTE)

Definitions

- Superficial thrombophlebitis: pain, tenderness, erythema along superficial vein
- Deep venous thrombosis (DVT)

  Proximal: thrombosis of iliac, femoral, or popliteal veins (nb, “superficial” femoral vein part of deep venous system)

  Distal: calf veins below knee; lower risk of PE/death than prox (*Thromb Haem* 2009;102:493)
- Pulmonary embolism (PE): thrombosis originating in venous system and embolizing to pulmonary arterial circulation; 1 case/1000 person y; 250,000/y (*Archives* 2003;163:1711)

Risk factors

- Virchow's triad for thrombogenesis

  stasis: bed rest, inactivity, CHF, CVA w/in 3 mo, air travel >6 h (*NEJM* 2001;345:779)

  injury to endothelium: trauma, surgery, prior DVT, inflammation, central catheter

  thrombophilia: APC resistance, protein C or S deficiency, APS, prothrombin gene mutation,↑ factor VIII, hyperhomocysteinemia, HIT, OCP, HRT, tamoxifen, raloxifene
- Malignancy (12% of “idiopathic” DVT/PE)
- History of thrombosis (greater risk of recurrent VTE than genetic thrombophilia)
- Obesity, smoking, acute infection, postpartum (*JAMA* 1997;277:642; *Circ* 2012;125:2092)

- Statin therapy ↑ risk (*NEJM* 2009;360:1851)

Thromboprophylaxis (*Chest* 2012;141:e195S, 227S, 278S)

Patient & situation	Prophylaxis
Low-risk med; same-day surg & <40 y	Early, aggressive ambulation
Minor surgery in mobile Pt	Mechanical Ppx
High-risk medical (eg, immobilized, h/o VTE, thrombophilia or cancer) Most surgery Pts	**UFH** 5000 U SC bid or tid, or **LMWH**, or fonda (if HIT ⊕), or mech Ppx (espec if high bleed risk)
High-risk surg (eg, trauma, recent stroke or spinal cord injury, h/o VTE or thrombophilia)	**[LMWH** or **UFH** SC**] + mech Ppx**
Orthopedic surgery	**LMWH** [or fonda, direct oral anticoag (qv) or warfarin (INR 2-3)] **+ mech Ppx** Start before or shortly after (<12 h) surgery & cont. up to **35 d** (hip) or 1**0-14 d** (knee). LMWH or fonda favored over UFH or VKA. Direct oral anticoagulants overall appear favorable vs LMWH.

For enoxaparin, 30 mg bid for highest risk or 40 mg qd for moderate risk or spinal/epidural anesth. Dose adjust: qd in CrCl <30 mL/min, ↑ 30% if BMI >40 (*Ann Pharmacother* 2009;43:1064).

- **Direct oral anticoagulants vs LMWH** (*Annals* 2012;156:710)

  Dabigatran (approved in Europe & Canada; 110 mg 1-4 h after surgery & hemostasis or 220 mg if not initiated on day of surgery; 220 mg qd maintenance) noninferior to LMWH after hip and knee surgery (*Lancet* 2007;370:949)

  Rivaroxaban (10 mg qd 6-10 h postop) ↓ VTE by ˜25-50% vs enox 40 mg qd, with ≈ bleeding after hip or knee replacement (*NEJM* 2008;358:2765 & 2776; *Lancet* 2009;373:1673)

  Apixaban (2.5 mg bid 12-24 h postop) ↓ VTE by ˜50% vs enox 40 mg qd, with ≈ bleeding after hip replacement (*NEJM* 2010;363:2487)

  Edoxaban (30 mg qd 6-24 h after surgery) ↓ VTE vs enox *20 mg qd,* but no comparison to standard dose enox (*Thromb Res* 2014;134:1198)

- Evolving role for Ppx in ambulatory cancer Pts w/ low bleeding risk and additional VTE risk factors (*NEJM* 2012;366:601). Khorana score (cancer site, plt & WBC counts, Hb, BMI) risk predictor (*Blood*

2008;111:4902). Semuloparin (ultra LMWH) ↓ VTE by ˜2/3 w/o ↑ major bleeding in Pts w/ met. or locally adv. cancer receiving chemo (*NEJM* 2012;366:601).

Clinical manifestations—DVT

- Calf pain, swelling (>3 cm c/w unaffected side), venous distention, erythema, warmth, tenderness, palpable cord, ⊕ Homan's sign (calf pain on dorsiflexion, seen in <5%)
- *Phlegmasia cerulea dolens:* massive proximal DVT → stagnant blood → edema, *cyanosis,* pain, compartment syndrome → can lead to limb loss or death
- 50% of Pts with sx DVT have asx PE
- Palpable tender superficial veins c/w superficial thrombophlebitis rather than DVT
- Popliteal (Baker's) cyst: related to knee pathology, may result in calf pain & may lead to DVT due to compression of popliteal vein

"Simplified Wells" Pretest Probability Scoring of DVT (*JAMA* 2006;295:199)

Clinical variable	Point score
◦ Active cancer (Rx ongoing or w/in 6 mo or palliative)	1
◦ Paralysis, paresis, or recent immobilization of lower extremities	1
◦ Recently bedridden for ≥3 d or major surgery w/in 12 wk	1
◦ Localized tenderness along distribution of deep venous system	1
◦ Entire leg swelling	1
◦ Calf ≥3 cm larger than asx calf (at 10 cm below tibial tuberosity)	1
◦ Pitting edema confined to sx leg	1
◦ Collateral superficial veins (nonvaricose)	1
◦ Previous DVT	1
◦ Alternative dx at least as likely as DVT	-2

Pretest Probability Assessment

Score ≤0	Score 1 or 2	Score ≥3
Low probability (5%)	Moderate probability (17%)	High probability (53%)

- For UE DVT, + 1 point each for venous cath, local pain, & unilateral edema, -1 if alternative dx. ≤1 = unlikely; ≥2 = likely. U/S if likely or if unlikely but abnl D-dimer (*Annals* 2014;160:451).

Diagnostic studies—DVT

- D-dimer: <500 helps r/o; ? use 1000 as threshold if low risk (*Annals* 2013;158:93)
- Compression U/S >95% Se & Sp for sx DVT (lower for asx DVT); survey whole leg rather than just proximal if ≥mod prob (*JAMA* 2010;303:438); venography rarely used

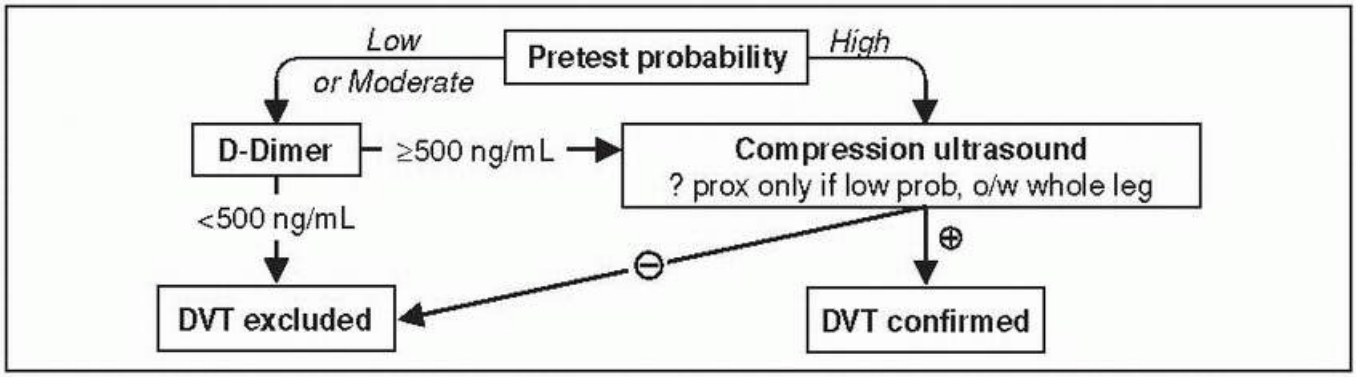

Figure 1-5 Approach to suspected DVT (*Chest* 2012;141:e351S)

Clinical manifestations—PE

- Dyspnea (73%), pleuritic chest pain (66%), cough (37%), hemoptysis (13%)
- ↑ RR (>70%), crackles (51%), ↑ HR (30%), fever, cyanosis, pleural friction rub, loud P_2
- *Massive:* syncope, HoTN, PEA; ↑ JVP, R-sided S3, Graham Steell (PR) murmur

Simplified Wells Pretest Probability Scoring for PE (*Annals* 2011;154:709)

- Prior PE or DVT
- Active cancer
- Immobilization (bed rest ≥3 d) or surgery w/in 4 wk
- Alternative dx less likely than PE
- Clinical signs of DVT
- HR >100 bpm
- Hemoptysis

Dichotomized Wells Probability Assessment

≤1 Variable = "Unlikely" (13% probability)

> 1 Variable = "Likely" (39% probability)

Diagnostic studies—PE (*NEJM* 2010;363:266)

- CXR (limited Se & Sp): 12% nl, atelectasis, effusion, ↑ hemidiaphragm, Hampton hump (wedge-shaped density abutting pleura); Westermark sign (avascularity distal to PE)
- ECG (limited Se & Sp): sinus tachycardia, AF; signs of RV strain → RAD, P pulmonale, RBBB, $S_IQ_{III}T_{III}$ & $TWIV_1$-V_4 (McGinn-White pattern; *Chest* 1997;111:537)
- ABG: hypoxemia, hypocapnia, respiratory alkalosis, ↑ A-a gradient (*Chest* 1996;109:78), 18% w/ room air P_aO_2 85-105 mmHg, 6% w/ nl A-a gradient (*Chest* 1991;100:598)
- D-dimer (*JAMA* 2015;313:1668): high Se, poor Sp (˜25%); ⊖ ELISA has >99% NPV ∴ use to r/o PE if "unlikely" pretest prob. (*JAMA* 2006;295:172) consider age-specific cutpoint: 500 if <50 y, 10× age if ≥50 y (*JAMA* 2014;311:1117)
- Echocardiography: useful for risk stratification (RV dysfxn), but not dx (Se <50%)
- V/Q scan: high Se (˜98%), low Sp (˜10%). Sp improves to 97% for high prob VQ. Use if pretest prob of PE high and CT not available or contraindicated. Can also exclude PE if low pretest prob, low prob VQ, but 4% false ⊖

(*JAMA* 1990;263:2753).

- **CT angiography** (CTA; see Radiology inserts; *JAMA* 2015;314:74): Se ~90% & Sp ~95% w/ MDCT (*NEJM* 2006;354:2317); PPV & NPV >95% if imaging concordant w/ clinical suspicion, ≤80% if discordant ([need to consider both); CT may also provide other dx
- Lower extremity compression U/S shows DVT in ~9%, sparing CTA, but when added to CTA, does not Δ outcomes (*Lancet* 2008;371:1343)

- Pulmonary angio: ? gold standard (morbidity 5%, mortality <0.5%), infrequently performed
- MR angiography: Se 84% (segmental) to 100% (lobar) (Lancet 2002;359:1643); if add MR venography, Se 92%, Sp 96% (Annals 2010;152:434)

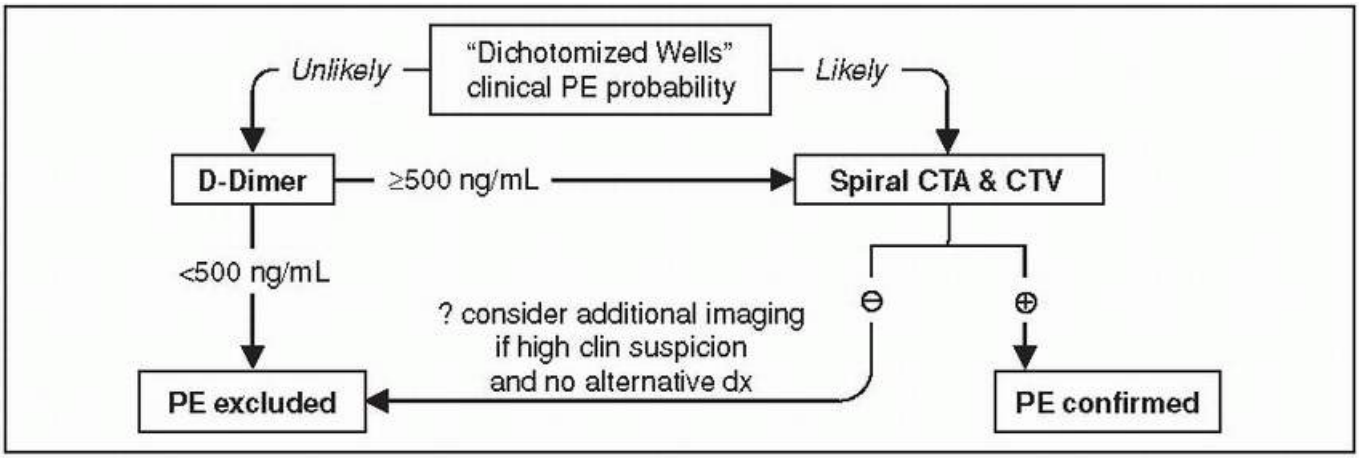

Figure 1-6 Approach to suspected PE using CTA

Workup for idiopathic VTE

- **Thrombophilia workup:** ✓ if ⊕ FH, may be helpful but consider timing as thrombus, heparin and warfarin Δ results. May not be helpful for Pt if will not change management (eg, plan for long-term anticoagulation regardless), although could be of use to relatives (*JAMA* 2005;293:2352; *Blood* 2008;112:4432; *Am J Med* 2008;121:458).
- **Malignancy workup:** 12% Pts w/ "idiopathic" DVT/PE will have malignancy; ageappropriate screening adequate; avoid extensive w/u (*NEJM* 1998;338:1169 & 2015;373:697)

Risk stratification for Pts with PE

- **Clinical:** hypotension and/or tachycardia (~30% mortality), hypoxemia
- **CTA:** RV / LV dimension ratio >0.9 (*Circ* 2004;110:3276)
- **Biomarkers:** ↑ troponin & ↑ BNP a/w ↑ mortality; w/ ⊖ Tn, decomp extremely unlikely (*Circ* 2002;106:1263 & 2003;107:1576; *Chest* 2015;147:685)
- **Echocardiogram:** RV dysfxn (even if normal troponin) (*Chest* 2013;144:1539)
- Simplified PE Severity Index: 0 RFs → 1.1% mort.; ≥1 → 8.9% mort (*Archives* 2010;170:1383) RFs: age >80 y; h/o cancer; h/o HF or lung disease; HR ≥110; SBP <100; S_aO_2 <90%

Whom to treat (*Lancet* 2012;379;1835; *Chest* 2012;141:e419S)

- **Superficial venous thrombosis:** elevate extremity, warm compresses, compression stockings, NSAIDs for sx. *Anticoag* if high risk for DVT (eg, ≥5 cm, proximity to deep vein ≤5 cm, other risk factors) for 4 wk as ~10% have VTE w/in 3 mo (*Annals* 2010;152:218).
- **LE DVT:** proximal → anticoag. If distal: anticoag if severe sx, o/w consider serial imaging over 2 wk and anticoag if extends (although if bleeding risk low, many would anticoag).
- **UE DVT:** anticoagulate (same guidelines as LE; *NEJM* 2011;364:861). If catheter-associated, need not remove if catheter functional and ongoing need for catheter.
- **PE:** anticoagulate

Anticoagulation options (*Chest* 2012;141:e419S; *JAMA* 2014;311:717)

- *Initiate immediately if high clinical suspicion or intermed but dx test results delayed for ≥4 h*
- Either (a) initial parenteral anticoag → long-term oral anticoagulant (eg, warfarin or Xa inhibitor) or (b) solely with an oral Xa inhibitor
- **LMWH** (eg, enoxaparin 1 mg/kg SC bid *or* dalteparin 200 IU/kg SC qd)

  Preferred over UFH (espec in *cancer*) except: renal failure (CrCl <25), ? extreme obesity, hemodynamic instability or bleed risk (*Cochrane* 2004;CD001100)

  No need to monitor anti-factor Xa unless concern re: dosing (eg, renal insuffic.)

  Attractive option as outPt bridge to long-term oral anticoagulation
- If cancer, LMWH ↓ recur. & mort. c/w UFH & warfarin (*NEJM* 2003;349:146; *Lancet Oncol* 2008;9:577; *JAMA* 2015;314:677); ✓ head CT for brain mets if melanoma, renal, thyroid, chorioCA
- **Fondaparinux:** 5-10 mg SC qd (*NEJM* 2003;349:1695); use if HIT ⊕; avoid if renal failure
- DVT & low-risk PE can be treated completely as outPt (*Lancet* 2011;378:41)
- **IV UFH:** 80 U/kg bolus → 18 U/kg/h → titrate to PTT 1.5-2.3 × cntl (eg, 60-85 sec); preferred option when contemplating thrombolysis or catheter-based Rx (qv)
- IV Direct thrombin inhibitors (eg, argatroban, lepirudin) used in HIT ⊕ Pts
- **Warfarin** (goal INR 2-3): start same day as parenteral anticoag unless instability and ? need for lytic, catheter-based Rx or surgery; overlap ≥5 d w/ parenteral anticoag & until INR ≥2 × ≥24 h
- **Oral Xa inhibitor:** effect wears off w/in 24 h, but not easily immediately reversed

  Can give as sole anticoag (nb, initial doses higher than for AF): **rivaroxaban** (15 mg bid for 1st 3 wk → 20 mg/d) as good/better than LMWH → warfarin in preventing recurrent VTE, ↓ bleeding (*NEJM* 2010;363:2499 & 2012;366:1287); **apixaban** (10 mg bid × 7 d → 5 bid) ≈ LMWH → warfarin in preventing recurrent VTE, ↓ bleeding (*NEJM* 2013;369:799)

  Can initiate after ≥5 d of parenteral anticoag (1st dose when d/c IV UFH or w/in 2 h before when next LMWH dose would have been due): both **dabigatran** (150 mg bid) & **edoxaban** (60 mg qd) ≈ warfarin but w/ ↓ bleeding (*NEJM* 2009;361:2342 & 2013;369:1406)

Systemic thrombolysis (*Chest* 2012;141:e419S)

- Typically TPA 100 mg over 2 h or wt-adjusted TNK bolus

- Indications & efficacy below; risk of ICH ~1.5%, ↑ w/ age; see contraindications in "ACS"
- **Massive PE** (hemodynamic compromise): ↓ death and recurrent PE each by ~50% (*Circ* 2004;110:744; *JAMA* 2014;311:2414; *EHJ* 2015;36:605) & lower PVR long term (*JACC* 1990;15:65)
- **Submassive PE** (hemodyn. stable but RV dysfxn on echo or enlargement on CTA, or ? marked dyspnea or severe hypoxemia): ↑ death & ↑ bleeding; may consider if low bleed risk (see lytic contra-indic.; *EHJ* 2015;36:605). Benefit/risk may be more favorable if <75 y (*NEJM* 2014;370:1402; *JAMA* 2014;311;2414). Some centers prefer catheter-directed Rx (qv).
- **Moderate PE w/ large clot burden** (≥2 lobar arteries or main artery on CT or high prob VQ w/ ≥2 lobes w/ mismatch): *low-dose lytic* (50 mg if ≥50 kg or 0.5 mg/kg if >50 kg; for both 10 mg bolus → remainder over 2 h) ↓ pulm HTN w/ ≈ bleeding vs heparin alone; await further validation (*Am J Cardiol* 2013;111:273)
- **DVT:** consider if all are present (a) acute (< 14 d) & extensive (eg, iliofemoral), (b) severe symptomatic swelling or ischemia (phlegmasia cerulea dolens), (c) catheter-directed Rx not available, and (d) low bleeding risk

Mechanical intervention

- **Catheter-directed therapy** (fibrinolytic & thrombus fragmentation/aspiration)

  Consider if extensive DVT (see above) and to ↓ post-thrombotic synd (*Lancet* 2012;379:31)

  Consider if PE w/ hemodyn. compromise or high risk & not candidate for systemic lysis or surgical thrombectomy (*Circ* 2011;124:2139). Preferred to systemic lytic by some centers.

  U/S-assisted → improves hemodynamics & RV fxn vs anticoag alone (*EHJ* 2015;36:597)
- **Thrombectomy:** if large, proximal PE + hemodynamic compromise + contra. to lysis; consider in experienced ctr if large prox. PE + RV dysfxn (*J Thorac CV Surg* 2005;129:1018)
- **IVC filter:** use instead of anticoagulation if latter contraindicated

  No benefit to adding to anticoag (including in submassive) (*JAMA* 2015;313:1627)

  Consider removable filter for temporary indications

  Complications: migration, acute DVT, ↑ risk of recurrent DVT & IVC obstruction (5-18%), which may lead to worsening LE sx (*Archives* 1992;152:1985)

Duration of full-intensity anticoagulation

- Superficial venous thrombosis: 4 wk
- 1st prox DVT *or* PE 2° reversible/time-limited risk factor *or* distal DVT: 3-6 mo
- 1st *unprovoked* prox DVT/ PE: ≥3 mo, then reassess; benefit to prolonged Rx (see below). Consider bleeding risk, Pt preference and intensity of extended Rx.
- 2nd VTE event or cancer: indefinite (or until cancer cured) (*NEJM* 1997;336:393 & 2003;348:1425)
- Does *not* appear that can rely on D-dimer testing to guide d/c (*Annals* 2015;162:27)

Extended antithrombotic strategies (*JAMA* 2015;314:72)

- After ≥6 mo of anticoag, following strategies have been compared w/ *no extended* Rx*:*
- Full-dose dabigatran, rivaroxaban, or apixaban: 80-90% ↓ recurrent VTE, 2-5× bleeding, but no signif excess

in major bleeding (*NEJM* 2010;363:2499; 2013;368:699 & 709)

- Full-dose warfarin: 85% ↓ reduction in recurrent VTE (*JAMA* 2015;314:31)
- Low-intensity warfarin (INR 1.5-2.0): 64% ↓ reduction in recurrent VTE (*NEJM* 2003;348:1425)
- Low-intensity apixa (2.5 mg bid): 80% ↓ recur. VTE, w/o signif ↑ bleeding (*NEJM* 2013;368:699)
- Aspirin: 32% ↓ recurrent VTE (*NEJM* 2012;366:1959 & 367:1979)

Other therapeutic interventions

- Early ambulation
- For DVT: fitted graduated compression stockings (min 20-30 mmHg → 30-40 mmHg) for sx & to ↓ risk of postthrombotic synd (occurs in 23-60%; *J Thromb Thrombolysis* 2009;28:465)
- Leg elevation and exercise (use of calf muscle pump) also may be helpful
- Anticoag teaching: avoidance of high-risk activities, med alert bracelet, dietary instructions

Complications & prognosis

- Post-thrombotic syndrome (23-60%): thrombosis → injury to vein/valves → pain, edema, venous ulcers (*J Thromb Thrombolysis* 2009;28:465)
- Recurrent VTE: 1%/y (after 1st VTE) to 5%/y (after recurrent VTE) after only 6 mo of Rx: 5%/y & > 10%/y, respectively

  predictors: abnl D-dimer 1 mo after d/c anticoag (*NEJM* 2006;355:1780); ⊕ U/S after 3 mo of anticoag (*Annals* 2002;137:955); thrombin generation >400 nM (*JAMA* 2006;296:397)
- Chronic thromboembolic PHT after acute PE ~3.8% (*NEJM* 2004;350:2257), consider thromboendarterectomy
- Mortality: ~10% for DVT and ~10-15% for PE at 3-6 mo (*Circ* 2008;117:1711)

PULMONARY HYPERTENSION (PHT)

PA *mean pressure ≥25 mmHg at rest*

Pathobiology (*NEJM* 2004;35:1655)

- Smooth muscle & endothelial cell proliferation; mutations in bone morphogenic protein receptor 2 (*BMPR2*) in ~50% familial & ~26% sporadic cases of IPAH (*NEJM* 2001;345:319)
- Imbalance between vasoconstrictors and vasodilators

  ↑ vasoconstrictors: thromboxane A_2 (TXA_2), serotonin (5-HT), endothelin-1 (ET-1)

  ↓ vasodilators: prostacyclin (PGI2), nitric oxide (NO), vasoactive peptide (VIP)
- *In situ* thrombosis: ↑ TXA_2, 5-HT, PAI-1; ↓ PGI_2, NO, VIP, tissue plasminogen activator

Etiologies of Pulmonary Hypertension (Revised WHO Classification)	
Pulmonary arterial HTN	• Idiopathic (IPAH): mean age of onset 36 y (♂ older than ♀); ♀:♂= ~2:1,

(PAH) (group 1)	usually mild ↑ in PAP • Familial (FPAH) • Associated conditions (APAH) Connective tissue disorders: CREST, SLE, MCTD, RA, PM, Sjögren Congenital: L→R shunts: ASD, VSD, PDA, 1° PHT of newborn Portopulmonary HTN (? 2° vasoactive substances not filtered in ESLD; ≠ hepatopulmonary syndrome) HIV; drugs & toxins: anorexic agents, rapeseed oil, L-tryptophan • Pulmonary veno-occlusive disease: ? 2° chemo, BMT; orthopnea, pl eff, nl PCWP; art vasodil. *worsen* pulm edema (*AJRCCM* 2000;162:1964) • Pulmonary capillary hemangiomatosis
Left heart disease (group 2)	• Left atrial or ventricular (diastolic or systolic) dysfunction • Left-sided valvular heart disease (eg, MS/MR > AS/AR) • Congenital: left-sided inflow/outflow obstruction, CMP
Lung diseases and/or chronic hypoxemia (group 3)	• COPD • ILD • Sleep apnea • Alveolar hypoventilation (eg, NM disease) • Chronic hypoxemia (eg, high altitude) • Developmental abnormalities
Chronic thrombo-embolic dis (group 4)	• Prox or distal PEs; ~½ w/o clinical h/o PE (*Circ* 2014;130:508) • Nonthrombotic emboli (tumor, foreign body, parasites)
Miscellaneous (group 5) (*Circ* 2013;62:25S)	• Sarcoidosis, histiocytosis X, LAM, schistosomiasis • Metab: thyroid, glycogen storage, Gaucher • Heme: chronic hemolytic anemia, myeloprolif d/o, splenectomy • Other: compression of pulm vessels (adenopathy, tumor, fibrosing mediastinitis, histoplasmosis, XRT); HHT (multifactorial)

Clinical manifestations

- Dyspnea, exertional syncope (hypoxia, ↓ CO), exertional chest pain (RV ischemia)
- Symptoms of R-sided CHF (eg, peripheral edema, RUQ fullness, abdominal distention)
- WHO class: I = asx w/ ordinary activity; II = sx w/ ord. activ.; III = sx w/ min activ.; IV = sx at rest

Physical exam

- PHT: prominent P_2, R-sided S4, RV heave, PA tap & flow murmur, PR (Graham Steell), TR
- ± RV failure: ↑ JVP, hepatomegaly, peripheral edema

Diagnostic studies & workup (*Circ* 2014;130:1820)

- *IPAH yearly incidence 1-2 per million, ∴ r/o 2° causes*

- High-res chest CT: dil. & pruning of pulm arteries, ↑ RA and RV; r/o parenchymal lung dis.
- ECG: RAD, RBBB, RAE ("P pulmonale"), RVH (Se 55%, Sp 70%)
- PFTs: disproportionate ↓ $D_L$co, mild restrictive pattern; r/o obstructive & restrict. lung dis.
- ABG & polysomnography: ↓ P_aO_2 and S_aO_2 (espec w/ exertion), ↓ P_aCO_2, ↑ A-a gradient; r/o hypoventilation and OSA
- TTE: ↑ RVSP (but estimate over/under by ≥10 mmHg in ½ of PHT Pts; *Chest* 2011;139:988)

  ↑ RA, RV (RV:LV area >1) and PA size; TR, PR

  ↑ RVSP → interventricular septum systolic flattening ("D" shape)

  ↑ RAP → interatrial septum bowing into LA

  ↓ RV systolic fxn: TAPSE (tricuspid annular plane systolic excursion) < 1.6 cm; lateral-septal tissue-Doppler imaging disparity (reflecting relatively more systolic dysfxn of RV lateral wall vs septum, which is shared with LV)

  ↑ PA impedance ↑ RVOT Doppler notching

  r/o LV dysfxn, MV or AoV disease, and congenital heart disease
- RHC: ↑ RA, RV, & PA pressures; ✓ L-sided pressures and for shunt if PAH: nl PCWP, ↑ transpulm gradient (mean PAP-PCWP > 12-15), ↑ PVR, ± ↓ CO if 2° to L-heart disease: PCWP (or LVEDP) > 15; if PVR nl → "passive PHT"; PVR >240 suggests mixed picture: if ↓ PCWP → ↓ PVR, then "reactive" PHT; if no Δ, then "fixed"

- CTA (large/med vessel), V/Q scan (small vessel to r/o CTEPH), ± pulmonary angiogram: r/o PE and chronic thromboembolic disease
- Vasculitis labs: ANA (˜40% ⊕ in PAH), RF, anti-Scl-70, anticentromere, ESR
- LFTs & HIV: r/o portopulmonary and HIV-associated PAH
- 6-min walk test (6MWT) or cardiopulmonary exercise testing to establish fxnl capacity

Differentiating Left Heart Disease from Alternative PHT Etiologies

Feature	Favors Left Heart Disease	Favors Alternative Etiology
History	Prior MI, CMP,AoV or MV disease, CV risk factors (HTN, diabetes), ↑ age	Family hx PHT, connective tissue disorder, pulm, liver or hematologic disease, HIV, h/o VTE
PEx	L-sided S3, S4 L-sided murmurs Displaced apical impulse Coarse rales	Cyanosis, clubbing Fine rales; signs of COPD Raynaud's, sclerodactyly, telangiectasia Splenomegaly, spider angiomata
ECG	Q waves, LVH, LBBB	Isolated RAE, RVH, $S_IQ_{III}T_{III}$ pattern

Echo	LV systolic or diastolic dysfxn LVH, ↑ LA size ≥Moderate MV or AoV disease	Isolated RV or RA enlargement Interventricular septum systolic flattening and/or interatrial septum bowing into LA ↓ RV systolic fxn
RHC	↑ L-sided filling pressures Abrupt ↑ PCWP (to > 20-25) w/ exercise or volume loading	PCWP <15 mmHg Exercise PCWP <20-25 mmHg

Treatment (*JACC* 2013;62:25S & 2015;65:1976)

- Principles

  1) prevent and reverse vasoactive substance imbalance and vascular remodeling

  2) prevent RV failure: ↓ wall stress (↓ PVR, PAP, RV diam); ensure adeq. systemic DBP

- **Supportive**

  Oxygen: maintain S_aO_2 >90-92% (reduces vasoconstriction)

  Diuretics: ↓ RV wall stress and relieve RHF sx; *gentle* b/c RV is preload dependent

  Digoxin: control AF, ? counteract neg. inotropic effects CCB

  Dobutamine and inhaled NO or prostacyclin for decompensated PHT

  Anticoagulation: ↓ VTE risk of RHF; ? prevention of *in situ* microthrombi; ? mortality benefit even if in NSR, no RCTs (*Circ* 1984;70:580; *Chest* 2006;130:545)

  Supervised exercise training (*Eur Respir J* 2012;40:84)

- **Vasodilators** (right heart catheterization prior to initiation) *acute vasoreactivity test:* use inhaled NO, adenosine or prostacyclin to identify Pts likely to have a long-term response to oral CCB (⊕ vasoreactive response defined as ↓ PAP ≥10 mmHg to a level <40 mmHg with ↑ or stable CO); ˜10% Pts are acute responders; no response → still candidates for other vasodilators (*NEJM* 2004;351:1425)

Vasoactive agents	Comments (data primarily in Group 1 PAH)
Oral CCB Nifedipine, diltiazem	If ⊕ acute vasoreactive response; <½ will be long-term responder (NYHA I/II & near-nl hemodynamics) & have ↓ mortality. Side effects: HoTN, lower limb edema (*NEJM* 1992;327:76; *Circ* 2005;111:3105).
IV Prostacyclin Epoprostenol (Flolan)	Vasodilation, ↓ plt agg, ↓ smooth muscle proliferation; benefits ↑ w/ time (? vascular remodeling). ↑ 6MWT, ↑ QoL, ↓ mortality. Side effects: HA, flushing, jaw/leg pain, abd cramps, nausea, diarrhea, catheter infxn (*NEJM* 1996;334:296 & 1998:338:273; *Annals* 2000;132:425).
Prostacyclin analogues Iloprost (inhaled) Treprostinil (IV, inh, SC) Beraprost (PO)	Same mechanism as prostacyclin IV, but easier to take, ↓ side effects, and w/o risk of catheter infxn, ↓ sx, ↑ 6MWT; trend to ↓ clinical events w/ iloprost but not treprostinil. Beraprost w/o sustained outcome improvement (n/a in U.S.) (*NEJM* 2002;347:322; *AJRCCM* 2002;165:800).

Endothelin receptor antagonists (ERAs) Bosentan, ambrisentan, macitentan	↓ Smooth muscle remodeling, vasodilation, ↓ fibrosis, ↓ sx, ↑ 6MWT, ↓ worsening PAH or need for prostanoids w/ trend for ↓ PAH mortality (w/ macitentan). Side effects: ↑ LFTs, headache, anemia, edema, teratogen (*NEJM* 2002;346:896; *JACC* 2005;46:529; *Circ* 2008;117:3010; *NEJM* 2013;369:809).
PDE-5 Inhibitor Sildenafil, tadalafil	↑ cGMP → vasodilation, ↑ smooth muscle proliferation, ↓ sx, ↑6MWT, no data on clinical outcomes. Low side-effect profile: HA, vision Δ's, sinus congestion (*NEJM* 2009;361:1864).
Soluble guanylate cyclase stimulator Riociguat	NO-independent ↑ cGMP → vasodilation, ↑ smooth muscle proliferation, ↓ sx, ↑ 6MWT in PAH; ↓ sx, ↓ PVR, ↑ 6MWT in CTEPH (*NEJM* 2013;369:319 & 330)

- Up front combination Rx (tadalafil + ambrisentan vs monotherapy): ↓ sx, ↓ NT-BNP, ↑ 6MWT, ↓ hospitalizations (*NEJM* 2015;373:834)
- Treat underlying causes of 2° PHT; can use vasodilators, although little evidence beyond riociguat use for CTEPH as described above
- Refractory PHT:

  balloon atrial septostomy: R→ L shunt causes ↑ CO, ↓ S_aO_2, net ↑ tissue O_2 delivery lung transplant (single or bilateral); heart-lung needed if Eisenmenger physiology

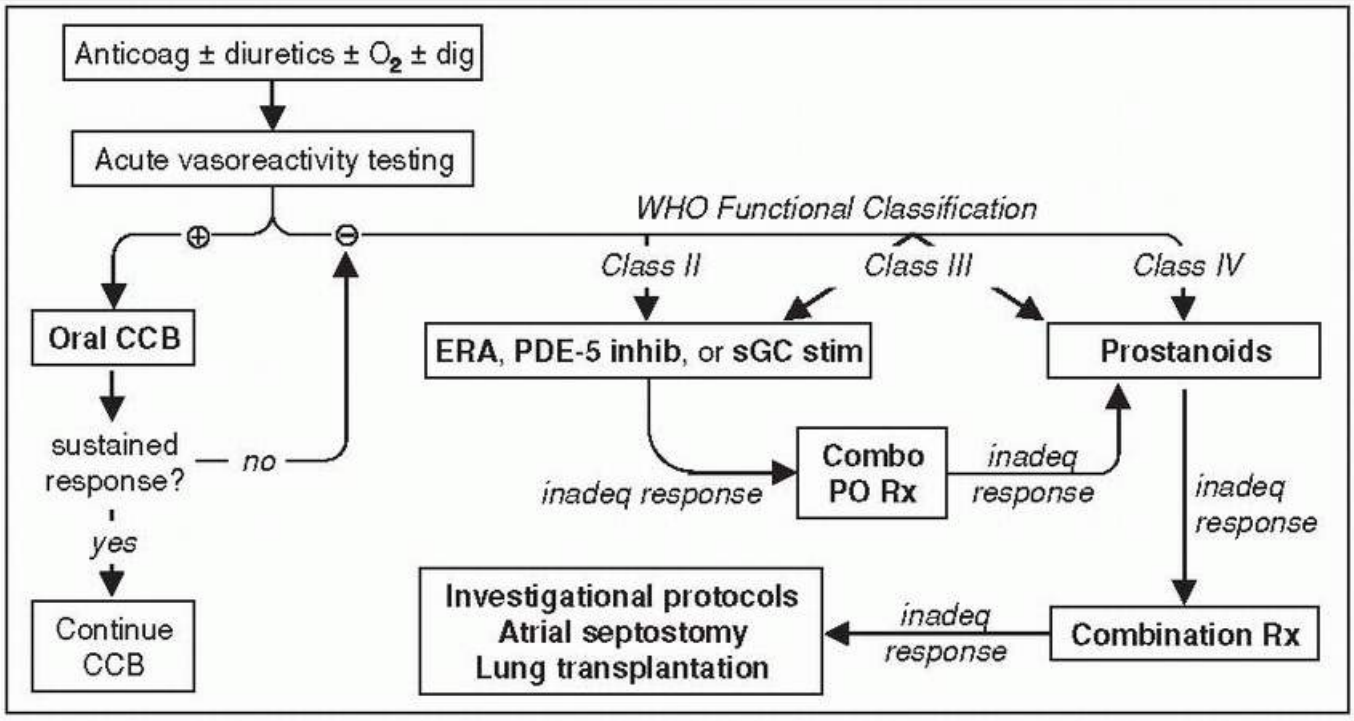

Figure 1-7 Treatment of PAH (modified from *JACC* 2009;54:S78)

Management of ICU patient

- Avoid overly aggressive volume resuscitation
- Caution with vasodilators if any L-sided dysfunction
- May benefit from inotropes/chronotropes
- Mechanical RV support (RVAD, ECMO) (*Circ* 2015;132:526)
- Consider fibrinolysis if acute, refractory decompensation (eg, TPA 100 mg over 2 h)

Prognosis

- Median survival after dx ~2.8 y; PAH (all etiologies): 2-y 66%, 5-y 48% (*Chest* 2004;126:78-S)
- Poor prognostic factors: clinical evidence of RV failure, rapidly progressive sx, WHO (modified NYHA) class IV, 6MWT <300 m, peak VO_2 <10.4 mL/kg/min, ↑ RA or RV or RV dysfxn, RA >20 or CI <2.0, ↑ BNP (*Chest* 2006;129:1313)
- Lung transplant: 1-y survival 66-75%; 5-y survival 45-55% (*Chest* 2004;126:63-S)

Arrhythmias

BRADYCARDIA AND AV BLOCK

BRADYCARDIAS

Sinus bradycardia (SB) (*NEJM* 2000;342:703)

- Etiologies: **meds** (incl βB, CCB, amio, Li, dig), → **vagal tone** (incl. in athletes, sleep, IMI), **metabolic** (hypoxia, sepsis, myxedema, hypothermia, ↓ glc), OSA, ↑ ICP
- Treatment: if no sx, none; atropine, β_1 agonists or long-term permanent pacing if sx
- Most common cause of sinus pause is *blocked premature atrial beat*

Sick sinus syndrome (SSS)

- Features may include: periods of unprovoked SB, SA arrest, paroxysms of SB and atrial tachyarrhythmias ("tachy-brady" syndrome), chronotropic incompetence w/ ETT
- Treatment: meds alone usually fail (adeq. control of tachy → unacceptable brady); usually need **combination of meds** (βB, CCB, dig) for tachy & **PPM** for brady

Pseudobradycardia

- Intermittent PVCs (with low stroke volume and hence low pulse wave) followed by compensatory pause can cause ascertainment of HR by palpation of radial pulse to be artifactually low

AV BLOCK AND AV DISSOCIATION

AV Block

Type	Features
1°	Prolonged PR (>200 ms), all atrial impulses conducted (1:1)
2° Mobitz I (Wenckebach)	Progressive ↑ PR until impulse not conducted (↑ "grouped beating") Due to **AV node** conduction delay: ischemia (IMI), inflammation (myocarditis, MV surgery), high vagal tone (athletes), drug-induced QRS duration most often normal AVB usually worsens w/ carotid sinus massage, improves w/ atropine & exercise Often paroxysmal/nocturnal/asymptomatic; no Rx required
2° Mobitz II	Occasional or repetitive blocked impulses w/ consistent PR interval. Nb, do not confuse with APBs in bigeminal pattern; to dx AVB, atrial rate should be *regular* and P waves should be the *same.* Due to **His-Purkinje** conduction delay: ischemia (AMI), degeneration of conduction system, infiltrative disease, inflammation/valve surgery QRS duration most often prolonged AVB usually improves w/ carotid sinus massage, worsens w/ atropine & exercise (both of which should be *avoided* if dx suspected) Risk of progression to 3° AVB. Zoll at bedside when recognized; temp pacing wire or PPM often required.

3° (complete)	No AV conduction, with ventricular rhythm slower than atrial rhythm Escape, if present is regular and can be narrow (jxnal) or wide (vent.) Urgent temporary pacing as bridge to permanent pacing is appropriate in most scenarios, especially when syncope present

Nb, if 2:1 block, cannot distinguish type I vs II 2° AVB (no chance to observe PR prolongation); usually categorize based on other ECG & clinical data. High-grade AVB usually refers to block of ≥2 successive impulses. All categories above assume SR in atrium, criteria do not apply during rapid atrial rates, such as in atrial flutter or tachycardia.

AV dissociation

- *Default:* slowing of SA node allows subsidiary pacemaker (eg, AV junction) to take over
- *Usurpation:* acceleration of subsidiary pacemaker (eg, AV junctional tach, VT)
- *3° AV block:* atrial pacemaker unable to capture ventricles, subsidiary pacemaker emerges; distinguish from *isorhythmic dissociation* (A ≈V rate, some P waves nonconducting)

Temporary pacing wires

- Consider w/ bradycardia with hemodyn instability or unstable escape rhythm when perm pacer not readily available. Risks: RV perf, VT, PTX, CHB if existing LBBB, etc.
- Consider instead of PPM for sx bradycardia due to reversible cause (βB/CCB O/D, Lyme, myocarditis, SBE, s/p cardiac surgery/trauma), TdP, acute MI (sx brady, high-grade AVB)

SUPRAVENTRICULAR TACHYCARDIAS

PALPITATIONS

Etiologies

- PACs, PVCs; SVT, AF, VT, respiratory sinus arrhythmia; pauses; noncardiac

Workup

- History: duration & frequency; initiating & aggravating factors: exercise, alcohol, stimulants (caffeine, pseudoephedrine, other prescription & recreational drugs); h/o presyncope or syncope; FHx of arrhythmia, CMP, SCD
- Structural evaluation w/ echo; consider ETT if exercise-induced or other RF; TFTs
- Ambulatory cardiac monitoring: *must monitor during symptoms to diagnose!* Holter (worn continuously): if sx typically occur within a 24-48-hr period Looping event monitor (worn continuously): if sx fleeting Nonlooping event monitor (put on during sx): if rarer episodes lasting minutes

Treatment (for SVT and VT, see respective sections)

- Simple ectopy in structurally normal heart: reassurance, βB, CCB. If refractory, frequent sx with poor QoL, antiarrhythmic drug, such as flecainide, can be tried in consultation w/ electrophysiologist. Rarely catheter ablation for frequent PVCs.

- If NICM and > 13% PVCs, elim of ectopy w/ catheter ablation can significantly ↑ EF (*JACC* 2013;62:1195). However, risk of *developing* CMP due to frequent PVCs not established.

SUPRAVENTRICULAR TACHYCARDIAS (SVTS)

Arise above the ventricles, ∴ ***narrow QRS*** *unless aberrant conduction or pre-excitation*

Common Etiologies of SVT (*NEJM* 2006;354:1039 & 2012;367:1438)

	Type	Features
Atrial	Sinus tachycardia (ST)	Caused by pain, fever, hypovolemia, hypoxia, anemia, anxiety, β-agonists, etc.
	Atrial tachycardia (AT)	Originate at site in atria other than SA node. Seen w/ CAD, COPD, ↑ catechols, EtOH, dig.
	Multifocal atrial tachycardia (MAT)	↑ automaticity at multiple sites in the atria. Seen with underlying pulmonary disease.
	Atrial flutter (AFL)	Macroreentry, usually w/in right atrium
	Atrial fibrillation (AF)	Chaotic atrial activation and rapid, irregular bombardment of AVN
	AV nodal reentrant tach (AVNRT)	Reentrant circuit using dual pathways w/in AVN
	AV reciprocating tachycardia (AVRT)	Reentrant circuit using AVN antegrade and accessory pathway retrograde. When in sinus rhythm may show pre-excitation (WPW) or not (concealed accessory pathway).
AV Jxn	Paroxysmal junctional reciprocating tachycardia (PJRT)	Reentry using AVN & slowly conducting concealed posterosept acc path. More common in peds, at times w/ tachy-induced CMP.
	Nonparoxysmal junctional tachycardia (NPJT)	↑ jxnal automaticity. May see retrograde P's & AV dissoc. A/w myo/endocarditis, cardiac surg, IMI, dig.

Diagnosis of SVT Type (*NEJM* 2006;354:1039 & 2012;367:1438)

Onset	Abrupt on/off argues against sinus tachycardia

Rate	Not dx as most can range from 140-250 bpm, *but:* ST usually <150; AFL often conducts 2:1 → vent. rate 150; AVNRT & AVRT usually >150
Rhythm	Irregular → AF, AFL w/ variable block, or MAT
P wave	Long RP: ST (P same as sinus), AT, MAT (≥3 morphologies), PJRT Short RP, P inverted in inf. leads → *retrograde* atrial activation via AVN AVNRT: buried in or distort terminal portion of QRS (pseudo-RSR' in V_1) AVRT: slightly after QRS (RP interval > 100 ms favors AVRT vs AVNRT) NPJT: either no P wave or retrograde P wave similar to AVNRT *Fibrillation or no P waves* → AF *Saw-toothed "F" waves* (best seen in inferior leads & V_1) → AFL
Response to vagal stim. or adenosine	Slowing of HR often seen with ST, AF, AFL, AT, whereas reentrant rhythms (AVNRT, AVRT) may abruptly terminate (classically w/ P wave after last QRS) or no response. Occ AT may terminate. AFL & AF → ↑ AV block → unmasking of "F" waves or fibrillation

Short RP: P wave closer to preceding than following QRS (ie, RP < PR). Long RP: P wave closer to following than preceding QRS (ie, PR < RP).

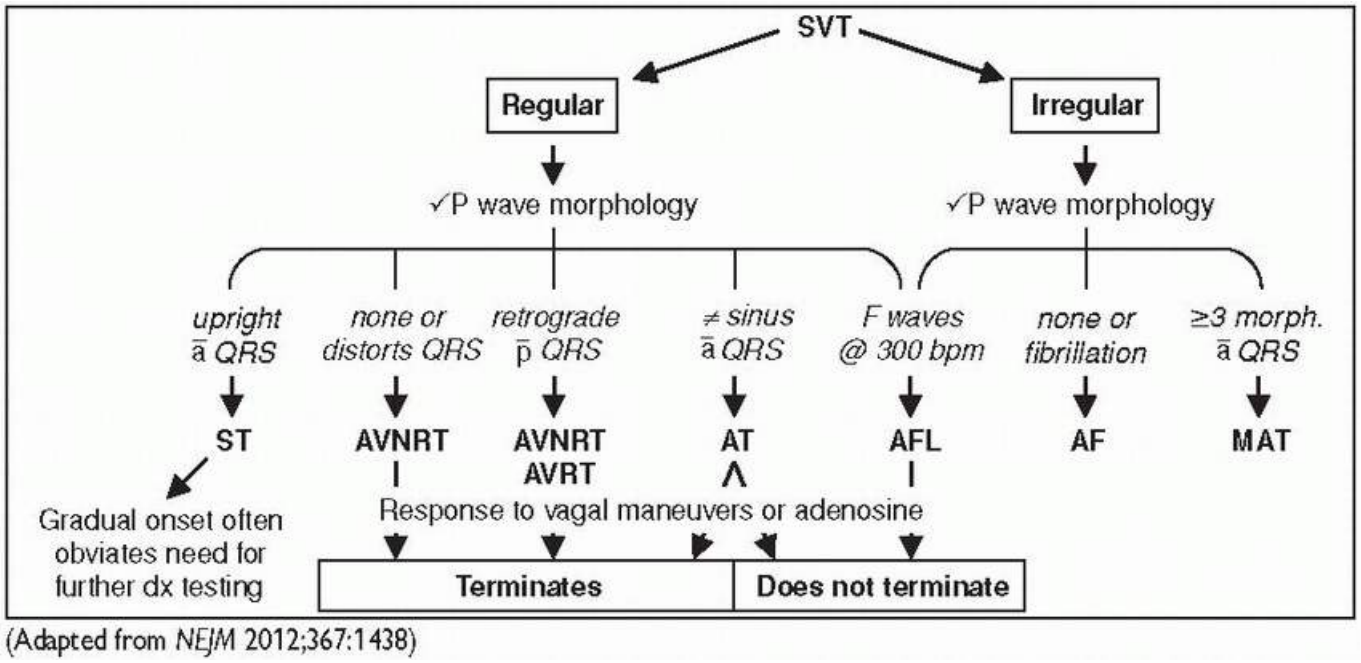

Figure 1-8 Approach to SVT

Treatment of SVT

Rhythm	Acute treatment	Long-term treatment
Unstable	**Cardioversion** per ACLS	n/a

ST	Treat underlying stressor(s)	n/a
AT	βB, CCB or amiodarone; ? vagal maneuvers or adenosine	βB or CCB, ± antiarrhythmics, possibly radiofrequency ablation (RFA)
AVNRT or AVRT	**Vagal maneuvers** **Adenosine** (caution in AVRT*) **CCB** or βB	*For AVNRT* (*see next section for AVRT*): **RFA.** CCB or βB (chronic or prn) ± Class IC antiarrhythmics (if nl heart)
NPJT	**CCB, βB, amiodarone**	Rx underlying dis. (eg, dig tox, ischemia)
AF	**βB, CCB, digoxin, AAD**	See "Atrial Fibrillation"
AFL	**βB, CCB, digoxin, AAD**	RFA; βB or CCB ± antiarrhythmics
MAT	CCB or βB if tolerated	Treat underlying disease process AVN ablation + PPM if refractory to meds

*Avoid adenosine & nodal agents if accessory pathway + preexcited tachycardia, see below (*JACC* 2003;42:1493)

- *Catheter ablation:* high overall success rate (AFL/AVNRT ˜95%, AVRT ˜90%, AF ˜80%) Complications: stroke, MI, bleeding, perforation, conduction block (*JAMA* 2007;290:2768)

ACCESSORY PATHWAYS (WOLFF-PARKINSON-WHITE)

Definitions

- **Accessory pathway** (bypass tract) of conducting myocardium connecting 
atria & ventricles, allowing impulses to bypass normal AVN delay
- **Preexcitation (WPW) pattern:** ↓ PR interval, ↑ QRS width w/ δ wave (slurred onset, *can be subtle*), ST & Tw abnl (can mimic old IMI);

  only seen w/ pathways that conduct antegrade (if pathway only conducts retrograde then ECG will be normal during SR; "concealed" bypass tract)

  PAC can exaggerate preexcitation if AV node conduction slowed
- **WPW syndrome:** accessory pathway + paroxysmal tachycardia

Classic tachycardias of WPW

- **Orthodromic AVRT:** *narrow-complex* SVT (typically), conducting ↑ AVN & ↑ accessory pathway; requires retrograde conduction and ∴ can occur w/ concealed bypass tracts
- **Antidromic AVRT** (less common): *wide-complex* regular tachycardia, conducting ↓ accessory pathway & ↑

AVN. Can meet many ECG morphology criteria for VT. Requires antegrade conduction and ∴ should see WPW pattern during SR.

- **AF** w/ rapid conduction down accessory pathway; ∴ wide-complex irregular SVT; requires antegrade conduction; ∴ should see WPW pattern in SR. Rarely can degenerate into VF.

Treatment

- **AVRT:** vagal, βB; caution w/ adenosine (can precip. AF); *have defibrillator ready*
- **AF/AFL** w/ conduction down accessory pathway: need to Rx arrhythmia *and* ↑ pathway refractoriness; use **procainamide**, **ibutilide**, or DCCV; avoid CCB & βB, dig/adenosine (can ↓ refractoriness of pathway → ↑ vent. rate ↑ VF)
- **Long term:** Rx sx tachycardias w/ RFA, antiarrhythmics (IA, IC) if not candidate for RFA.

  Consider RFA if asx but AVRT or AF inducible on EPS (*NEJM* 2003;349:1803) or if rapid conduction possible (✓ w/ EPS if preexcitation persists despite exercise testing).

  Risk of SCD related to how short RR interval is in AF and # of accessory pathways present. Exercise testing to look for loss of pre-excitation can be used as a proxy for short RR interval in AF: if pathway still present at peak exercise, more concerning.

ATRIAL FIBRILLATION

Classification (*Circ* 2014;130:2071)

- **Paroxysmal** (terminates spontaneously or w/ Rx w/in 7 d) vs **persistent** (sustained >7 d) vs **long-standing persistent** (>1 y) vs **permanent** (no plan to restore or maintain SR)
- **Nonvalvular** (AF absent rheumatic MS, prosthetic valve or mitral valve repair) vs **valvular**
- **Lone AF** = age <60 y and w/o clinical or echo evidence of cardiac disease (including HTN)

Pathophysiology

- Disorganized atrial electrical activity → ineffective atrial mechanical contraction
- For paroxysmal AF, >90% triggered by rapid firing in pulmonary veins (*NEJM* 1998;339:659)

Epidemiology and etiologies (*Annals* 2008;149:ITC5-2)

- 1-2% of pop. has AF (8% of elderly); lifetime risk 25%; mean age at presentation ~75 y
- Acute (up to 50% w/o identifiable cause)

  Cardiac: HF, myo/pericarditis, ischemia/MI, hypertensive crisis, cardiac surgery

  Pulmonary: acute pulmonary disease or hypoxia (eg, COPD flare, PNA), PE, OSA

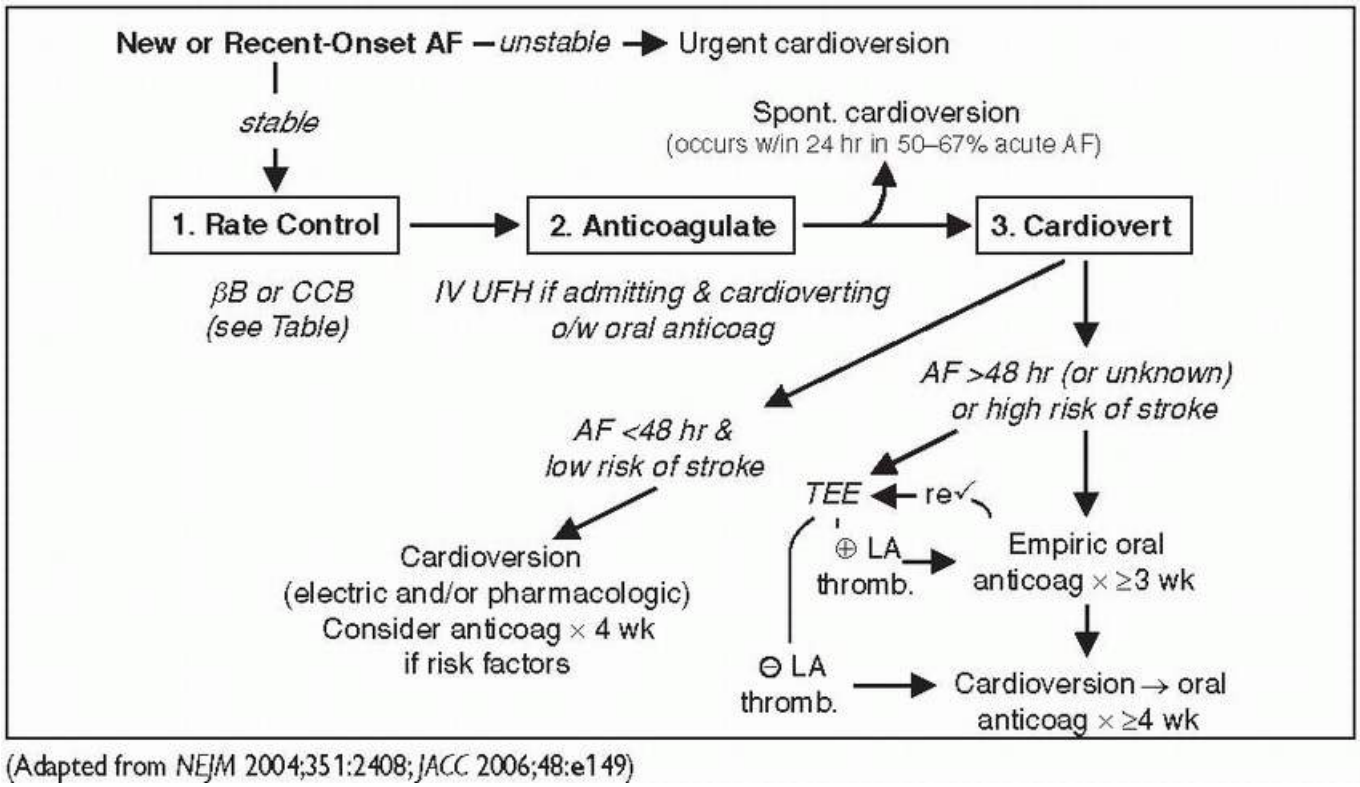
  Metabolic: high catecholamine states (stress, infection, postop, pheo), thyrotoxicosis

  Drugs: alcohol (“holiday heart”), cocaine, amphetamines, theophylline, caffeine

  Neurogenic: subarachnoid hemorrhage, ischemic stroke
- Chronic: ↑ age, HTN, ischemia, valve dis. (MV, TV, AoV), CMP, hyperthyroidism, obesity

Evaluation

- H&P, ECG, CXR, TTE (LA size, thrombus, valves, LV fxn, pericardium), K, Mg, FOBT before anticoag, TFTs; r/o MI not necessary unless other ischemic sx



(Adapted from *NEJM* 2004;351:2408; *JACC* 2006;48:e149)

Figure 1-9 Approach to acute AF

Rate control

- If sx, goal HR <80; if asx & EF >40%, goal HR <110 at rest (*NEJM* 2010;362:1363)
- AV node ablation + PPM if pharmacologic Rx inadequate (*NEJM* 2001;344:1043; 2002;346:2062)

Rate Control for AF

Agent		Acute (IV)	Maint. (PO)	Comments
CCB	**Verapamil**	5-10 mg over 2′ may repeat in 30′	120-360 mg/d in divided doses	↓ BP (Rx w/ Ca gluc) Can worsen HF Preferred if severe COPD Can ↑ dig levels
	Diltiazem	0.25 mg/kg over 2′ may repeat after 15′ 5-15 mg/h infusion	120-360 mg/d in divided doses	
βB	**Metoprolol**	2.5-5 mg over 2′ may repeat q5′ × 3	25-100 mg bid or tid	↓ BP (Rx w/ glucagon) Preferred if CAD Risks: HF & bronchospas.

Digoxin* (onset >30 min)	0.25 mg q2h up to 1.5 mg	0.125-0.375 mg qd (adj for CrCl)	Consider in HF or low BP Poor exertional HR ctrl
Amiodarone	300 mg over 1 h → 0.5-1 mg/min × 24 h	100-200 mg QD	Consider in HF or low BP Long-term potential tox

IV βB, CCB and digoxin ***contraindicated*** if evidence of WPW (ie, pre-excitation or WCT) since may facilitate conduction down accessory pathway leading to VF; ∴ use procainamide, ibutilide or amiodarone

*Many meds incl. amio, verapamil, quinidine, propafenone, macrolides & azole antifungals ↑ digoxin levels.

Cardioversion

- Consider pharm or electrical cardioversion w/ 1st AF episode or if sx; if AF >48 h, 2-5% risk stroke w/ cardioversion (*pharmacologic or electric*) ∴ either TEE to r/o thrombus or ensure therapeutic anticoagulation for ≥3 wk prior if need to cardiovert urgently, anticoagulate acutely (eg, IV UFH)
- Likelihood of success ∝ AF duration & atrial size; control precip. (eg, vol status, thyroid)
- Consider pre-Rx w/ antiarrhythmic drugs (eg, ibutilide), espec if 1st cardioversion fails
- For pharmacologic cardioversion, class III and IC drugs have best proven efficacy
- If SR returns (spont. or w/ Rx), atria may be *mech. stunned;* also, high risk of recurrent AF over next 3 mo. ∴ **Anticoag postcardioversion ≥ 4 wk** (? unless <48 h and low risk).

Rhythm control (*Lancet* 2012;379:648; *Circ* 2014;130:2071)

- No clear survival benefit or ↓ stroke risk vs rate control (*NEJM* 2002;347:1825 & 2008;358:2667)
- Consider if *symptomatic* w/ rate control (eg, heart failure), difficult to control rate, or tachycardia-mediated cardiomyopathy

Antiarrhythmic Drugs (AAD) for AF (*Circ* 2011;123:104 & 2012;125:381; *EHJ* 2012;33:2719)

Agent	Conversion	Maintenance	Comments
Amiodarone	5-7 mg/kg IV over 30-60′ → 1 mg/min, 10 g load	200-400 mg qd (most effective AAD for SR)	↑ QT, but TdP rare Low rate of acute conversion. May convert wks after load, ∴ attention to anticoag Pulm, liver, thyroid toxicity ✓ PFTs, LFTs, TFTs Potentiates warfarin, ∴ → warfarin by ˜50%
Dronedarone	n/a	400 mg bid	↓ side effects but also ↓ effic. c/w amio;

				contraindic. in perm AF or sx HF / ↓ EF; risk of liver toxicity
III				
	Ibutilide	1 mg IV over 10′ may repeat × 1	n/a	Contraindic. if ↓ K or ↑ QT ↑ QT, 3-8% risk of TdP Mg 1-2 g IV to ↓ risk TdP Lasts 4-6 h
	Dofetilide	500 mcg PO bid	500 mcg mg bid	↑ QT, ↑ risk of TdP; renal adj
	Sotalol	n/a	80-160 mg bid	✓ for ↓ HR, ↑ QT; renal adj
	Flecainide	300 mg PO × 1	100-150 mg bid	PreRx w/ AVN blocker *Contraindic. if structural or ischemic heart disease*
IC				
	Propafenone	600 mg PO × 1	150-300 mg tid	
IA	Procainamide	10-15 mg/kg IV over 1 h	n/a	↓ BP; ↑ QT ± PreRx w/ AVN blocker

Underlying disease	**Maintenance AAD of choice**
None or minimal (incl HTN w/o LVH)	class IC (“pill in pocket”), sotalol, dronedarone
HTN w/ LVH	amiodarone
CAD	sotalol, dofetilide, amiodarone, dronedarone
HF	amiodarone, dofetilide

Radiofrequency ablation (*JAMA* 2015;314:278)

- **Rationale:** Controlling triggers in pulmonary veins can control AF when little atrial scar present. As progress to persistent and permanent, LA substrate more complex due to scarring and is likely harder to ablate with pulmonary vein isolation alone.
- **Indication:** reasonable alternative to AAD in structurally normal heart
- **Approach:** for paroxysmal AF, circumferential pulm. vein isolation done via ablation in LA myocardium (ablation in PVs causes stenosis) w/ ~80% success (*Lancet* 2012;380:1509). In AF w/o ↑ ↑ LA or ↓ EF, RFA still superior to AAD, but lower success rate w/ AF recurring in ~1/2 over 2 y and 2nd RFA often required to prevent LA flutter (*NEJM* 2012;367:1587; *JAMA* 2014;311:692). Utility of upfront additional lines of block unclear (*NEJM* 2015;372:1812).
- Often performed on uninterrupted/minimally interrupt. warfarin or Xa inhib (*Circ* 2014;129:1688)

- **Risks and complications**

  → arrhythmia & pericarditis during healing post ablation

  left atrial flutters may persist and need additional "touch up" ablation

  rarer complications (1-2%): stroke, tamponade, phrenic nerve injury, PV stenosis, LA-esophageal/mediastinal communication (˜3 wk after procedure, severe dysphagia, fever, CNS signs of thromboembolism; dx w/ CT scan or barium study, *no* TEE*; emergent* thoracic surgery)

- Surgical "maze" procedure (70-95% success rate) option if undergoing cardiac surgery

Oral anticoagulation (*Circ* 2014;130:2071; *JAMA* 2015;313:1950)

- *All valvular* AF (ie, rheum MS, valve prosthesis or repair), as stroke risk very high
- Nonvalvular AF (NVAF): stroke risk ˜4.5%/y, but varies depending on patient; anticoagulation → 68% ↓ stroke but carries risk of bleeding; ∴ use a risk score to guide Rx
- **CHA_2DS_2-VASc: C**HF (1 point), **H**TN (1), **A**ge ≥75 y (2), **D**M (1), **S**troke/TIA (2), **V**ascular disease (MI, PAD, or aortic plaque) (1), **A**ge 65-74 y (1), ♀ **S**ex **c**ategory (1) annual risk of stroke (*Lancet* 2012;379:648): at low end, ˜1% per point: 0 → ˜0%, 1 → 1.3%, 2 → 2.2%, 3 → 3.2%, 4 → 4.0%; at higher scores, risk ↑ ↑ (5 → 6.7%, ≥6 → ≥10%)
- Anticoagulation recommendations: **score ≥2 → anticoagulate**

  score 1 → consider anticoagulation or antiplatelet Rx (? latter reasonable if risk factor 65-74 y, vasc disease or ♀) or no Rx

  score 0 → reasonable to not anticoagulate
- **HAS-BLED** (*Chest* 2010;138:1093)

  HTN (1 point if >160 mmHg), **A**bnl renal/liver fxn (1 for each), **S**troke (1), **B**leeding hx or predisposition (eg, anemia), **L**abile INR (time in therapeutic range <60%), **E**lderly (eg, age >65, frailty), **D**rugs/alcohol concom (1 point for antiplt or NSAID; 1 for alcohol)

  ≥3 → ↑ risk for bleeding, ∴ consider closer monitoring or different drug/dose selection
- Special situations in Pts w/ indication for anticoagulation:

  plan for rhythm control: continue anticoagulation

  Pt refuses anticoag: ASA + clopi or, even less effective, ASA alone (*NEJM* 2009;360:2066) underwent PCI: ? Rx w/ anticoagulant & clopidogrel, omit ASA (*Lancet* 2013;381:1107)
- **Anticoagulant options: factor Xa or direct thrombin inhib** (NVAF only) or **warfarin** (INR 2-3; w/ UFH bridge if high risk of stroke)
- Periop rate of arterial embolization in AF (w/o mech valve) <0.5%; Ø benefit to bridging anticoag w/ LMWH & ↑ bleeding c/w stopping warf 5 d before (*NEJM* 2015;373:823)

Novel Oral Anticoagulants for Nonvalvular AF

Anticoag	Dosing	Efficacy & safety vs warfarin

Dabigatran (Direct thromb inhib)	150 mg bid (110 not avail in U.S.) (75 mg bid if CrCl 15-30)	150 mg: ↓ ischemic stroke & ICH 110 mg: ≈ ischemic stroke & ↓ major bleed/ICH Risks: GI side effects, ↑ MI c/w warfarin
Rivaroxaban (FXa inhib)	20 mg qd (15 mg qd if CrCl 15-50) w/ pm meal	≈ ischemic stroke & ↓ major bleed incl ICH
Apixaban (FXa inhib)	5 mg bid (2.5 mg bid if ≥2 risks: ≥80 y, ≤60 kg, Cr ≥1.5 mg/dL)	≈ ischemic stroke & ↓ major bleed incl ICH, 11% ↓ death. In Pts felt not cand for warfarin, apixa 55% ↓ stroke w/o ↑ bleed vs ASA alone.
Edoxaban (Fxa inhib)	60 mg qd if CrCl 51-95 (30 mg if CrCl 15-50) (30/15 mg regimen not available in U.S.)	60/30 mg: ≈ ischemic stroke & ↓ major bleed incl ICH, 14% ↓ CV death 30/15 mg: ↑ ischemic stroke & ↓ ↓ major bleed incl ICH, 15% ↓ CV death

- Rapid onset (w/in several hrs) and offset. Consequently do not need to bridge when starting. However, missing 1 dose could lead to inadequate protection.
- No monitoring required
- Require dose adjustment based on renal fxn, which should be monitored while on drug
- Difficult to reverse if bleeding. Prothrombin complex concentrate or recombinant FVIIa needed. Dabi can be reversed w/ idarucizumab (Ab frag; *NEJM* 2015;373:511).

(*NEJM* 2009;361:1139; 2011;364:806; 365:883 & 981; 2013;369:2063; *Lancet* 2014;383:955)

Nonpharmacologic stroke prevent (ACC/HRS/SCAI 2015 Overview, *JACC* 2015)

- Percutaneous occlusion of left atrial appendage (LAA) w/ watchman device (nitinol cage w/ polyethylene membrane). Postprocedure: warfarin × ˜45 d followed by clopi × ˜4.5 mo and ASA lifelong. In NVAF w/ $CHADS_2$ ≥1-2, c/w warfarin, ≈ stroke (↓ hemorrhagic, ↑ ischemic), ≈ bleeding (↑ procedural, ↓ non-proc), ↓ CV death (*JACC* 2015;65:2614). Does not address issue of high-risk anticoag Pt w/ *existing* LAA thrombus.
- Epicardial snare to ligate LAA (lariat device). High rate of initial technical success (*JACC* 2013;62:108), but long-term clinical outcomes & safety to be defined.
- Surgical LAA resection reasonable if another indication for cardiac surgery. Resection superior to ligation, which can recanalize.

Atrial flutter

- Macroreentrant atrial loop typically involving cavotricuspid isthmus (usually counter-clockwise w/ flutter waves ⊖ in inf leads & ⊕ in V_1, but can be clockwise).
- Risk of stroke similar to that of AF; ∴ same mandate for stroke prevention.
- Ablation of cavotricuspid isthmus has 95% success rate w/ only 0.5% complication rate. Pts remain at risk for atrial fibrillation.

WIDE-COMPLEX TACHYCARDIA (WCT)

Etiologies (*Lancet* 2012;380:1520)

- **Ventricular tachycardia (VT):** accounts for 80% of WCT in unselected population
- **SVT conducted with aberrancy:** either fixed BBB, rate-dependent BBB (usually RBBB), conduction via an accessory pathway or atrially triggered ventricular pacing

Monomorphic ventricular tachycardia (MMVT)

- All beats look similar; predominantly upward in V_1 = RBBB-type vs downward = LBBB-type
- Most commonly in obviously ***structurally abnormal heart*: prior MI** (scar); **CMP**

  mechanism is most commonly re-entry around areas of electrically silent scar tissue with slow myocardial conduction through adjacent areas of surviving myocytes

  focal arrhythmias also occur (RVOT, Ao root, fascicles, papillary muscles)

  re-entry utilizing the Purkinje system is also seen (Bundle Branch Reentry); "typical" form occurs in Pts w/ LBBB in sinus and VT w/ very similar morphology to sinus

- May occur in ***apparently* nl *heart that is actually diseased:***

  Arrhythmogenic (RV) CMP (ACM, qv): incomplete RBBB, ε wave (terminal notch in QRS) & TWI in V_1-V_3 on resting ECG, LBBB-type VT, dx w/ MRI (*Lancet* 2009;373:1289)

  subtle HCMP sarcoid; myocarditis (incl giant cell); anom coronary

- In structurally ***normal heart*** w/ nl resting ECG (prog generally good):

  RVOT VT: LBBB-type VT w/ inferior axis; often seen immediately after exercise; can suppress with CCB or βB or ablate

  idiopathic LV VT: RBBB-type VT w/ superior axis; responds to verapamil or can ablate

Polymorphic ventricular tachycardia (PMVT)

- QRS morphology and/or axis changes from beat to beat
- Etiologies: **ischemia; CMP**

  torsades de pointes (TdP = "twisting of the points," PMVT + ↑ QT): ↑ QT ***acquired*** (meds, lytes, stroke; see "ECG") w/ risk ↑ w/ ↑ HR, freq PVCs (pause dependent) *or* ***congenital*** (K/Na channelopathies) w/ resting Tw abnl & TdP triggered by sympa-thetic stimulation (eg, exercise, emotion, sudden loud noises) (*Lancet* 2008;372:750)

  Brugada syndrome (Na channelopathy): ♂ > ♀; pseudo-RBBB w/ STE in V_1-V_3 (provoked w/ class IA or IC) on resting ECG

  catecholaminergic (CPVT): familial; mutations in ryanodine receptor or calsequestrin 2; presents during emotional or physical stress

Diagnostic clues that favor VT (assume until proven otherwise)

- **Prior MI, CHF** or **LV dysfxn** *best predictors* (90%) that WCT is VT (*Am J Med* 1998;84:53)

- Hemodynamics and rate do *not* reliably distinguish VT from SVT
- MMVT is regular, but may have initial "warmup period" and may be slightly irregular (as compared w/ SVT, which is extremely regular); *grossly* irregularly irregular rhythm suggests PMVT or AF w/ aberrancy
- More the QRS morphology is like QRS morphology in SR, more likely SVT
- ECG features that favor VT (*Circ* 1991;83:1649; *EHJ* 2007;28:589)

  AV *dissociation* (independent P waves, capture or fusion beats) proves VT; physical exam correlates: variable S_1 and cannon *a* waves on JVP

  very wide QRS (> 140 ms in RBBB-type or > 160 in LBBB-type)

  extreme axis deviation; RBBB-type w/ LAD; LBBB-type w/ RAD; shift in axis >40°; initial R wave in aVR

  QRS morphology atypical for BBB

  RBBB-type: absence of tall R′ (or presence of monophasic R) in V_1, r/S ratio <1 in V_6

  LBBB-type: onset to nadir >60-100 ms in V_1, q wave in V_6 longest RS interval in any precordial lead > 100 ms and R wider than S ratio of voltage Δ in initial 40 msec to Δ in terminal 40 ms ≤1

  concordance (QRS in all precordial leads w/ same pattern/direction)

Acute management

- If stable: conscious sedation & sync cardioversion; if unstable (↓ BP, angina, ΔMS, HF): emergent cardioversion; if pulseless → ACLS w/ CPR & cardioversion
- Refractory: consider amiodarone, procainamide, and lidocaine (if suspect ischemia)
- If suspect PPM-mediated tachycardia → place magnet (switches device to VOO or DOO)
- If ICD: should deliver Rx, but do not rely on for VT resolution. If stable, can interrogate ICD. If repeated, appropriate & successful shocks → antiarrhythmics to suppress arrhythmia. If repeated shocks (approp or inapprop) w/o arrhythmia term → disable device (magnet).

Long-term management (*JACC* 2006;48:1064)

- Workup: **echo** to ✓ LV fxn, **cath** or **stress test** to r/o ischemia, ? MRI and/or RV bx to look for infiltrative CMP or ARVC, ? **EP study** to assess inducibility

- **ICD:** 2° prevention after documented VT/VF arrest (unless due to reversible cause) 1° prev. if high risk, eg, EF <30-35%, ACM, Brugada, certain LQTS, severe HCM. See "Cardiac Rhythm Management Devices." ? Wearable vest if reversible etiology while waiting for ICD (*Circ* 2013;127:854).

  Antitachycardia pacing (ATP = burst pacing faster than VT) can terminate VT w/o shock
- **Meds:** βB, antiarrhythmics (eg, amio, mexiletine) to suppress VT, which could trigger shock
- If med a/w TdP → QT >500 ± VPBs: d/c med, replete K, give Mg, ± pacing (*JACC* 2010;55:934)
- **Radiofrequency ablation** if isolated VT focus or if recurrent VT triggering ICD firing; ablation before ICD implantation ↓ discharge rate by 40% (*Lancet* 2010;375:31)

SUDDEN CARDIAC DEATH (SCD)

Definition

- Sudden cessation of cardiac activity with hemodynamic collapse
- Technically sudden cardiac arrest (SCA) or "aborted SCD" if resuscitated
- Frequently due to sustained VT/VF

Etiologies

- **Coronary artery disease** (~60-70%)

  acute ischemia: ACS; spasm; congenital coronary artery anomaly

  scar from prior MI
- **Structurally abnormal heart or vasculature** (~10-15%)

  cardiomyopathy: DCM, HCM, ACM; myocarditis

  valvular heart disease

  myocardial rupture, tamponade, Ao dissection

  PE
- **Apparently structurally normal heart** (~10-15%)

  LQTS (acquired or congenital); Brugada syndrome; catecholaminergic polymorphic VT

  ACM or infiltrative cardiomyopathy

  Wolff-Parkinson-White (typically w/ antegrade conduction of AF → VF)

  complete heart block

  commotio cordis (*NEJM* 1995;333:337)

Precipitants

- Ischemia
- Drugs: antiarrhythmics, QT-prolonging, diuretics
- Electrolytes (usually not sufficient to cause SCD; always search for underlying cause)

Workup (*JACC* 2006;48:1064)

- Hx (usually very limited): may have had prodrome c/w ACS or HF; PMH; meds; FHx
- Exam: signs of cardiovascular disease
- ECG: ischemia, infarction, conduction block, QT, pre-excitation, abnormal V_1-V_3 (eg, pseudo-RBBB + STE, ε wave + TWI), LVH
- Echocardiogram; MRI if echo unrevealing and no other obvious cause
- Coronary angiography (? or CT angio)

  if STE or ? chest pain prodrome, urgent angio (unless poor neurologic prognosis)

  even w/o STE, 33-40% will have evidence of acute occlusion (*NEJM* 1997;336:1629 & *JACC Intv* 2015;8:1031)

- EP study (qv) if above workup unrevealing, programmed stimulation to look for accessory pathway, drug infusions to provoke arrhythmia from CPVT, LQTS, Brugada
- Exercise testing to provoke CPVT or assess resolution of pre-excitation to risk stratify WPW
- If genetic or unexplained SCD, evaluation of family members

SYNCOPE

Definition

- Sudden transient loss of consciousness due to global cerebral hypoperfusion
- If CPR or cardioversion required, then SCD (qv) and not syncope (different prognosis)
- Presyncope = prodrome of light-headedness without LOC

Epidemiology

- Incidence ↑ w/ age, particularly above 70 y; similar in men & women
- Lifetime incidence ~1 in 3

Etiologies (*NEJM* 2002;347:878; *JACC* 2006;47:473; *EHJ* 2009;30:2631)

- **Neurocardiogenic** (a.k.a. vasovagal, ~25%; *NEJM* 2005;352:1004)

  ↑ sympathetic tone → vigorous contraction of LV → mechanoreceptors in LV trigger ↑ vagal tone (hyperactive Bezold-Jarisch reflex) → ↓ HR (cardioinhibitory) and/or ↓ BP (vasodepressor)

  cough, deglutition, defecation, & micturition → ↑ vagal tone and thus can be precipitants

  carotid sinus hypersensitivity is a related disorder w/ an exaggerated vagal resp to carotid massage

- **Cardiovascular** (~20%, more likely in men than women)

  Arrhythmia (15%): challenging to dx as often transient

  Bradyarrhythmias: SSS, high-grade AV block (Stokes-Adams attack), ⊖ chronotropes, PPM malfunction

  Tachyarrhythmias: VT, SVT (syncope rare unless structural heart disease or WPW)

  Mechanical (5%)

  Endocardial/Valvular: AS, MS, PS, prosthetic valve thrombosis, atrial myxoma

  Myocardial: outflow obstruction from HCMP (can also cause VT), MI (more likely VT)

  Pericardial: tamponade

  Vascular: PE, PHT, aortic dissection, ruptured AAA, subclavian steal

- **Orthostatic hypotension** (~10%) hypovolemia/diuretics, deconditioning; vasodilat. (espec if combined w/ ⊖ chronotropes) autonomic neuropathy

  1° = Parkinson's, Shy-Drager, Lewy body dementia, postural orthostatic tachycardia syndrome (POTS, dysautonomia in the young)

  2° = DM, EtOH, amyloidosis, CKD (*NEJM* 2008;358:615)

- **Neurologic** (~10%): vertebrobasilar insufficiency (occlusion, dissection or steal), impaired perfusion to all

cerebral vessels (very rare), SAH

- Remainder of cases with unknown etiology
- Misc. causes of LOC (but not syncope): seizure, TIA/stroke, migraine, hypoglycemia, hypoxia, anemia, anaphylaxis, narcolepsy, psychogenic

Workup (etiology cannot be determined in ˜40% of cases)

- *H&P incl. orthostatic* VS *have highest yield and most cost-effective* (*Archives* 2009;169:1299)
- **History** (from Pt and *witnesses* if available) activity and posture before the incident precipitating factors:

  exertion → AS, HCMP PHT

  positional Δ → orthostatic hypotension

  stressors such as sight of blood, pain, emotional distress, fatigue, prolonged standing, warm environment, N/V, cough/micturition/defecation/swallowing ↑ vasovagal

  head turning or shaving → carotid sinus hypersensitivity arm exercise → subclavian steal

  prodrome: sx such as diaphoresis, nausea, blurry vision for >˜5 sec suggests vasovagal; abrupt onset suggests cardiac or seizure

  associated sx: chest pain (MI), palpitations (tachycardia)

  neuro: aura prior to event, neuro sx, postictal state, bowel/bladder incontinence, & lateral tongue biting suggestive of seizure; brief convulsive activity for < 10 sec may occur w/ syncope & mimic seizure, but true tonic then clonic activity is indicative of seizure
- **PMH:** prior syncope, previous cardiac or neurologic dis.; no CV disease at baseline → 5% cardiac, 25% vasovagal; CV disease → 20% cardiac, 10% vasovagal (*NEJM* 2002;347:878)
- **Medications that may act as precipitants** vasodilators: α-blockers, nitrates, ACEI/ARB, CCB, hydralazine, phenothiazines, antidep. diuretics; ⊖ chronotropes (eg, βB and CCB)

  proarrhythmic or QT prolonging: class IA, IC or III antiarrhythmics (see "ECG") psychoactive drugs: antipsychotics, TCA, barbiturates, benzodiazepines, EtOH
- **Family history:** CMP, SCD, syncope (vasovagal may have genetic component)

- **Physical exam**

  VS including *orthostatics* (⊕ if supine → standing results in >20 mmHg ↓ SBP, >10 mmHg ↓ DBP, or > 10-20 bpm ↑ HR), BP in both arms

  persistently abnormal VS *concerning*

  cardiac: HF (↑ JVP, displ. PMI, S_3), murmurs, LVH (S_4, LV heave), PHT (RV heave, ↑ P_2)

  vascular: ✓ for asymmetric pulses, carotid/vertebral/subclavian bruits

  carotid sinus massage to assess for carotid hypersensitivity (if no bruits and no h/o TIA or stroke); ⊕ if asystole >3 sec or ↓ SBP >50 mmHg

  neurologic exam: focal findings, evidence of tongue biting; FOBT
- **ECG** (abnormal in ˜50%, but only definitively identifies cause of syncope in <10%)

  Conduction abnl: SB <40 bpm, repetitive sinus pauses >3 sec, AVB (partic. Mobitz II 2° or 3°), IVCD or BBB

(partic. bifascicular block or alternating BBB) (*EHJ* 2009;30:2631)

Arrhythmia: ectopy, ↑ (or ↓) QT, preexcitation (WPW), Brugada, ε wave (ACM), SVT/VT Ischemic changes (new or old): atrial or ventricular hypertrophy

- Place on telemetry while diagnostic workup ongoing
- Lab: glc, Hb, preg test (child-bearing age ♀), ? D-dimer, ? troponin (low yield w/o other s/s)

Life-threatening dx

- *Arrhythmia:* VT, high-grade AVB, long sinus pauses
- *Cardiovascular structural disease:* critical AS, HCMP tamponade, aortic dissection, PE
- *Massive hemorrhage* (eg, large GIB, Ao rupture, splenic rupture, ectopic preg, RP bleed)
- *Neurologic:* SAH (headache + syncope)

High-risk features (*J Emerg Med* 2012;42:345)

- Advanced age (? >60 y), h/o CAD, HF/CMP, valvular or congenital heart disease, arrhythmias, or FHx SCD
- Syncope c/w cardiac cause (lack of prodrome, exertional, supine, or resultant trauma) or recurrent syncope (risk of recurrence if ≥2 prior episodes >50%)
- Complaint of chest pain or dyspnea; abnl VS or cardiac, pulmonary or neuro exam
- Abnormal ECG suggesting arrhythmia, conduction abnormality, ischemia/infarction; Pt w/ PPM/ICD (unless interrogated and found to have no arrhythmia)

Disposition

- High-risk Pts should usually be admitted w/ telemetry and further testing (qv)
- Low-risk Pts may be discharged with follow-up testing
- Obvious vasovagal syncope can be discharged

Other diagnostic studies (consider based on results of H&P and ECG)

- Ambulatory ECG monitoring: if suspect arrhythmogenic syncope

  Holter monitoring (continuous ECG 24-48 h): useful if *frequent* events arrhythmia + sx (4%); asx but signif. arrhythmia (13%); sx but no arrhythmia (17%)

  Event recorder (activated by Pt to record rhythm strip): limited role, as only useful if established prodrome (because must be Pt activated)

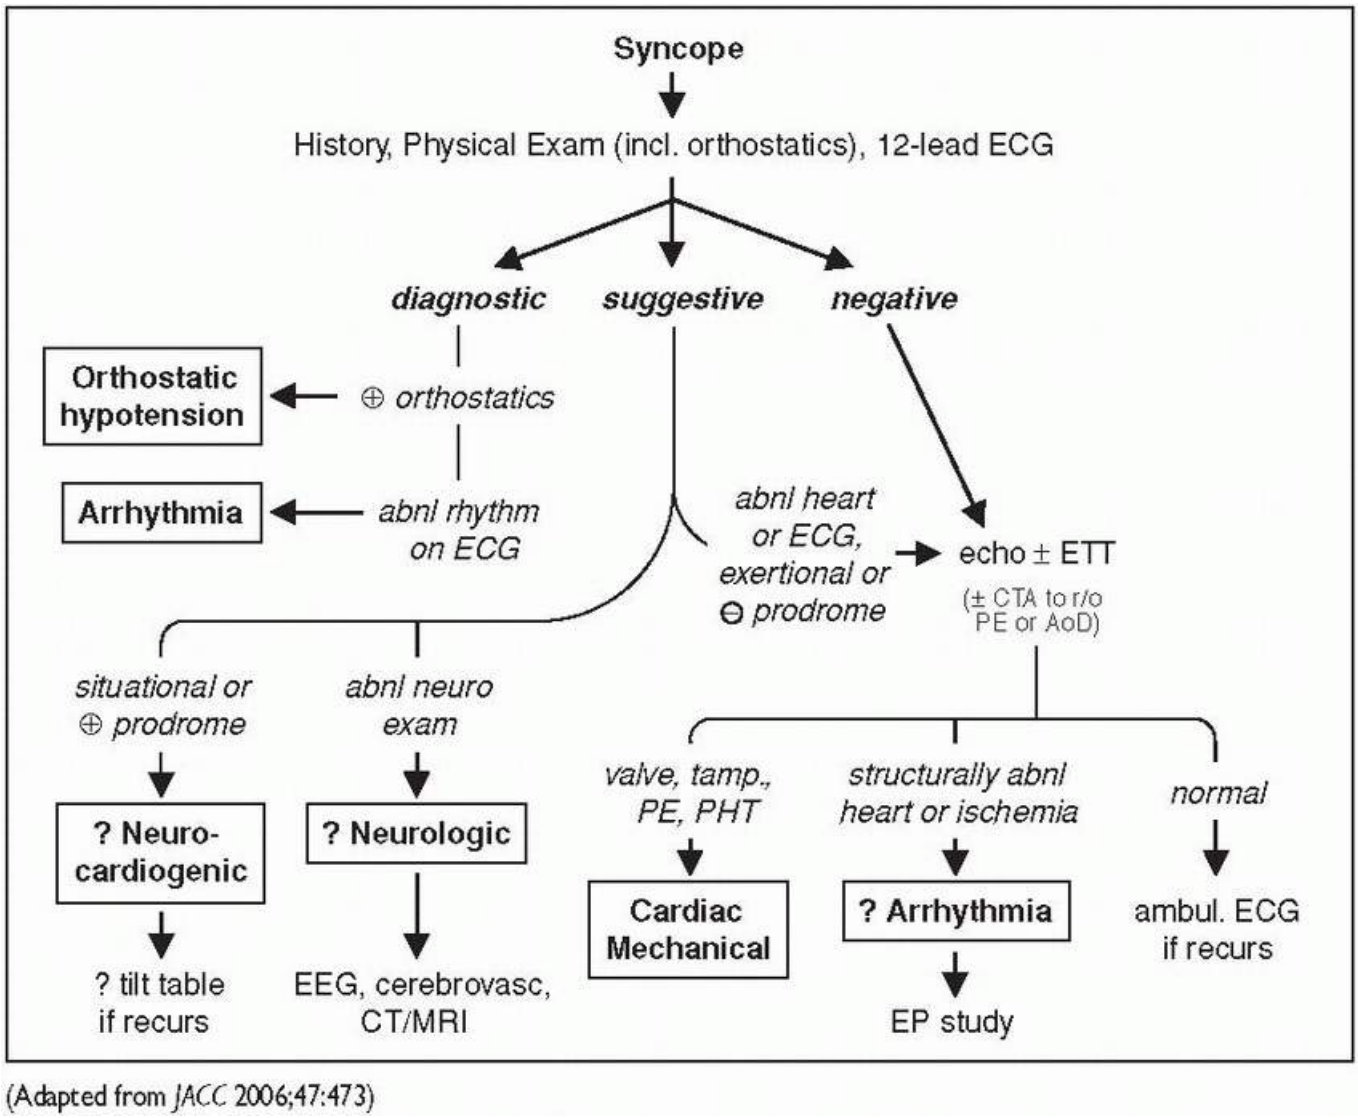
  External intermittent loop recorders (continuously saves rhythm, ∴ can be activated *after* an event): useful for episodes (including w/o prodrome) likely to occur w/in 1 mo

  Implantable loop recorders (inserted SC; can record up to 3 y): useful for infrequent episodes (< 1/mo); recommended for recurrent syncope w/o prodrome. Appears to establish a dx (often bradycardia) more frequently (55% vs 19%) than conventional testing (external loop recorder, tilt table, etc.; *Circ* 2001;104:46)
- Echo: consider to r/o structural heart disease (eg, CMP [incl HCMP & ACM], valvular disease [incl AS, MS, MVP], myxoma, amyloid, PHT, ± anomalous coronaries)
- ETT: espec w/ exertional syncope; r/o ischemia- or catecholamine-induced arrhythmias

- Cardiac catheterization: consider if noninvasive tests suggest ischemia
- Electrophysiologic studies (EPS, qv): consider in high-risk Pts in whom tachy or brady etiology is strongly suspected but cannot be confirmed;

  50% abnl (inducible VT, conduction abnormalities) if heart disease, but ? significance

  3-20% abnl if abnl ECG; <1% abnl if normal heart and normal ECG (*Annals* 1997;127:76)
- ? Tilt table testing: utility is debated due to poor Se/Sp/reproducibility; consider only if vasovagal dx suspected but cannot be confirmed by hx
- Cardiac MRI: helpful to dx ARVC if suggestive ECG, echo (RV dysfxn) or ⊕ FHx of SCD
- Neurologic studies (cerebrovascular studies, CT, MRI, EEG): if H&P suggestive; low yield



(Adapted from *JACC* 2006;47:473)

Figure 1-10 Approach to syncope

Treatment

- Arrhythmia, cardiac mechanical or neurologic syncope: treat underlying disorder
- Vasovagal syncope (*Int J Cardiol* 2013;167:1906): benefit for midodrine, SSRI

  ? 16 oz of H_2O before at-risk situations (*Circ* 2003;108:2660)

No proven benefit w/ βB (*Circ* 2006;113:1164) or tilt training

No benefit w/ PPM in RCT comparing active pacemaker vs pacemaker programmed in backup mode only. However, guidelines permit implant if ≥3 episodes/2y & loop recorder w/ asystole >3 sec (*Circ* 2012;125:2566).

No data for fludrocortisone, disopyramide

- Orthostatic syncope: volume replete (eg, 500 mL PO q a.m.); if chronic → rise from supine to standing *slowly,* compressive stockings, midodrine, atomoxetine (HTN 2014;64:1235), fludrocortisone, high Na diet

Prognosis (*Ann Emerg Med* 1997;29:459; *NEJM* 2002;347:878)

- 22% overall recurrence rate if idiopathic, else 3% recurrence
- Cardiac syncope: 2-fold ↑ in mort., 20-40% 1-y SCD rate, median survival ˜6 y
- Unexplained syncope w/ 1.3-fold ↑ in mort., but noncardiac or unexplained syncope w/ nl ECG, no h/o VT, no HF, age <45 → low recurrence rate and <5% 1-y SCD rate
- Vasovagal syncope: Pts not at increased risk for death, MI or stroke
- ✓ state driving laws and MD reporting requirements. Consider appropriateness of Pt involvement in exercise/sport, operating machinery, high-risk occupation (eg, pilot).

ANTIARRHYTHMIC DRUGS (AAD)

Procainamide (class IA = moderate Na channel blocker)

Dose	10-15 mg/kg IV over 1 h; 1-2 g bid (oral form not available in U.S.)
Uses	Converting AF & maint. SR; emergent Rx of VT or WCT of ? etiology
Side effects	→ QT, TdP. HoTN (w/ IV use); lupus-like synd. Metab by hepatic N-acetylation. NAPA K channel blocker and renally cleared; ✓ proc & NAPA levels.

Quinidine (class IA = moderate Na channel blocker)

Dose	200-648 mg tid (slowly uptitrate); can be given IV
Uses	Prevention of VT (used mainly in refractory cases). Blocks I_{TO} (Rx VF storms in Brugada syndrome).
Side effects	→ QT, TdP. Diarrhea often limiting. Moderate anticholinergic effects. α blockade → HoTN. Tinnitus, hemolytic anemia, thrombocytopenia.

Disopyramide (Norpace) (class IA = moderate Na channel blocker)

Dose	200-600 mg bid (slowly uptitrate)
Uses	Rx for AF in HCMPP Rx for HCMPP(b/c ⊖ inotrope)
Side effects	→ QT, TdP. Marked anticholinergic effects. ⊖ inotrope (∴ contraindic in Pts w/ ↓ EF).

Lidocaine (class IB = mild Na channel blocker)

Mech	Blocks activated & inactivated but not resting Na channels; ∴ selectively blocks ischemic arrhythmogenic tissue
Dose	100 mg IVB, subsequent 50 mg IVB prn × 2; infusion 1-4 mg/min
Uses	Emergent treatment of VT/VF
Side effects	Δ MS, slurred speech, twitching; ✓ lido levels, toxicity can manifest as seizure
Other	**Mexiletine:** IB that can be given PO (200-300 tid) to suppress VT/VF

Flecainide (Tambocor) (class IC = marked Na channel blocker)

Dose	50-150 mg bid (slowly uptitrate); 200-300 mg × 1 (pill-in-pocket)
Uses	Maintenance of SR (PAF, PSVT); acute cardioversion (test in-hosp first!) PreRx with AV nodal blocker to prevent rapid ventricular conduction.
Side effects	→ mortality if structural heart disease (∴ *contraindic if ischemic or structural heart disease*). Metallic taste, negative inotropy.
Other	**Propafenone** (Rhythmol): similar indications & contrindic. Also βB. 150-300 mg tid or 225-425 bid (slowly uptitrate); 450-600 mg × 1 (pill-in-pocket).

Amiodarone (Cordarone) (class III = K channel blocker)

Mech	Primarily K channel blocker, but also Na channel blocker, βB, & CCB
Dose	IV load: 150 mg over 10 min → 1 mg/min × 6 h → 0.5 mg/min × 18 h → cont IV drip or Δ PO load for total ~10 g. PO load: 400 mg tid → total ~10 g Maintenance: 200 (for AF) to 400 (for VT) qd Emergent Rx of VT/VF: 300 mg IVB ± another 150 mg IVB if persists/recurs
Uses	Cardioversion of AF & maintenance of SR; treatment & suppression of VT/VF
Side effects	HoTN when given IV; bradycardia. Hypo- (~10%) or hyper- (~3%, typically in iodine-defic Pts) thyroidism. ↑ LFTs; pneumonitis or pulmonary fibrosis.
Other	**Dronedarone:** noniodine-containing derivative of amio w/ ↓ efficacy but better tolerability. Used for paroxysmal AF (400 mg bid). Contraindic if HF or perm AF.

Sotalol (Betapace) (class III = K channel blocker)

Mech	K+ blocker, and nonselective βB *d* and *l* isomers, respectively
Dose	Start 80 mg bid, ↑ to 120 and then up to 160 mg bid as needed.
Uses	Maintenance of SR in Pts w/ AF, prevention of VT in pts with ICD
Side effects	→ QT (contraindic if QTc >450 msec, adjust dose to keep <500 ms), TdP. ∴ monitor in hospital for ≥3 days on maintenance dose. Renally cleared.

Ibutilide (Corvert) (class III = K channel blocker)

Dose	1 mg IV over 10 min, may repeat × 1. Mg 2 g IV routinely during infusion.
Uses	Conversion of AF
Side effects	→ QT, TdP (~5%). Replete K & Mg before Rx. Continuous ECG monitoring (including for several hrs after last dose) and be prepared to defibrillate.
Other	**Dofetilide** (Tikosyn): maintenance of SR in Pts w/ AF. 0.5 mg bid. ↑ QT, TdP.

ELECTROPHYSIOLOGY STUDY (EPS)

Indications

- Syncope (w/ high-risk features or abnl ECG); identification of unsuspected tachyarrhythmias; distal

conduction disease (not good for ruling out paroxysmal sinus node dysfunction)

- Determination of mechanism of narrow [eg, AVNRT (dual AV node physiology), AVRT (bypass tract), ectopic atrial tachycardia] and wide complex tachycardias
- Diagnosis in Pts post cardiac arrest
- Risk stratification for SCD (ie, inducibility of VT/VF) in structural heart disease

Preprocedural evaluation

- Coronary angiography to r/o signif CAD (either as cause of ischemia-induced arrhythmia and/or to fix before inducing VT)
- TEE to r/o LA clot before left atrial procedures

Commonly used catheters and measurements

- Most often electrode catheters placed via femoral vein and placed at high right atrium (HRA), His bundle (HBE) and right ventricular apex (RVA). For SVT, also have a catheter in coronary sinus (CS), coursing to left side of heart around mitral annulus.

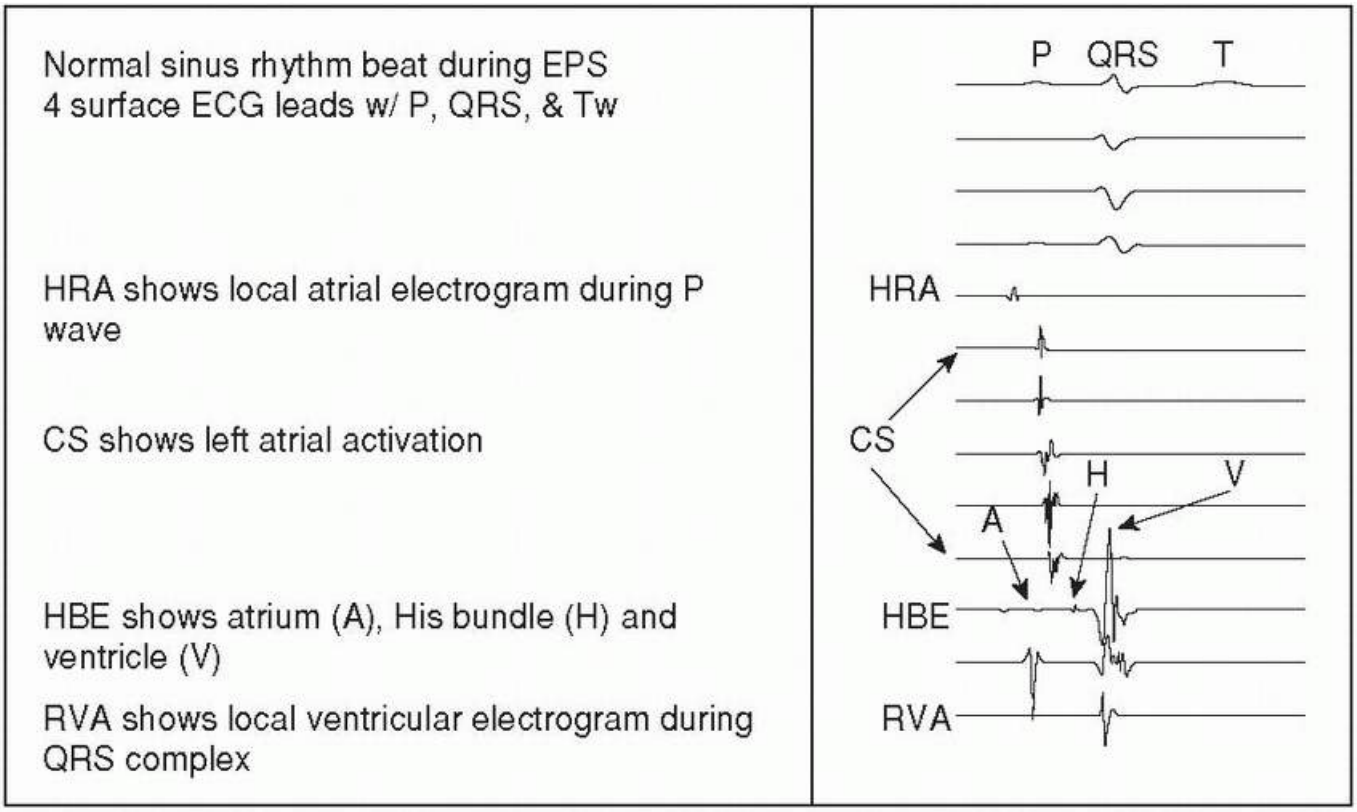


Figure 1-11 Tracing from EPS

- His bundle electrogram allows measurement of AVN conduction (AH interval) and distal conduction system (HV interval, nl 35-55 ms):

  HV interval <35 ms: pre-excitation (WPW)

  HV interval >35 ms: conduction system disease. LBBB typically 55-65 ms, > 70 ms w/ syncope needs PPM, > 100 ms needs PPM

- Current driven through electrodes used to pace heart and introduce extra beats following 8-beat drive train (programmed electrical stimulation, PES) usually done at HRA and RVA

- Atrial PES can be used to reveal evidence of dual AVN pathways or accessory pathways. Can also be used to induce SVT, AF, AFL.
- Ventricular PES can be used to reveal evidence of concealed accessory pathways, assess inducibility of VT/VF (and thereby risk of SCD), particularly in ischemic heart disease.
- Drug infusions (eg, epinephrine, procainamide) can help to dx LQTS, CPVT and Brugada

Complications

- Vascular injury at site of access
- Damage to tricuspid valve
- Arrhythmias
- Cardiac chamber perforation ± tamponade
- If ablation:

  heart block ± need for PPM

  chamber perforation ± tamponade for AF ablation: PV stenosis, phrenic nerve injury, atrio-esophageal fistula

CARDIAC RHYTHM MANAGEMENT DEVICES

Pacemaker Code

A, atrial; V, vent; O, none; I, inhibition; D, dual; R, rate-adaptive	1st letter	2nd letter	3rd letter	4th letter
	Chamber paced	Chamber sensed	Response to sensed beat	Program features

Common Pacing Modes

VVI	Ventricular pacing on demand w/ single lead in RV. Sensed ventricular beat inhibits V pacing. Used in chronic AF with symptomatic bradycardia.
DDD	A & V sensing/pacing (RA & RV leads). Native A beat inhib A pacing & *triggers V pacing* → tracking of intrinsic atrial activity. Maintains AV synchrony, ↓ AF.
Mode Switch	In atrial tachyarrhythmia (usually atrial flutter or fibrillation), pacemaker switches from DDD to nontracking mode (like VVI) in order to prevent pacing the ventricle at the upper rate limit (max rate at which PPM will pace ventricle) in an attempt to track the rapid atrial arrhythmia

Magnet (place over generator)	Pacemaker will pace at fixed rate regardless of intrinsic activity (= VOO/DOO). ICD: no detection/shock, but pacing programming preserved. Indications: ✓ ability to capture; ✓ battery life (to which rate will be proportional; uses less energy than programmer and does not require a programmer); during surgery w/ electrocautery; hemodynamic instability due to inappropriate PPM inhib, failure to mode switch or PM-mediated tachy; inapprop ICD shocks.

Indications for Permanent Pacing (*Circ* 2012;126:1784)

AV block	3° or type II 2° AVB a/w sx or w/ either HR <40 or asystole ≥3 sec (≥5 sec if in AF) while awake; ? asx 3° or type II 2° AVB; bifascicular or alternating left & right BBB
Sinus node	SB, pauses, chronotropic incompet a/w sx or ? if sx w/o clear assoc
Tachy-arrhythmia	Most common: AF w/ SSS, where pacing permits rate support of sinus rhythm in setting of rate controlling drugs for episodes of AF Pacing after AV junctional ablation for uncontrolled rates in AF Sustained pause-dependent VT Selected Pts w/ congenital long QT may benefit from pre-emptive pacing from their ICD
Syncope	Carotid sinus hypersensitivity with asystole >3 sec ? Neurocardiogenic syncope w/ prominent cardioinhib. response ? Syncope with bi/trifascicular block and not likely 2° to other causes

Pacing Complications (Pacemaker or ICD)

Issue	Manifestation	Description
Failure to pace	Bradycardia	Oversensing (ie, inappropriate inhibition) due to noise from lead fracture or set screw problem, myopotentials, EMI source outside body such as electrocautery or metal detector Sensitivity too low Battery depletion
Failure to capture	Pacing impulses delivered, but no P waves or QRS evoked	Elevated pacing threshold due to lead dislodgement, local tissue reaction or injury
Failure to sense	Inapprop. pacing	Lead dislodgment or disease of local myocardium (measured electrogram from leads too small to sense) or sensing threshold too high
PM-	WCT at device	Seen w/ DDD. VA retrograde conduction; sensed by A lead →

mediated tachycardia	upper rate	triggers V pacing → etc.
PM syndrome	Palpit, HF	Seen w/ VVI in Pts w/ intact AV conduction, due to loss of AV synchrony
SVC syndrome	Facial plethora	Thrombosis acutely or scarring a/w chronic intravascular lead(s)
Infection	Fever, ⊕ BCx	See below

Cardiac resynch therapy (CRT)/Biventricular (BiV) pacing (*Circ* 2012;126:1784)

- LBBB and standard RV apical pacing w/ resultant LBBB-like morphology causes dyssynchrony: LV septum activated before LV lateral wall. Wasted myocardial energy due to: prolonged time of contraction (sometimes continuing after AoV closure), sequential rather than simultaneous activation of papillary muscles → functional MR.
- 3-lead pacemaker (RA, RV, coronary sinus to LV lateral wall - LV lead can also be placed surgically by thoracotomy); pre-excites LV lateral wall in attempt to overcome dyssynchrony. R>S in V_1 & predominantly negative in I suggests approp LV capture. QRS width depends on degree of LV pre-excitation; can be narrower or wider than baseline.
- **Indications:** LVEF ≤35% + NYHA II-IV despite med Rx + SR + LBBB ≥150 (? ≥120) ms; mortality benefit only if LBBB (regardless of QRS width) (*NEJM* 2014;370:1694) can also consider in AF, but rate control or AVN ablation necessary to allow ventricular capture, as the greater proportion of time paced, the greater the CRT effect;

  ? NYHA I w/ LVEF ≤30% + LBBB ≥150 ms;

  ? EF ≤50% w/ AVB + indic for PPM (*NEJM* 2013;368:1585)
- **Benefits**

  acutely: simultaneous contraction of LV walls and reduction in MR

  after 3-6 mo: improvement in one NYHA class in 2/3 of Pts; some "super-responders" will normalize EF

  clinically: ↓ HF sx, ↓ HF hosp., ↑ survival (*NEJM* 2005;352:1539; 2010;363:2385)

  ineffective when LV lead location poor or LV scarring prevents pacing and/or improvements in wall motion

Implantable cardiac defibrillator (ICD) (*NEJM* 2003;349:1836; *JACC* 2009;54:747)

- RV lead: pacing and sensing like pacemaker lead, coils plus outside housing of ICD can participate in shocking circuit (± antitachycardia pacing [ATP] = burst pacing faster than VT rate to stop VT w/o painful shocks); ± RA lead for dual chamber pacing
- Uninterrupted warfarin at time of ICD (or PPM) placement ↑ risk of pocket hematoma vs bridging with UFH (*NEJM* 2013;368:2084)
- Subcutaneous ICD contains only shocking function (no ATP, no pacing) implanted in the left parasternal area with pulse generator in left lateral thoracic area. Reasonable for those with poor central access and those w/o

pacing requirement (*Circ* 2013;127:854).

- Wearable defibrillator vest can act as a “bridge” for Pts who cannot have an implanted defibrillator for weeks to a few months due to infection or other issue. Not yet demonstrated benefit as a bridge for those who do not yet meet guidelines for ICD (eg, early post MI or new NICMP (*JACC* 2013;62:2000). Data do not support home AED for these Pts either (*NEJM* 2008;358:1793).
- **Pt selection** (*NEJM* 2004;350:2151 & 351:2481; 2005;352:225; 2009;361:1427; *Circ* 2012;126:1784)

  2° prevention: survivors of VF arrest, unstable VT w/o reversible cause (*NEJM* 1997;337:1576); structural heart disease & spontaneous sustained VT (even if asx)

  1° prevention:

  LVEF ≤30% & post-MI *or* LVEF ≤35% & NYHA II-III *or* LVEF ≤40% & inducible VT/VF wait ≥40 d if post-MI, >9 mo after dx of NICM, or if presumed reversible; *however,* consider ICD if hemodyn signif VT/VF w/in window (& >48 h after AMI) (*Circ* 2014;130:94)

  consider for HCM, ARVC, Brugada, sarcoid, LQTS, Chagas or congenital heart disease if risk factors for SCD

  life expectancy must be > 1 y
- **Benefits:** ↓ mortality from SCD c/w antiarrhythmics or placebo
- **Risks:** inapprop shock in ~15-20% at 3 y (most commonly due to misclassified SVT); lead fracture
- ICD discharge: ✓ device to see if approp; r/o ischemia, other proximate cause; if recurrent VT, ? drug Rx (eg, amio + βB; *JAMA* 2006;295:165) or VT ablation (*NEJM* 2007;357:2657); ablation at time of ICD ↑ risk of VT by 40% (*Lancet* 2010;375:31)
- Telemonitoring may improve outcomes (*Lancet* 2014;384:583)

Device infection (*Circ* 2010;121:458; *JAMA* 2012;307:1727; *NEJM* 2012;367:842)

- Presents with one or more of the following: *pocket infection* (warmth, erythema, tenderness), *fever, bacteremia* and/or *sepsis*
- Incidence ~2% over 5 y; if *S. aureus* bacteremia, infxn in ≥35%
- More common a complication of generator change
- TTE/TEE used to help visualize complic. (eg, vegetation), but even ⊖ TEE does not r/o
- Treatment: abx and *removal of system* if evidence of pocket infection or GPC bacteremia (*Heart Rhythm* 2009;7:1085)
- Prophylaxis: no recommendation for routine abx prior to invasive procedure

APTT Activated partial thromboplastin time
ARB Angiotensin receptor blocker
ARVC Arrhythmogenic right ventricular cardiomyopathy
AS Aortic stenosis
AST Aspartate transaminase
AV Atrio-ventricular
AVNRT A-V nodal re-entry tachycardia
AVRT A-V re-entry tachycardia
BBB Bundle branch block
BNP B-type natriuretic peptides
BP Blood pressure
bpm beats per minute
CCBs Calcium channel blockers
CK-MB Creatinine kinase myocardial isoenzyme
CMR Cardiac magnetic resonance
COPD Chronic obstructive pulmonary disease
CPAP Continuous positive airway pressure
CPR Cardiopulmonary resuscitation
CRP C-reactive protein
CRT Cardiac resynchronisation therapy
CRT-D Cardiac resynchronisation therapy – defibrillator
CRT-P Cardiac resynchronisation therapy – pacemaker
CT Computed tomography
CXR Chest X-ray
DCCV Direct current cardioversion
DCM Dilated cardiomyopathy
ECG Electrocardiogram
EDV end diastolic volume
eGFR Estimated glomerular filtration rate
ESR Erythrocyte sedimentation rate
FBC Full blood count
GTN Glyceryl trinitrate
HbA1c Glycated haemoglobin
HCM Hypertrophic cardiomyopathy

HF	Heart failure
HF-PEF	Heart failure with Preserved Ejection Fraction
HF-REF	Heart failure with Reduced Ejection Fraction
ICD	Implantable cardioverter defibrillator
IE	Infective endocarditis
JVD	Jugular venous distension
LAD	Left anterior descending coronary artery
LAFB	Left anterior fascicular block
LBB	Left bundle branch
LBBB	Left bundle branch block
LCx	Left circumflex
LDL	Low-density lipoproteins
LMWH	Low molecular weight heparin
LPFB	Left posterior fascicular block
LQTS	Long QT syndrome
LV	Left ventricle
LVEDP	Left ventricular end diastolic pressure
LVEDV	Left ventricular end diastolic volume
LVF	Left ventricular failure
LVH	Left ventricular hypertrophy
LVOT	Left ventricular outflow tract
mV	millivolts
MR	Mitral regurgitation
NOAC	Non-vitamin K oral anti-coagulant
NSAIDs	Non-steroidal anti-inflammatory drugs
NSTEMI	Non ST-segment elevation myocardial infarction
NT-proBNP	N-terminal prohormone of brain natriuretic peptide
NYHA	New York Heart Association
PA	Posterior-anterior
P-PCI	Primary percutaneous coronary intervention
PCI	Percutaneous coronary intervention
PDA	Posterior descending artery
PEA	Pulseless electrical activity
PMH	Past medical history
PVCs	Premature ventricular contractions
QTc	Corrected QT
RAAS	Renin-angiotensin-aldosterone system
RBB	Right bundle branch
RBBB	Right bundle branch block
RCA	Right coronary artery
RV	Right ventricle
RVH	Right ventricular hypertrophy
RVOT	Right ventricular outflow tract
SA	Sino-atrial (node)
SCN5A	Sodium channel gene 5A

STEMI	ST-segment elevation myocardial infarction
SVT	Supraventricular tachycardia
TAVI	Transcutaneous aortic valve implantation
TEVAR	Thoracic endovascular aortic repair
TOE	Trans-oesophageal echocardiogram
TC	Takotsubo cardiomyopathy
TOE	Transoesophageal echocardiogram
TTE	Trans-thoracic echocardiogram
UA	Unstable angina
U&E	Urea and electrolytes
UFH	Unfractionated heparin
VF	Ventricular fibrillation
VT	Ventricular tachycardia
WPW	Wolff-Parkinson-White

Preface

Many cardiac conditions present suddenly, requiring a rapid response from healthcare practitioners. 'Rapid Cardiac Care' provides a concise text to guide the assessment and management of patients experiencing a variety of cardiac conditions. A systematic approach has been used to structure your assessment of the patient data and to prioritise management interventions. An overview of cardiac anatomy and physiology precedes sections on cardiac assessment, investigations, history taking, physical examination, symptom review and cardiac rhythm evaluation. The 12-lead ECG is a pivotal investigation in the evaluation of many cardiac conditions and therefore a tool to guide rapid interpretation is also provided. The care of patients with a range of cardiac conditions is presented in an A–Z format, which will direct the reader straight to the relevant sections.

Acknowledgements

We would like to thank the team at Wiley for their assistance throughout the production of this book.

Sincere thanks are extended to our families, for their constant support, patience and encouragement. We would especially like to acknowledge our fathers who influenced our lives immensely.

Anatomy

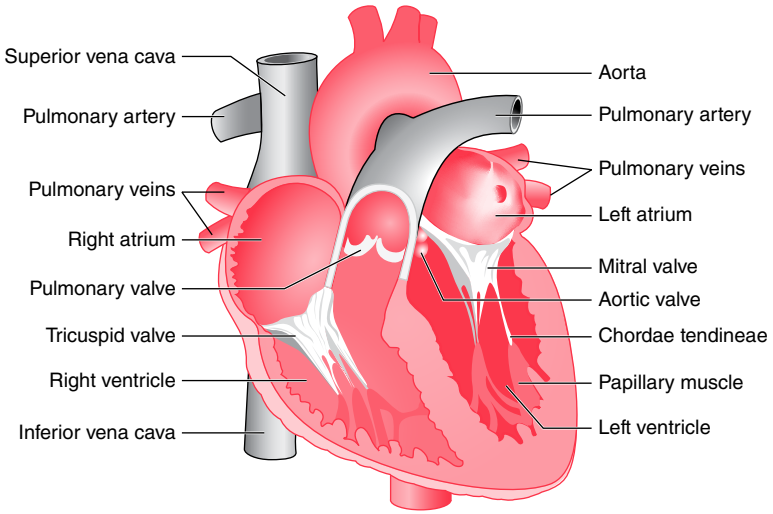

Figure 1.1 Cardiac anatomy.

The heart is a cone-shaped, muscular organ with four chambers that propel blood through the circulatory system (Figure 1.1). The two upper chambers, the atria, and the ventricles below are separated by the annulus fibrosus (AV ring), a layer of connective tissue that forms the cardiac skeleton, seen on the external surface of the heart as the atrio-ventricular (AV) groove. The mitral and tricuspid (AV) valves and aortic and pulmonary (semilunar) valves form part of the AV ring. Each valve consists of two or three cusps arising from an annulus. Healthy valves maintain forward blood flow through the heart, opening and closing in response to changes in pressure between the chambers. The interatrial septum separates the two atria; the ventricles are separated by the interventricular septum, which is visible on the outside of the heart as anterior-posterior interventricular groove.

The heart wall is formed from three layers of tissue that provide different functions. The external layer is the pericardium, which surrounds the heart and the roots of the aorta and pulmonary arterial trunk. It consists of two distinct layers: the outermost fibrous layer and serous layer beneath. The serous pericardium has a visceral layer, known as the epicardium, which surrounds the myocardium and doubles back on itself to form the parietal pericardium, which lines

the tough, outer fibrous layer. The space between the two layers contains a small volume of fluid to reduce friction during myocardial contraction. The central, thickest layer of the heart wall is the myocardium. It contains clusters of cardiac muscle cells known as myocytes, each surrounded by connective tissue and a network of capillaries. The internal surface of the heart is lined with a single, continuous layer of endothelial cells known as the endocardium. This facilitates smooth blood flow through the chambers and across the valves and provides some protection from the formation of thrombi.

Cardiac cycle

Cardiac output is the volume of blood ejected from the left ventricle (LV) in one minute, i.e. heart rate × stroke volume. It is approximately 4–7 L/min. The cardiac conduction system controls heart rate variability and co-ordinated systolic (contraction) and diastolic (relaxation and filling) activity of the cardiac chambers to maximise cardiac output.

The superior and inferior vena cava empty into the right atrium, enabling the return of deoxygenated blood to the heart. The coronary sinus, a large cardiac vein, also drains deoxygenated blood from the myocardium into the right atrium. The tricuspid valve opens to permit blood to enter the right ventricle (RV); atrial contraction provides extra force to expel blood from the chamber, known as the 'atrial kick', to optimise the end diastolic volume (EDV) of the ventricles.

During systole, the three papillary muscles in the RV contract, tightening the chordae tendineae, attached to the cusps of the tricuspid valve to ensure the valve leaflets remain closed, preventing regurgitation of blood into the right atrium. Pressure within the RV will rise until it exceeds the pressure within the pulmonary circulation beyond, forcing the pulmonary valve to open and blood to flow into the pulmonary arterial trunk. During ventricular diastole, the pulmonary arteries will rapidly recoil to enable blood to fall back towards the RV, closing the pulmonary valve.

Having completed gaseous exchange within the alveoli and pulmonary capillaries, oxygenated blood returns to the left atrium via four pulmonary veins. The increase in pressure within the atrial chamber forces the mitral valve to open and ventricular filling to begin. During diastole, the ventricular myocytes will stretch to accommodate the volume of blood, which directly correlates with the force of contraction that occurs during systolic contraction (Frank Starling's Law). The two papillary muscles contract first, once systole begins, tightening the chordae tendineae attached to the two cusps of the mitral valve to prevent regurgitation. The LV and septum then contract to increase the pressure (preload) within the LV. Once the preload pressure exceeds the pressure in the aorta beyond the aortic valve (afterload), blood will leave the LV, referred to as the stroke volume, crossing the aortic valve into the aorta to supply the arterial circulation. The term 'ejection fraction' refers to the stroke volume as a percentage of the left ventricular EDV (LVEDV), usually approximately 60–70% at rest. As systole ends, diastole begins again and a small volume of blood in the aorta will return towards the LV, closing the aortic valve cusps and simultaneously perfusing the coronary arteries originating at the aortic root.

Cardiac conduction system

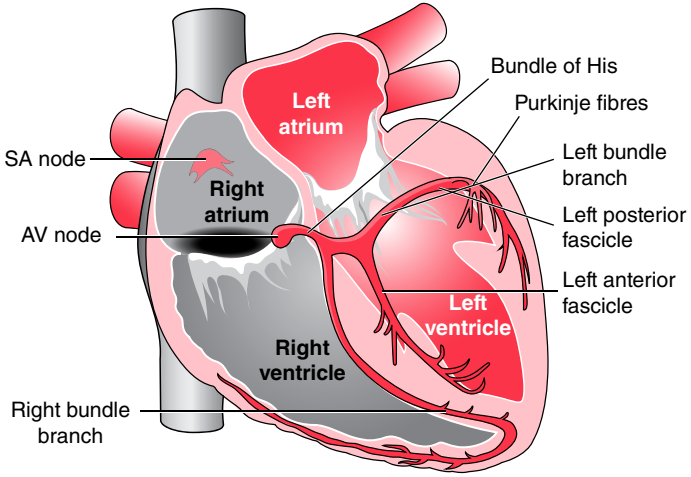

Figure 1.2 Cardiac conduction system.

The cardiac conduction system lies beneath the endocardium within the myocardium and consists of specialised myocytes responsible for generating and transmitting an impulse across the heart (Figure 1.2). The sino-atrial (SA) node, located on the posterior wall of the right atrium, is the primary pacemaker of the heart and therefore determines heart rate. It is capable of regular spontaneous depolarisation without external stimulus. However, the autonomic nervous system controls the SA nodal firing rate, permitting heart rate variability in response to fluctuating metabolic demand. Increased sympathetic activity will cause an increase in the SA nodal firing rate, for example during exercise. The heart rate is slowed via the vagus nerve, part of the parasympathetic nervous system.

Transition cells surrounding the SA node transfer the impulse across to the surrounding atrial myocytes, which in turn propagate the impulse to the remaining atrial cells, causing depolarisation and contraction. The annulus fibrosus, or AV ring, prevents direct transmission of the impulse to the ventricle. In response to atrial stimulation, the AV node transmits the impulse to the ventricular myocardium via the His-Purkinje system. After leaving the AV node, the impulse traverses the Bundle of His, which divides into two bundle branch systems. The right bundle branch is a thin, long strand, which runs down the right side of the interventricular septum and supplies conduction to the RV. The left bundle branch comprises shorter, thicker fibres, which divide into two branches called fascicles. The left anterior fascicle is the thinner of the two fascicles and supplies the septum,

anterior and lateral walls of the LV. The shorter, thicker left posterior fascicle supplies the electrical impulse to the posterior wall of the LV. A network of Purkinje fibres deliver the impulse first to the papillary muscles and then rapidly across the ventricles, resulting in simultaneous contraction. If the SA node fails to fire, the AV node, His-Purkinje system and ventricular myocardium are capable of generating an electrical impulse but at a slower rate than the SA node.

Movement of ions across the cell membrane, using diffusion and active transport mechanisms, is necessary to initiate myocardial depolarisation (systole) and repolarisation (diastolic relaxation).

The movement of ions across the cell membrane, known as the cardiac action potential, is responsible for initiating myocardial depolarisation (systole) and repolarisation (relaxation). A difference in electrical charge exists across the cell membrane, created by differences in the concentration of ions in the intracellular and extracellular fluid. This is known as the transmembrane potential. During the resting phase of the cardiac cycle, the transmembrane potential is approximately –90 mV (phase 4). At this stage, there is a higher concentration of intracellular potassium and lower concentration of intracellular sodium relative to their respective extracellular levels. This creates a concentration gradient, permitting the movement of ions across the cell membrane by diffusion and altering the transmembrane potential. Once this reaches –70 mV (threshold potential), early myocardial depolarisation will be triggered. Therefore, a sodium-potassium (Na^+/K^+) pump within the cell membrane uses active transport to move sodium out of the cell and potassium back into the cell to maintain the resting transmembrane potential of –90 mV during phase 4.

Myocardial depolarisation begins when sodium channels within the cell membrane open, permitting entry of sodium into the cell (phase 0). Once the transmembrane potential reaches the threshold potential of approximately –70 mV, fast sodium channels open, increasing the transmembrane potential to +30 mV. Repolarisation of the cell begins immediately afterwards, with a slight drop in transmembrane potential due to the closure of the sodium channels and an influx of chloride ions (phase 1). Myocardial contraction is maintained through the influx of calcium ions into the cell, causing the transmembrane potential to plateau at approximately 0 mV (phase 2). Repolarisation continues as the potassium channels open, allowing potassium to leave the cell, causing a dramatic fall in transmembrane potential (phase 3) until the resting membrane potential of –90 mV is reached and maintained using the Na^+/K^+ pump, rendering the cell inactive again (phase 4).

Coronary circulation

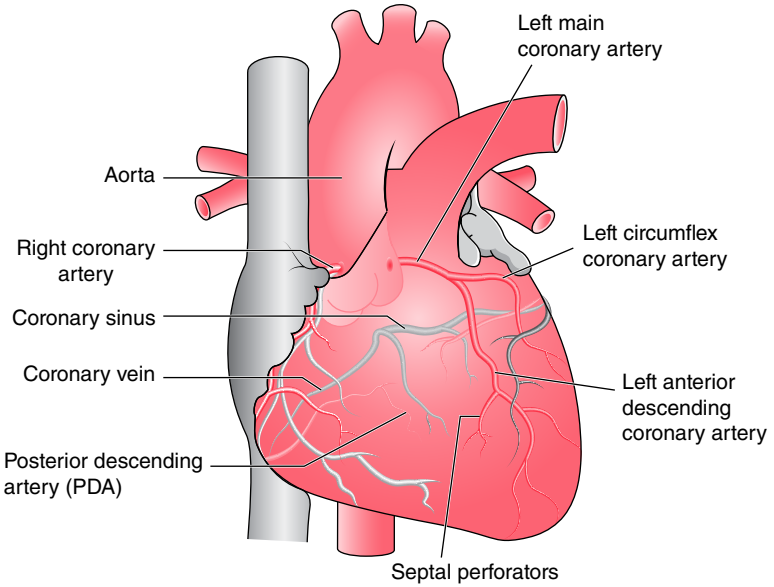

Figure 1.3 Coronary circulation.

Situated within the epicardium, the coronary arterial circulation is a network of arteries, arterioles and capillaries that penetrate the myocardium to provide the oxygen and nutrients necessary for aerobic metabolism (Figure 1.3). The right and left coronary arteries arise from two sinuses positioned at the root of the aorta behind two of the aortic valve cusps. Perfusion of the arteries occurs only during the diastolic phase of the cardiac cycle as the cusps of the aortic valve obstruct the sinuses during systole. The coronary arteries have four distinct layers of tissue: the endothelium, tunica intima, media and adventitia.

The right coronary artery (RCA) extends along the right side of the AV groove to the posterior wall of the heart, from where it proceeds inferiorly towards the apex and then terminates. The RCA provides perfusion for the right atrium, RV and the inferior surface of the LV, as well as the SA and AV node, in the majority of the population. The RCA also perfuses the posterior fascicle of the left bundle branch via the posterior descending artery (PDA).

The left coronary artery emerges from the aortic root, extending down the left atrium to the AV groove, where it bifurcates into the left anterior descending (LAD) and circumflex arteries. The LAD gives rise to diagonal branches and septal perforators, which perfuse the anterior surface of the LV, the anterior papillary muscle and the anterior aspect of the interventricular septum, including the right

bundle branch and the left anterior fascicle of the left bundle branch. The circumflex extends around the left AV groove to supply the lateral wall of the LV, via the obtuse marginal branches, as well as the left posterior fascicle, which is also supplied by the LAD.

The term dominance is used to describe the RCA when it perfuses the PDA, supplying the posterior wall of the LV and the AV nodal artery. Approximately 80–85% of the population have a dominant RCA. The circumflex is considered the dominant vessel in approximately 10–15% of the population, when the PDA emerges from the circumflex. A co-dominant circulation exists in approximately 5% of people in which both the RCA and circumflex extend to supply the posterior wall of the LV.

A collateral circulation exists between arterioles across the myocardium. In addition, portions of the subendocardial layer of myocardium may be perfused directly from the LV via the Thebesian veins.

Venous return from the myocardium occurs via the coronary veins, which follow the same route as the arterial circulation. The coronary veins drain into the coronary sinus, a large vessel situated along the posterior AV groove, which returns the deoxygenated blood into the right atrium. The myocardium also has a lymphatic circulation, which is also aligned with the arterial circulation.

Part 2 Rapid Cardiac Assessment

Rapid Cardiac Care, First Edition. Emma Menzies-Gow and Christine Spiers.

2

Introduction

A systematic approach to patient assessment is fundamental to undertaking a comprehensive review of the acutely ill adult. The assessment should raise concerns about red flags, identify unsuspected problems and generate logical differential diagnosis to guide investigation and treatment. A set of vital signs: respiratory rate and character, oxygen saturations, heart rate and rhythm, bilateral blood pressure (BP), temperature and blood glucose will allow comparison of patient findings to those expected in a normal subject.

Cardiac history taking

The history-taking process is fundamental and should not be omitted unless the patient is in a critical state and requires an ABDCE assessment. Accurate history taking should take a systematic approach and be conducted in a logical manner.

Presenting complaint

A variety of cardiac and non-cardiac specific symptoms may be elicited; cardinal symptoms include:

- Chest/arm/back pain – tightness or discomfort.
- Breathlessness – on exertion, lying flat, at night.
- Palpitations – fast, slow, irregular.
- Syncope/fainting/dizziness – related to exercise, on standing, at rest.
- Pain in legs or calves – on walking, at rest.
- Ankle swelling.

Symptom assessment

Further elucidation of the symptom/complaint should establish the frequency, duration, exacerbation and severity of symptoms; assessment tools provide a framework for assessment and SOCRATES is a popular tool:

S – Site
O – Onset
C – Character
R – Radiation
A – Associated symptoms
T – Timing
E – Exacerbating factors
S – Severity.

Chest pain assessment

Chest pain is a commonly presenting symptom and the underlying diagnosis may range from trivial to potentially life threatening. Assessment can be augmented with the addition of other tests such as 12-lead ECG, blood tests for markers of cardiac injury (Troponin, CK-MB) or infection (CRP). Echocardiography, CXR and CT scans can provide further valid information. Cardiac causes of chest pain include acute coronary syndromes (ACS), pericarditis, myocarditis and aortic dissection. Respiratory conditions such as pneumonia, pneumothorax and pulmonary embolism can also present with chest pain. Musculoskeletal causes of chest pain include chest wall injuries, costochondritis and secondary tumours of the ribs.

S - Site – the pain of myocardial ischaemia may be located in the jaw, throat, both arms, retrosternally and in the back. The pain from

pericarditis may be in the central chest, back or in the shoulders. Aortic dissection pain is located retrosternally and radiates into the back and the abdomen.

O - Onset – angina may be precipitated by exercise, emotion or cold weather. Pain associated with ACS may present at rest, on exertion or in the early hours of the morning on wakening. Pericardial pain may follow a period of flu-like symptoms or occur 3-6 weeks after acute MI.

C - Character – myocardial ischaemia is described as tight and crushing, but may also be an ache or heaviness. Aortic dissection pain has a tearing quality and pericardial pain is severe and constant.

R - Radiation – cardiac pain tends to radiate; ischaemic pain may radiate from the chest to the arms, jaw or back. The pain of aortic dissection often radiates into the back and occasionally the abdomen. Pericardial pain is frequently referred to the trapezius ridge (shoulder).

A - Associated symptoms – patients with myocardial infarction may present with dyspnoea, diaphoresis, nausea, syncope and extreme anxiety. Patients with ACS may present with one or several symptoms. In pericarditis, the pain is worse on inspiration. Aortic dissection may be associated with collapse and neurological involvement if a major vessel to the head and neck is compromised by the dissection.

T - Timing – myocardial ischaemia may have a sudden onset and the pain may last for longer than 20 minutes without relief. Aortic dissection tends to be of sudden onset and remains constant. Pericarditis and myocarditis may be preceded by a history of viral or flu-like symptoms.

E - Exacerbating factors – angina may be exacerbated by exercise, emotion, following meals or extreme weather temperatures. Pericardial pain is relieved by leaning forwards and made worse by deep inspiration.

S - Severity – whilst many patients with cardiac pain will describe the pain on the high end of a scale of 0–10, some patients, notably older patients and those with diabetes may experience little or no pain.

Risk factors

An evaluation of lifestyle and risk factors pertinent to cardiac disease should be undertaken. It is important to be non-judgemental but to ask questions sensitively and objectively. Key lifestyle factors include: cigarette smoking, misuse of alcohol, recreational drug use, lack of exercise and/or obesity. Cigarette smoking is the strongest modifiable risk factor for heart disease. Seek to evaluate if the patient has ever

smoked and if so, how much and for how many years. Clarification of number of pack years is calculated by the following formula and is used to estimate the risk of smoking-related health problems:

$$\frac{\text{Number of cigarettes smoked per day} \times \text{Number of years smoked}}{\text{20 (number of cigarettes per pack)}}$$

Estimate the amount of alcohol consumed per week; hazardous drinking is more than 2 units of alcohol per day for women, 3 units for men. One unit of alcohol is equivalent to a small glass of wine or half a pint of beer. Excessive alcohol use is implicated in hypertension, atrial fibrillation and dilated cardiomyopathy.

The increasing use of recreational drugs, particularly amphetamines and 'legal highs', is implicated in tachyarrhythmias. Cocaine may cause coronary artery vasospasm leading to ACS. Intravenous drug injection may act as a source for bacterial endocarditis. Obesity increases the risk of heart disease by inducing hypertension, hyperlipidaemia and diabetes. Diabetes is a significant risk factor for vascular and heart disease. Diabetes also magnifies the effects of other risk factors for cardiovascular disease.

Medications and allergies

Establish whether any medications have been prescribed and question whether these are being taken. The patient's current medications may help to confirm a suspected diagnosis, whilst newly prescribed drugs may have caused or aggravated symptoms; bronchodilators may precipitate tachycardia, beta-blockers may exacerbate heart failure or peripheral vascular disease and calcium channel blockers can cause oedema. Specific questioning around alternative, supplementary or 'over-the-counter' medications may raise suspicion of a drug-induced event; 'recreational' drugs such as cocaine may induce coronary artery spasm and ACS. Take note of any known allergies to medications.

Family history

Any known inherited or familial problems should be documented. A positive family history is a specific risk factor in coronary heart disease, and premature death in first degree relatives (<55 in males, < 60 years in females) indicates a familial risk. Similarly, a sudden premature death in the family may indicate undiagnosed arrhythmic syndromes such as Brugada or Long QT syndrome or structural abnormalities such as Hypertrophic Cardiomyopathy. Familial hyperlipidaemia leads to premature coronary artery disease and familial clotting disorders may precipitate venous thromboembolism.

Past medical history (PMH)

PMH and cardiovascular risk factors should be considered in the context of the presenting complaint. Links between other diseases such as hypertension, diabetes mellitus, respiratory and renal disease should also be considered. Recent cytotoxic therapy may be the aetiology of acute heart failure, whereas obstructive pulmonary disease may lead to chronic right-sided heart failure. Hyperthyroidism may cause tachyarrhythmias such as atrial fibrillation and patients with Marfan's syndrome may present with acute aortic dissection. Immunisation and any recent foreign travel may also be relevant.

Physical examination

The aim of the physical examination is to gather objective data to confirm or refute any differential diagnoses identified from the focussed history. Initial assessment should clarify if the patient is in pain or anxious, and any evidence of dyspnoea, pallor, diaphoresis or cyanosis would require urgent investigation. Examination of the cardiovascular system should include the whole circulatory system, not just the heart and utilises the following approach: inspection, palpation and auscultation.

Inspection

Inspection of the face, eyes, neck, hands, feet and chest will often provide evidence of heart disease. Facial dysmorphic features raise the suspicion of Down's syndrome and William's syndrome, which may cause significant structural heart disease. Evidence of hyperlipidaemia may be evident in xanthelasma (yellowish deposits in the skin near the eyelids) or corneal arcus (a white ring around the iris). Malar flush may be associated with mitral stenosis or chronic low-output states. Pallor may indicate anaemia (a cause of chest pain), and cyanosis is seen in patients with cyanotic congenital heart disease. Pallor and cyanosis is best evaluated in the mucous membranes of the eyes or by inspection of the mouth and tongue. Gingivitis and poor dental hygiene is a common source of bacterial endocarditis. A high arched palate with crowded teeth is seen in patients with Marfan syndrome.

Evaluate the neck for evidence of jugular venous distension (JVD), which is seen in right-sided heart failure, pericardial constriction or superior vena cava obstruction. Raised JVD is identified if the jugular pulsation can be seen more than 3 cm above the clavicle with reference to the sternal notch when a patient is lying at an angle of 45°. The hands are a good source of cardiac signs – clubbing of the fingers is seen in cyanotic congenital heart disease, peripheral cyanosis may be evident at the fingertips and splinter haemorrhages may be evident in bacterial endocarditis. Chest wall or sternal abnormalities, such as pectus excavatum (funnel chest) or pectus carinatum (pigeon chest), may displace the heart and limit cardiac function. Any evidence of previous cardiac surgery (sternotomy or chest drain scars) and any infraclavicular scars from placement of cardiac devices (pacemakers and implantable cardioverter defibrillators) should be noted. Evaluation of the legs and feet for oedema, skin discolouration or loss of hair growth may indicate heart failure, peripheral vascular disease or venous insufficiency.

Palpation

Evaluate the rate, rhythm, character and volume of the peripheral pulses. Absence of a pulse is often indicative of ischaemia due to atherosclerosis or embolism. The radial pulse should be 60–100 beats

per minute (bpm) in an adult. Bradycardia (heart rate less than 60 bpm) may be normal in athletes and during sleep, but may also indicate hypothyroidism, heart block (AV block) or be drug induced – (Digoxin or beta-blockers). Tachycardia is normal during exercise or anxiety but may indicate sepsis, hyperthyroidism, shock due to blood or fluid loss, heart failure or drug overdose. Abnormalities of pulse volume or character are rare and generally seen when the underlying valvular disease such as aortic regurgitation and aortic stenosis is moderately severe. When a pulse is not palpable it may be audible by Doppler flow evaluation. Limb pulses should be equal and when deficits are identified this may be due to aortic dissection (radial to radial delay), aortic aneurysm (femoral to femoral delay), or atrial fibrillation (radial-apical deficit). The chest can be palpated for any evidence of palpable murmurs (thrills), heaves or thrusts in right ventricular or left ventricular enlargement. The apical impulse is identified in the fifth intercostal space in the mid-clavicular line and deviation from this site may indicate left ventricular enlargement. A 'tapping' quality to the apex beat may be due to mitral stenosis, and a diffuse apical impulse is commonly associated with mitral regurgitation.

Auscultation

The auscultation landmarks are identified in Figure 2.1. These landmarks correspond to the place where the sounds generated by each heart valve is heard best. The sounds, referred to as 'lub-dup', relate to the closure of first the atrioventricular (tricuspid and mitral) followed by closure of the outlet (pulmonary and aortic) valves. The diaphragm of the stethoscope identifies high-pitched sounds (normal

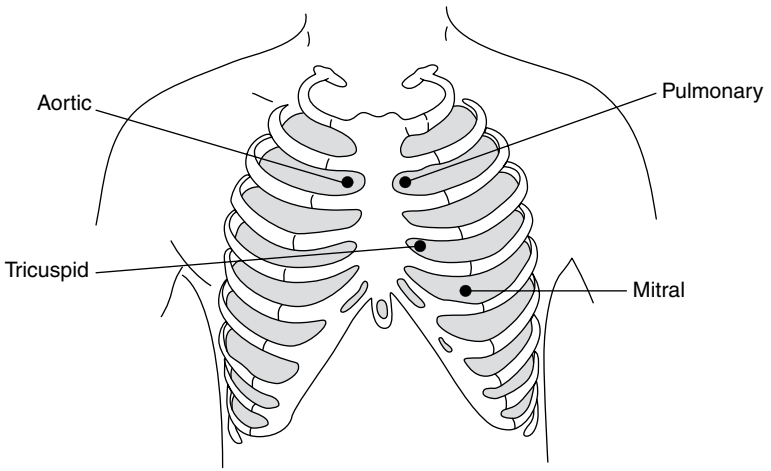

Figure 2.1 Cardiac auscultation landmarks.

heart sounds, systolic and diastolic murmurs), whereas the bell transmits the low-pitched sounds of mitral stenosis and the third and fourth heart sounds.

Auscultation of the lungs should include the anterior, posterior and lateral chest areas. Normal breath sounds are heard with the diaphragm of the stethoscope and include bronchial, broncho-vesicular and vesicular sounds.

Commonly identified murmurs in acute cardiac care include: third heart sound heard in heart failure, ejection systolic murmur in aortic stenosis and pan-systolic murmur in mitral regurgitation. Adventitious breath sounds in cardiac conditions include crackles associated with pulmonary oedema if bilateral and infection if unilateral.

Cardiac monitoring

Cardiac electrical activity can be recorded using a range of equipment that includes the 12-lead ECG and 3, 5 or 12-lead cardiac monitoring. Patients should be advised of the purpose of cardiac monitoring, their consent to proceed established and their dignity maintained throughout the procedure. The patient should be positioned comfortably and advised to remain resting while cardiac monitoring is being used, with a call bell available if help is needed. The electrodes must be placed directly onto clean, dry skin; hair may need to be removed to ensure good contact. If the patient's skin is clammy or has been recently moisturised, their skin should be cleaned with soap and water and thoroughly dried before applying electrodes.

In 3-lead monitoring, the limb lead electrodes should be positioned equidistant from the patient's heart around the upper chest and lower abdomen or on the upper and lower limbs, in the following sequence: Right Arm (red), Left Arm (yellow), Left Leg (green/black). If a fourth lead is available, this should be placed on the Right Leg (black). 5-lead monitoring involves an additional white lead, which should be connected to an electrode placed in the V_1 position (Figure 2.2). If 12-lead ECG monitoring is available, the electrodes should be positioned as for the 12-lead ECG.

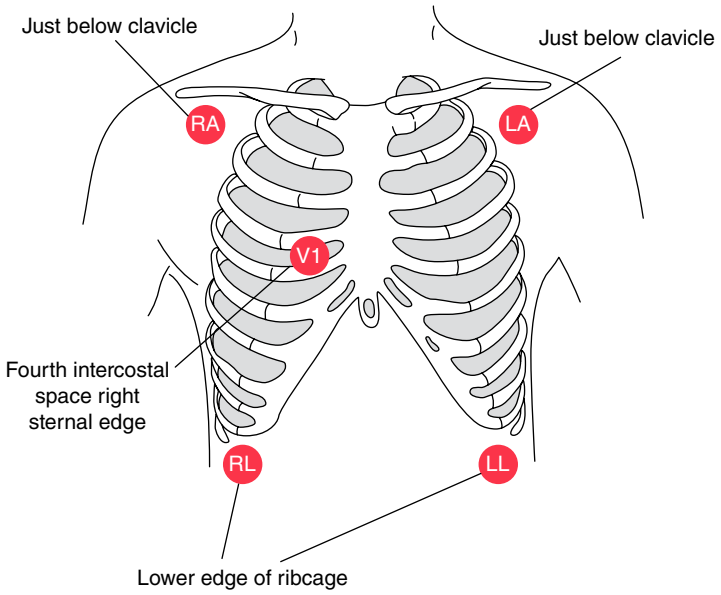

Figure 2.2 5-lead cardiac monitoring.

Lead II should be selected as it provides the clearest view of both atrial and ventricular activity. The size of the trace on the screen should be adjusted to ensure all waveforms are clearly visible. Artefact, or electrical interference, can severely affect the quality of the recording and impede rhythm recognition. It can be minimised by advising the patient to avoid excessive movement, ensuring the electrodes have good contact with skin and by limiting interference from nearby electrical equipment. The monitor alarm parameters should be adjusted for individual patients to alert the healthcare professional of a rise or fall in heart rate that may indicate the need for further assessment.

Rapid rhythm recognition

Once cardiac monitoring using lead II is established, systematic assessment can facilitate rapid rhythm recognition:

Assess ventricular rate and rhythm
Assess the QRS duration
Assess atrial activity, rate and rhythm
Assess relationship between atrial and ventricular activity
Assess PR and QT intervals
Identify the rhythm

The monitor records heart rate accurately but it can also be calculated from an ECG rhythm strip using the following formula:

$$\text{Heart rate} = \frac{1500}{\text{the number of small squares between two QRS complexes}}$$

Sinus rhythm: Normal waveforms and intervals

Sinus rhythm is the normal heart rhythm originating from the sino-atrial node. It is present when sequential conduction of the atria and ventricles, as described in Part 1, generates P, QRS and T waveforms that emerge from an isoelectric line. It is a regular rhythm, identified when the interval between consecutive QRS complexes, known as the R-R interval, is regular and constant, with a rate of between 60 and 100 bpm (Figure 2.3).

Normal atrial depolarisation, originating from the sinoatrial node, creates a small rounded P wave that emerges from the isoelectric line. In sinus rhythm, the P wave will be positive in lead II, appearing before the QRS complex. Each P wave should be followed by a QRS complex and T wave, representing ventricular depolarisation and repolarisation. The QRS duration will be less than 100 ms, indicating normal ventricular depolarisation using the His-Purkinje system. T waves should follow the direction of the QRS complex (concordant) in lead II, but can only be fully assessed using the 12-lead ECG.

The PR interval is a measurement taken to evaluate the delay in transmission though the AV node. Normally, the PR interval is 120–200 ms, measured from the beginning of the P wave to the beginning of the QRS complex. The QT interval is a measurement of the time taken for ventricular depolarisation and repolarisation to occur, measured from the beginning of the QRS complex to the end of the T wave. Rapid identification of a normal QT interval can be established if the QT interval is less than half the preceding R-R interval. However, as the QT interval is inversely proportional to rate, the corrected QT (QTc) interval should be calculated using Bazett's formula: $QT/\sqrt{RR}$ interval, as it adjusts the interval correctly for variation in heart rate.

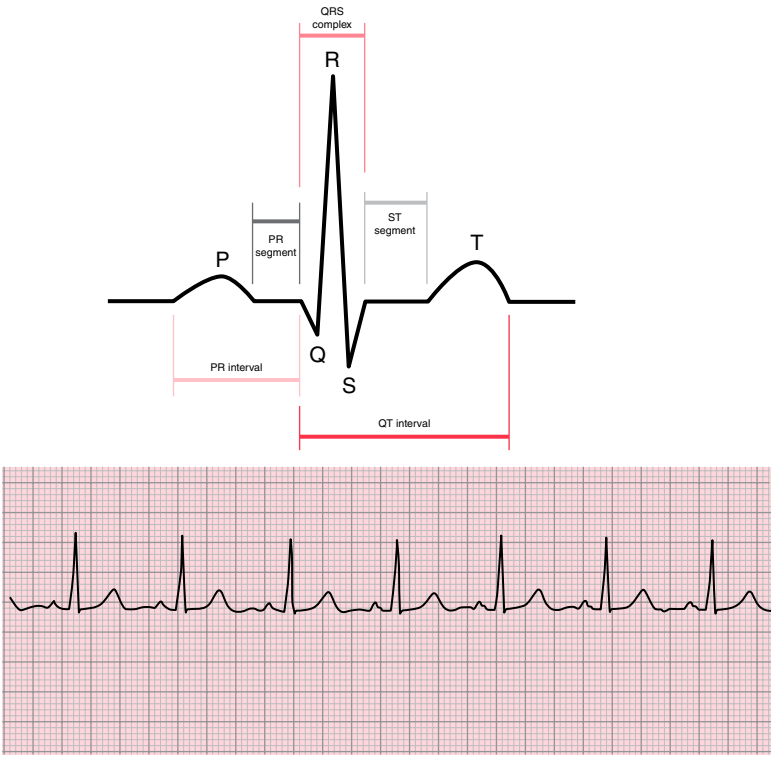

Figure 2.3 Normal ECG waveforms and sinus rhythm (lead II).

Sinus tachycardia

Sinus tachycardia is present when sinus rhythm has a QRS rate greater than 100 bpm. Stress and anxiety may cause an increase in sympathetic activity, increasing the sinoatrial node firing rate. However, sinus tachycardia may also occur in response to pain, ACS, sepsis, shock, heart failure or use of recreational drugs.

Sinus bradycardia

Sinus bradycardia is present when the sinus rhythm has a QRS rate of less than 60 bpm. This may be associated with high levels of fitness but may also be due to hypoxia, myocardial ischaemia, hypothermia or drugs that interfere with nodal conduction, such as beta-blockers.

Sinus arrhythmia

Sinus rhythm may appear to be irregular in some patients, particularly young people and the very elderly. This is known as sinus arrhythmia but is not considered an abnormal finding.

Cardiac investigations

Blood tests

A range of venous blood tests can provide data to aid the assessment, diagnosis and management of patients with suspected cardiac disease. Measurement of serum troponin I or T is useful in the diagnosis of patients presenting with chest pain or other symptoms associated with ACS. Troponin is a protein released as a result of myocardial damage. Most assays will begin to detect troponin around 4–6 hours after symptom onset. The sensitivity of available assays is improving with the emergence of high sensitivity troponins, able to detect troponin rise within 0–3 hours in patients with suspected ACS. However, other conditions may elevate troponin levels, such as arrhythmias, heart failure and chronic kidney disease. Creatine kinase (CK) and an isoenzyme of CK, CK-MB, are supplemental biochemical markers of current myocardial damage.

Elevated or low levels of potassium, magnesium, sodium, and calcium levels may cause atrial or ventricular ectopic beats and arrhythmias. Urea, creatinine levels and estimated glomerular filtration rate (eGFR) are used to assess renal function, which may be impaired in patients with cardiac conditions such as heart failure. Evaluation of renal function is particularly important for patients prior to coronary angiography or primary percutaneous coronary intervention (P-PCI), due to administration of radio-opaque contrast. The contrast is excreted by the kidneys and thus must be used with caution in patients with renal dysfunction.

The BNP and NT-pro-BNP will be elevated in patients with left ventricular dysfunction. Both assays correlate with the severity of heart failure and are predictive of cardiovascular events and mortality.

Liver function tests, including AST, ALT, LDH and ALP, may indicate hepatic dysfunction associated with heart failure or reveal a coagulopathy. Hyperthyroidism and hypothyroidism are both known risk factors for cardiovascular disease. Capillary blood glucose, fasting glucose and HbA1c assays are useful to diagnose diabetes, a known risk factor for cardiovascular disease and to ascertain the presence of hyperglycaemia during ACS. A fasting lipid profile can be used to guide lifestyle advice and medical therapy for patients with hyperlipidaemia. A full blood count will provide evidence of anaemia or infection.

Arterial and venous blood gases provide information on oxygen and carbon dioxide levels, acid-base balance and lactate levels, providing useful data in patients with, for example, dyspnoea and sepsis.

The 12-lead electrocardiograph (ECG)

A 12-lead ECG can be used to identify myocardial ischaemia and arrhythmia. Patients with symptoms of chest, neck, arm, jaw or

abdominal pain should have a 12-lead ECG as this may reveal ischaemia, as should patients presenting with palpitations, dyspnoea and syncopal symptoms. Ambulatory 24-hour ECG (Holter) monitoring and event recording can be used to identify paroxysmal arrhythmias, to record heart rate variability or a signal-averaged ECG, and to guide the use of implantable cardioverter defibrillator (ICDs). Tilt testing, during which BP and an ECG are continuously recorded, may be used to investigate patients with syncopal symptoms or vasovagal episodes. The ECG may used in exercise tolerance testing, in which the patient walks or runs on a treadmill to ascertain the presence of arrhythmia or ischaemia, although the use of this test is diminishing with the emergence of more sensitive imaging techniques such as stress echocardiography.

Cardiac imaging

The cardiac structures can be visualised using a chest X-ray taken in the posterior-anterior (PA) view and, if required, the lateral view when the patient has taken a deep breath. Chest X-ray (CXR) can facilitate assessment of heart size, dimensions of the thoracic aorta and pulmonary artery and signs of pericardial effusion, atrial and ventricular enlargement and ascending aortic dissection. A CXR may reveal signs of pulmonary oedema associated with heart failure.

Echocardiography uses ultrasound to assess cardiac function. A trans-thoracic echocardiogram (TTE) is recorded by placing a transducer on the patient's chest while they are lying on their left side, with their left arm out. A TTE can examine the movement of the chambers, septum and valves and approximate left ventricular ejection fraction, normally 50–65%. Doppler can be used to ascertain direction of blood flow, valuable in diagnosing valvular regurgitation. Three-dimensional echocardiography can be used to aid diagnosis of mitral and aortic disease and congenital heart disease. Stress echocardiography can establish the presence of hibernating or stunned myocardium. The 'stress' is produced through administration of dobutamine or by conducting the scan while the patient walks or runs on a treadmill, although there is an associated risk of inducing ventricular arrhythmias. Transoesophageal echocardiography (TOE), in which the transducer is advanced into the oesophagus, can provide high-quality images of valvular function and is used to visualise vegetation associated with endocarditis. This procedure requires local anaesthesia and sedation and is frequently used in the intensive care setting.

Cardiac magnetic resonance (CMR) imaging is an increasingly popular non-invasive technique used to investigate patients with cardiovascular disease. CMR can be used to provide diagnostic information for patients with a variety of cardiac conditions including

ischaemic, aortic, congenital and valvular heart disease. It is a non-invasive procedure that does not expose the patient to radiation nor require anaesthesia or sedation but may be unsuitable for patients with certain cardiac devices such as pacemakers.

A computed tomography (CT) coronary angiogram, using a peripheral infusion of contrast, is highly effective in the diagnosis of coronary artery disease. Other non-invasive cardiac investigations include the use of CT scans to assess the thoracic aorta if aneurysm or dissection is suspected and to undertake coronary artery calcium scoring in patients with ischaemic heart disease. A 'thallium' scan is a nuclear imaging test during which radioactive thallium is administered intravenously to identify areas of viable myocardium that may respond to reperfusion with coronary bypass graft surgery.

Invasive cardiac investigations

Cardiac catheterisation is an invasive procedure used to conduct coronary angiograms, aortography and investigate right heart function. During a coronary angiogram, X-rays are recorded of coronary blood flow while radio-opaque dye is injected into the right and left coronary arteries via a catheter inserted into the right femoral or radial artery. It can also be used to assess left ventricular ejection fraction. Angiography can be used to diagnose ischaemic heart disease and to determine if the patient would benefit from insertion of an intracoronary stent or from coronary artery bypass graft surgery.

Right heart function can be assessed using a venous catheter advanced into the right ventricle and pulmonary artery to directly measure pressure within each chamber. Pulmonary arterial 'wedge' pressure can be used as an indirect measure of left atrial pressure and left ventricular end-diastolic pressure. This test is conducted in patients prior to cardiac transplantation and in those with pulmonary hypertension.

In an electrophysiology study, electrodes are advanced via a venous catheter to locate abnormal electrical pathways, such as a re-entry circuit seen in supraventricular tachycardia (SVT). This information is used to establish the patient's suitability for interventions such as radiofrequency ablation, cryoablation or insertion of an ICD.

Part 3 Rapid 12-lead ECG Interpretation

Introduction

The Electrocardiogram (ECG) is a graphic record of the electrical activity generated by the cells of the heart, recorded at the body surface by electrodes and displayed onto a cardiac monitor or ECG paper as a visual record. The electrodes detect the electrical current generated by depolarisation and repolarisation of the atria and ventricles during each cardiac cycle.

ECGs are recorded onto grid paper that records time in seconds along the horizontal axis, and voltage or amplitude in millivolts (mV) on the vertical axis. Each small square is equivalent to 1 mm or 40 ms in time and 5 small squares is separated by a dark vertical line representing 5 mm or 200 ms. The ECG should be calibrated and recorded at 25 mm/second and 1 mV should produce a 10 mm deflection on the ECG.

Whereas cardiac monitoring employs three or four leads monitoring in a single plane, a 12-lead ECG evaluates the heart in two planes utilising 12 leads or 'views' to evaluate the electrical activity. Four electrodes are applied to the limbs in the following sequence: Right Arm (red), Left Arm (yellow), Left Leg (green), Right Leg (black) and six electrodes are applied to the chest or precordium. These leads are referred to as the 'V' leads or 'chest' leads and are recorded by applying the electrodes to prescribed areas over the anterior chest wall (V_1–V_6).

Simply put, an ECG lead is a recording of the heart's electrical activity from one viewpoint, the 12-lead ECG views the heart from 12 perspectives and helps to build up a three-dimensional picture of the cardiac electrical activity. Six of the leads view the frontal plane of the body and these leads are derived from the four electrodes placed on the limbs (the 'limb leads'). Leads V_1–V_6 view the horizontal or transverse plane of the body and are referred to as the 'chest leads' (Figure 3.1).

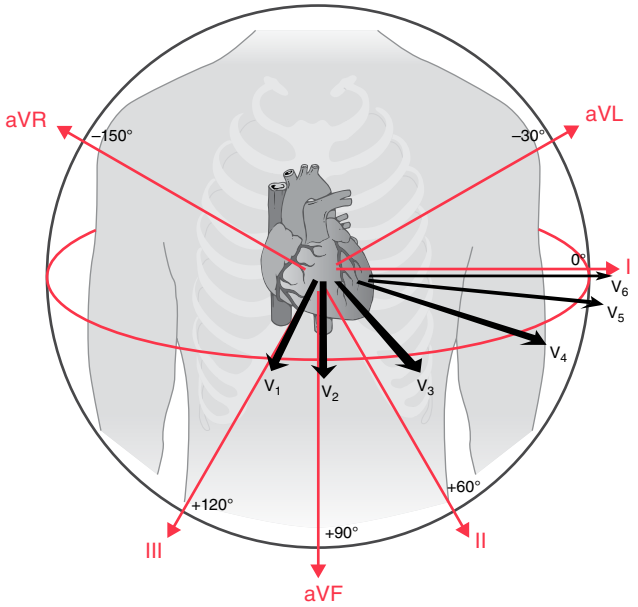

Figure 3.1 Orientation of the 12 ECG leads.

Cardiac vectors and axis

Atrial and ventricular depolarisation and repolarisation generates an electrical current that flows from the sino-atrial node, towards the atrio-ventricular node and downwards through the His-Purkinje system towards the left ventricular apex. The electrical current is described as the cardiac vector or the cardiac axis and this is a composite view of the general direction of the electrical current (Figure 3.2). The average direction of the vectors that result from ventricular depolarisation is called the mean QRS axis and this can be calculated using the 360° circle known as the hexaxial reference figure on which are inscribed the six limb leads. The figure is divided into quadrants by the bisection of lead axis I (at 0° on the circle) and aVF (at +90° on the circle). Axis deviation can result from many cardiac abnormalities and its calculation is an essential part of the initial interpretation of the 12-lead ECG.

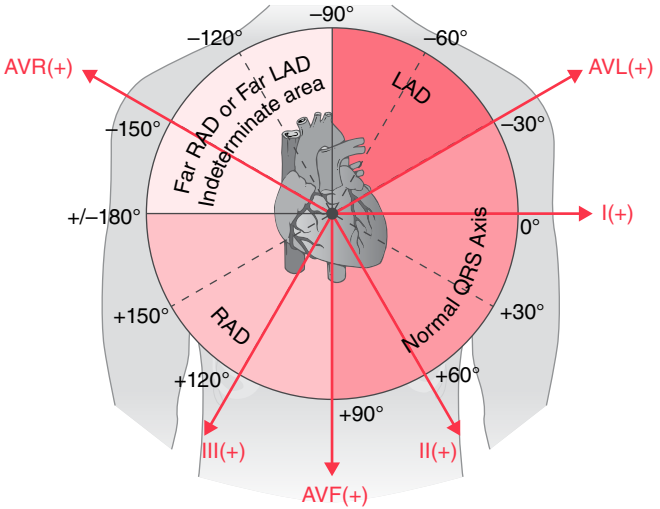

Figure 3.2 Hexaxial reference system showing four quadrants – normal, left, right and indeterminate axis.

Rapid ECG analysis tool

Rapid ECG assessment in the cardiac patient utilises a quick and systematic tool, which ensures that significant abnormalities are identified early and that important information is not missed.

Significant QRS abnormalities (QRS confounders) should be identified early: Wolff-Parkinson-White (WPW), bundle branch block (BBB) and fascicular block, all of which cause electrical impulses to be conducted abnormally throughout the ventricles and may mimic ischaemia and infarction to complicate the diagnosis. In this tool, significant QRS confounders are ruled out first before looking for evidence of myocardial ischaemia or infarction:

Rapid ECG Analysis Assessment:

Heart rate and rhythm using the rhythm analysis tool
QRS axis
Evidence of pre-excitation
Evidence of bundle branch and fascicular blocks
Evidence of myocardial ischaemia and infarction
Evidence of other conditions guided by the patient's clinical presentation

Rate and rhythm assessment

Heart rate and cardiac rhythm is an important aspect of patient assessment and this should be evaluated first by the analysis tool.

Assess ventricular rate and rhythm
Assess the QRS duration
Assess atrial activity, rate and rhythm
Assess relationship between atrial and ventricular activity
Assess PR and QT intervals
Identify the rhythm

QRS axis calculation

The QRS axis reflects the general direction of the electrical current as it flows across the heart. Normally the QRS axis is directed downwards and to the left due to the dominance of the left ventricle. The QRS axis is identified by using the hexaxial reference system and is measured using the frontal plane leads. A simple three-step method facilitates the measurement of the mean frontal plane QRS axis and is based on the understanding that the biphasic lead is 90° to the mean frontal plane axis. This method of axis determination is quick, simple and accurate:

1. Identify the biphasic lead – this is the lead which has the most equal positive and negative components and is often the smallest QRS complex.
2. Identify the lead that is oriented 90° or perpendicular to this lead using the hexaxial reference system.
3. Consider the direction of the QRS complex in the lead identified in step 2. If the QRS is predominantly positive, the axis is heading towards this lead on the hexaxial reference system. If the QRS is predominantly negative, the axis is heading away from this lead (identified as the negative pole on the hexaxial reference system). A list of possible causes of axis deviation is provided in Table 3.1.

Table 3.1 Causes of axis deviation

Right axis deviation +90° to +180°	Left axis deviation –30° to –90°
Can be normal in thin, tall, young individuals	Can be normal in elderly patients, obesity and third trimester of pregnancy
RBBB	LBBB
RVH	LVH
Left posterior fascicular block	Left anterior fascicular block
Pre-excitation syndrome left sided accessory pathway	Pre-excitation right-sided accessory pathway
Lateral wall myocardial infarction	Inferior wall myocardial infarction
COPD or acute pulmonary embolism	Hyperkalaemia
Dextracardia	Artificial cardiac pacing

Pre-excitation syndromes

The characteristic findings of shortened PR interval (<120 ms), a delta wave (a slurring of the proximal portion of the QRS) altering the normal shape, duration and voltage of the QRS complex and a subsequent discordant ST segment or T wave is the characteristic ECG pattern of ventricular pre-excitation known as Wolff-Parkinson-White (WPW) (Figure 3.3). Both WPW and a rarer form of ventricular pre-excitation, which results in a short PR interval but no other significant ECG abnormalities, put the patient at risk of supraventricular tachycardia.

The presence of accessory pathways, which conduct electrical impulses from the atria to the ventricles, bypassing the atrio-ventricular (AV) node, produces these characteristic ECG findings. This notching and widening of the QRS complex with discordant ST segments and T waves can mimic other pathological conditions including BBB, ventricular hypertrophy and myocardial infarction and therefore ventricular pre-excitation must be ruled out early in the ECG analysis. The accessory pathways may bypass the AV node with subsequent loss of the protective decremental properties of the AV node and allows a potentially fatal tachyarrhythmia to evolve.

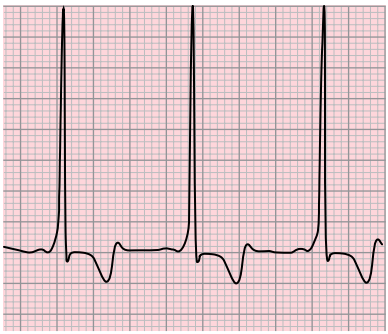

Figure 3.3 WPW pattern.

Bundle branch block and fascicular block

Bundle branch block and fascicular block typically cause axis deviation and abnormalities of the QRS complexes, ST-segments and T waves.

The intraventricular conduction system rapidly conducts electrical impulses to the ventricles. The right bundle branch (RBB) carries impulses to the right ventricle, and the left anterior fascicle and left posterior fascicle of the left bundle branch (LBB) depolarise the left ventricle. Normal conduction to the ventricles is fast and depolarisation of the ventricles occurs in a right to left sequence producing characteristic QRS complexes which are narrow (<100 ms). The initial depolarisation of the interventricular septum by the LBB is from left to right producing a small 'septal' r wave in V_1 lead. This is followed by simultaneous depolarisation of the right and left ventricles with the mean direction of current from right to left and thus the QRS complex primarily reflects depolarisation of the left ventricle.

When BBB occurs, the ventricle affected depolarises slower and aberrantly producing: QRS > 100 ms, abnormal QRS complexes with notching, ST segment and T wave abnormalities and axis deviation. The findings of BBB are best evaluated in the chest leads, primarily in V_1 and V_6.

Right Bundle Branch Block (RBBB)

A typical RBBB pattern produces a wide QRS complex (>100 ms) with an rSR′ wave in V_1 and V_2 (Figure 3.4) and a slurred S wave in V_6, with possible right axis deviation and ST and T wave abnormalities seen in V_1 and V_2.

In RBBB, septal activation occurs in the normal way from the LBB, and this wave of current is from left to right resulting in the normal small 'r' wave in V_1. The left ventricle is activated through the normally functioning LBB, causing an S wave in V_1 as the impulses travel away from the V_1 lead. The right ventricle depolarises late and abnormally via the myocardial cell structure, causing delayed RV activation and this results in a wide second R wave in V_1, V_2 (the characteristic rSR' pattern) and a slurred S wave in V_6. There may also be right axis deviation and ST and T wave abnormalities in the right-sided chest leads.

Left Bundle Branch Block (LBBB)

The left ventricle and the left bundle branch dominate the electrical forces on the ECG and thus LBBB produces changes, which are manifest in *most* or *all* leads on the 12-lead ECG. LBBB produces wide notched QRS complexes (>100 ms) in all ECG leads, QS (negative QRS) or rS in V_1 (Figure 3.5), a broad positive QRS in V_5,V_6, ST-segment deviation and T wave discordancy in *all* ECG leads. In particular, the

Figure 3.4 rSR' pattern associated with RBBB as seen in V_1.

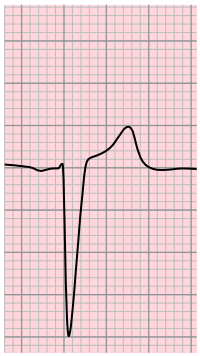

Figure 3.5 QS pattern associated with LBBB as seen in V_1.

patient may exhibit ST-segment elevation in V_1–V_3, which can mimic MI to the untrained eye.

In LBBB, the septum does not depolarise in the normal left to right direction and this causes the loss of the 'septal r wave' in V_1. The left ventricle depolarises late and abnormally via cell-to-cell conduction and this produces a wide (and sometimes notched) QRS complex in all leads. Additionally, there is abnormal repolarisation of the myocardial tissue and this results in ST segment and T wave discordance seen in all ECG leads.

Fascicular block

Fascicular block refers to abnormal, delayed or blocked conduction through the left anterior or left posterior fascicle of the LBB. Abnormal conduction through these fascicles disrupts normal ventricular depolarisation producing characteristic changes to QRS morphology and axis deviation.

Left anterior fascicular block (LAFB) causes left axis deviation of greater than –45° with an rS pattern in aVF and III, qR pattern in I and aVL.

Left posterior block causes right axis deviation of greater than 120° with a qR pattern in aVF and III and rS in I and aVL.

LAFB is more common than left posterior fascicular block, as the left anterior fascicle is more vulnerable to damage because of its anatomic position, single blood supply and close association with the aortic valve.

Bifascicular block

Fascicular blocks can occur alone or in conjunction with RBBB. LAFB and RBBB is the more usual presentation of bifascicular block (due to the shared LAD blood supply). Bifascicular block may deteriorate into complete heart block, particularly in the presence of acute MI. In the presence of first-degree AV block, trifascicular block is said to be present.

Myocardial ischaemia or infarction

Acute coronary syndromes (ACS) are sudden life-threatening events, which demonstrate classic ECG changes that are sequential and dynamic and create changes in T waves, ST segments and the Q wave:

- Myocardial ischaemia – T wave changes and ST-segment deviation.
- Myocardial infarction – ST-segment deviation and Q waves.

12-lead ECG changes indicative of ST-segment elevation myocardial infarction (STEMI) are:

- ST-segment elevation > 1 mm in any two contiguous leads except for V_2 and V_3 where the following rules apply:
  - Males under 40 years ST-segment elevation > 2.5 mm.
  - Males over 40 years ST-segment elevation > 2 mm.
  - Females any age ST-segment elevation > 1.5 mm.

12-lead ECG changes indicative of non-STEMI or unstable angina are:

- ST-segment depression 0.5 mm in two contiguous leads.
- T wave inversion in two contiguous leads.

Myocardial infarction and ischaemia manifest changes in the ST segments and T waves as indicated in Figures 3.6a–c.

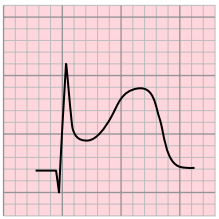

Figure 3.6a ST elevation.

Figure 3.6b ST depression.

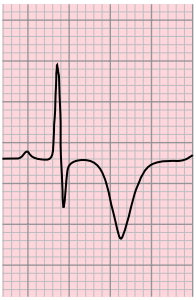

Figure 3.6c T wave inversion.

The leads in which these changes occur reflect the anatomical location of the damage, the likely culprit coronary artery and potential complications that can be identified in the Table 3.2 below:

Table 3.2 Possible complications due to 12-lead ECG changes

Culprit coronary artery	Anatomical territory/infarct area	ECG leads	Possible complications
LAD (septal branch)	Antero-septal LV	V_1–V_2	RBBB, Bifascicular block, LVF
LAD (diagonal branch)	Anterior LV	V_3–V_4	RBBB, Bifascicular block, LVF
LCx	Anterolateral LV	V_5–V_6, 1 and aVL	LVF, AV block
LCx or RCA	Posterior LV	Tall R waves V_1, V_2 or leads V_7–V_9	LVF, AV block
RCA	Inferior LV	II, III, aVF	Sinus node arrhythmias and AV block
Proximal RCA	Right ventricle	V_3R and V_4R	Hypotension, right heart failure

LAD Left anterior descending; LCx Left circumflex; RCA right coronary artery

Consider specific conditions based on the patient's history and presentation

Chamber enlargement such as atrial or ventricular hypertrophy can produce ECG waves of increased amplitude, duration and axis deviation. Left ventricular hypertrophy is characterised by:

- Tall R waves in leads facing the LV – V_5, V_6, I and aVL.
- QRS axis $\leq$ –30°.

- ST depression and/or T wave inversion in leads facing the LV – V_5, V_6, I and aVL.
- Wide notched P waves > 100 ms, demonstrating left atrial enlargement ('p mitrale').

Right ventricular hypertrophy is rare but is demonstrated by:

- Tall 'dominant' R waves in leads facing the RV – V_1 and V_2.
- QRS axis ≥ +90°.
- ST and/or T wave inversion in leads facing the RV – V_1 and V_2.
- Tall peaked P waves > 2.5 mm demonstrating right atrial enlargement ('p pulmonale').

Other clinical conditions may mimic the presence of infarction or make the ECG more difficult to analyse. Certain conditions such as Brugada syndrome, Takotsubo cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy (ARVC), pericarditis and myocarditis can all produce ST-segment elevation on the ECG and these conditions are known as infarct imposters. The reader is advised to read the relevant chapters elsewhere in this book.

Other abnormalities seen on the 12-lead ECG

To conclude the analysis, the ECG findings should be considered in the context of the patient's presenting signs, symptoms and other clinical criteria. If the patient has clinical symptoms but the ECG remains normal, serial ECG recordings should be undertaken alongside other clinical examinations and assessments. Additionally, supplemental leads and serial ECG recordings should be made in patients with clinical symptoms of ischaemia but non-diagnostic ECGs. In patients with inferior and suspected right ventricular involvement, V_3R and V_4R may demonstrate ST-segment elevation. Posterior wall (infero-basal) infarction should be suspected in patients with tall R waves in V_1, V_2 and ST-segment depression and the addition of leads V_7–V_9 is strongly recommended to evaluate the posterior myocardial wall.

Part 4 Cardiac Conditions A–Z

Rapid Cardiac Care, First Edition. Emma Menzies-Gow and Christine Spiers.

A

Acute coronary syndromes

'Acute coronary syndromes' (ACS) is an umbrella term referring to conditions caused by an episode of myocardial ischaemia occurring at rest or on minimal exertion. Sudden onset of chest pain is the most common symptom associated with ACS. The electrocardiogram (ECG) and cardiac biomarkers are used to differentiate between a diagnosis of ST-segment elevation myocardial infarction (STEMI), non-ST-segment elevation MI (NSTEMI) and unstable angina (UA). All three diagnoses are medical emergencies requiring rapid treatment to restore coronary perfusion and reduce the significant risk to mortality and morbidity.

Pathophysiology

ACS usually occur when there is erosion or disruption of a coronary atheromatous plaque, triggering thrombus formation within a coronary artery that can result in myocardial ischaemia, injury and necrosis (infarction). Cardiac risk factors such as hypertension, smoking and diabetes can contribute to the breakdown of the coronary endothelium and the fibrous cap around the plaque, leading to exposure of the thrombogenic lipid core to blood. This initiates rapid accumulation and activation of platelets and thrombosis within the coronary lumen. Activated platelets induce localised vasoconstriction, leading to rapid partial (NSTEMI/UA) or total occlusion (STEMI) of the coronary artery. This obstruction of coronary perfusion inhibits oxygenation of the myocardium beyond, causing ischaemia. Systolic activity of the ischaemic myocardium will initially continue while the myocytes function anaerobically. However, in the absence of rapid reperfusion, the affected portion of myocardium will soon cease contraction (myocardial injury) and eventually die (infarction).

History

Many patients live with chronic health issues that will significantly increase their risk of experiencing an ACS, such as diabetes, hypertension and obesity. Some have made lifestyle choices that also increase cardiovascular risk, such as smoking, adopting a high cholesterol, salt or sugar diet or taking limited or no regular exercise. Risk of ACS is significantly increased in patients who have a family history of heart disease and who may exhibit modifiable or non-modifiable risk factors that would contribute to the development of atherosclerosis.

Signs and symptoms

Many patients typically experience a sudden onset of retrosternal chest pain that is commonly described as a sharp pain, a crushing heaviness or a dull ache that radiates down their left arm or into their neck or lower jaw. These classic symptoms of ACS are caused by myocardial ischaemia. Others, particularly women, the elderly and patients with renal disease or diabetes, experience more ambiguous symptoms such as arm or jaw ache or heaviness, or nausea, vomiting and fatigue. Some will not experience any symptoms at all. The symptoms frequently commence at rest, for example while asleep, or during minimal exertion, but do not dissipate with rest or change in position. This differs significantly from the presentation of stable angina, where chest pain will ease with rest. Patients presenting with ACS may have had recent episodes of similar symptoms that have previously resolved, either with rest or with anti-anginal treatment, although for others this will be the first occurrence.

ACS can be life threatening and are the most common cause of sudden cardiac death among adults in the UK. Acute reduction in oxygenation of the myocardium not only induces chest pain but also increases the propensity for potentially fatal ventricular arrhythmias and acute heart failure, which could manifest as the initial clinical presentation. Additional symptoms may also be evident such as tachypnoea, arrhythmias, cool, clammy skin and a pale, grey pallor associated with increased sympathetic neurohormonal activity. Acute anxiety and distress frequently accompany ACS, with many patients expressing an overwhelming fear of imminent death. Ventricular tachycardia/ventricular fibrillation (VT/VF) cardiac arrest may occur soon after the onset of symptoms for which early defibrillation is essential to ensure survival.

The symptoms associated with ACS are common to all three diagnoses and, therefore, cannot be used to differentiate between UA, NSTEMI and STEMI. Similarly, the severity of symptoms is not a diagnostic indicator of the underlying form of ACS. Rapidly establishing a diagnosis is paramount for patients presenting with suspected ACS, to ensure that treatment is expedited swiftly to reduce the risk to mortality and long-term morbidity.

Assessment and investigations

Assessment should be prioritised to optimise patient safety. Initial observations should include assessment of respiratory rate, oxygen saturation level, pulse and blood pressure, which should be repeated at frequent intervals. Cardiac monitoring should be commenced rapidly to observe for arrhythmias and a 12-lead ECG recorded to diagnose or rule out ACS. If inconclusive, posterior and right ventricular lead ECGs should be recorded and the patient should have an urgent echocardiogram.

A focussed medical history should be obtained to ascertain the nature, onset and duration of the patient's symptoms and to establish the likelihood of ACS due to the existence of cardiac risk factors and family history of cardiac disease. Evaluating the nature, quality, onset and radiation of chest pain and the patient's response to anti-anginal therapy can be useful tools in establishing the likelihood of ACS where the ECG is inconclusive.

ACS is diagnosed from the patient's clinical presentation, ST-T wave changes on the 12-lead ECG and serum cardiac troponin levels. STEMI is present when there is 1 mm of ST-segment elevation, measured at the J point in two or more contiguous leads, other than in leads V_2 and V_3, where ST-segment elevation is higher and is age and gender specific. New left bundle branch block (LBBB) may also develop in the context of STEMI. The ECG changes associated with UA/NSTEMI are T wave inversion, ST-segment depression or transient ST-segment elevation in two contiguous leads. If the standard ECG is inconclusive, posterior (V_7–V_9) and right ventricular leads (V_3R and V_4R) should be recorded and analysed for signs of ischaemia.

A range of serum blood tests should be conducted, including samples for urea and electrolytes, cardiac troponins, full blood count and a clotting screen. Cardiac troponin levels should be assessed on initial presentation and repeated 12 hours later (high sensitivity troponin can be measured within 0 to 3 hours). The troponin level will be raised in STEMI and NSTEMI but remain negative in UA. GRACE and CRUSADE scores should be calculated to estimate prognosis and quantify bleeding risk respectively.

Treatment

Treatment of ACS should be expedited to ensure haemodynamic stability, alleviate symptoms and anxiety, establish coronary reperfusion and minimise short- and long-term risk of morbidity and mortality. Administration of opiate analgesia with anti-emetic should be prioritised while ensuring the patient remains on bed rest. Reassurance should be given where possible to help address anxiety. Resuscitation equipment should be immediately available, as patients with ACS are at risk of life-threatening arrhythmias and sudden cardiac death.

Dual anti-platelet (aspirin and P2Y12 inhibitor) and anti-thrombin therapies should be commenced as soon as possible in the absence of contraindications. Rapid delivery of primary percutaneous coronary intervention (P-PCI) is the mainstay of treatment for STEMI. Patients with NSTEMI/UA should also have percutaneous coronary intervention (PCI) but with less immediacy. However, PCI should be expedited for patients identified as being at high ischaemic risk by using the GRACE score or if the patient develops haemodynamic instability, refractory angina or life-threatening complications such as arrhythmias or heart failure.

Secondary prevention should be commenced at the earliest opportunity to prevent recurrence of ACS and complications associated with myocardial damage. Dual anti-platelet therapy should be continued in conjunction with a beta-blocker, an ACE-inhibitor and an HMG CoA reductase inhibitor (statin) in the absence of contraindications. Rivaroxaban may be commenced once the anti-thrombin agent has been stopped during the in-patient stay. Cardiac rehabilitation should be offered to patients 3–4 weeks post-discharge.

Acute coronary syndromes: treatment and interventions

Pathophysiology

Acute coronary syndromes (ACS) encompasses a range of clinical conditions which cause myocardial ischaemia, discussed in the preceding chapter. Patients who have sustained an ST-segment elevation myocardial infarction (STEMI) will undergo Primary Percutaneous Coronary Intervention (P-PCI) (angioplasty and stent implantation) but where timely P-PCI is not available, thrombolytic (fibrinolytic) therapy may be offered. Patients who have non-STEMI (NSTEMI) or unstable angina (UA) are also likely to undergo coronary angiography and intervention (stent deployment) to achieve perfusion to the jeopardised myocardium by reopening the culprit coronary artery. The onset of ACS generally results from rupture of the atheromatous plaque and exposure of the lipid core. Platelet adhesion at the site and platelet activation and aggregation leads to stimulation of the clotting cascade and potential thrombus formation. Antiplatelet therapy aims to inhibit platelet activation and aggregation and longer term pharmacological therapy aims to enhance thrombus resolution and prevent recurrent thrombotic events. In addition, optimisation of secondary preventive strategies prevents left ventricular remodelling and reduces the risk of further coronary events.

Antiplatelet strategies

Reducing platelet activation is crucial and, unless absolutely contraindicated, all patients should be prescribed *Aspirin* which exerts its antiplatelet effect by irreversibly binding to the cyclooxygenase-1 (COX-1) enzyme, reducing production of thromboxane A_2, a powerful vasoconstrictor. The addition of a second antiplatelet drug is indicated when a patient has received an intracoronary stent. Thienopyridines block the adenosine diphosphate (ADP) P2Y12 receptor on platelets and include *Clopidogrel*, *Prasugrel* and *Ticagrelor*. Clopidogrel is a prodrug that requires two stage metabolism to achieve the active metabolite. This results in a slow onset of efficacy and the dual hepatic activation results in variable individual patient response to the drug. The use of Prasugrel overcomes some of the limitations of Clopidogrel. Prasugrel also exerts its antiplatelet effect by irreversibly binding to the ADP P2Y12 receptor, but it only requires one metabolic step to become active and hence it achieves its effect faster and with less inter-patient variability of response. It does however cause an increased risk of bleeding and it is not recommended for use in patients older than 75 years or under 60 kg and patients who have previously sustained Transient Ischaemic Attacks or stroke should not take this drug. Ticagrelor is a reversible, oral ADP P2Y12 receptor antagonist that does not need metabolising; it has a short half-life of 12 hours

and thus twice daily dosing is required. It is a potent drug but this benefit comes with an increased risk of bleeding and in a trial comparing Ticagrelor with Clopidogrel, higher rates of dyspnoea were observed in the ticagrelor group.

Abciximab, Eptifibatide and *Tirofiban* are potent antiplatelet agents, which bind to the GP IIb/IIIa receptor and are administered intravenously. Their use has been superseded by the thienopyrodines discussed above, but they remain useful in the acute stage for ACS patients who are clinically unstable or when there is slow flow or no reflow following PCI.

Anticoagulant drugs

Anticoagulation is used to prevent acute thrombus formation at the site of the plaque rupture or to prevent in-stent thrombosis after PCI. ACS patients should receive *Fondaparinux*, low molecular weight heparin (LMWH), *Bivalirudin* or unfractionated heparin (UFH). Newer indirect factor-Xa inhibitors (Fondaparinux) and direct thrombin inhibitors (Bivalirudin) inhibit thrombin mediated platelet activation and are now recommended in national guidance. *LMWH (Enoxaparin)* inhibits factor Xa and anti-thrombin and has a more sustained and predictable anticoagulant effect than UFH. It is administered subcutaneously twice daily and does not require aPTT monitoring. *UFH* exerts a number of effects; action on circulating antithrombin, which inactivates factor IIa, factor IXa and factor Xa. This leads to marked variation in patient response to therapy and monitoring is required with aPTT. High risk ACS patients may be commenced on a direct factor Xa inhibitor within 7 days of the acute event but Rivaroxaban is only currently licensed with Aspirin and Clopidogrel.

Reperfusion therapy

P-PCI provides a mechanical means of enlarging the lumen of the affected coronary artery by the insertion of a balloon-tipped catheter into the affected artery and inflation of the balloon to dilate the arterial lumen in a procedure known as balloon angioplasty. This is followed by deployment of a coronary artery stent and thrombectomy or atherectomy. The efficacy of P-PCI over fibrinolysis (thrombolysis) as the appropriate reperfusion treatment option in ACS is now indisputable. However, in rare circumstances when P-PCI is not immediately available (rural settings where transport times to PCI centres are prolonged), thrombolysis can be used if given within 30 minutes of acute presentation. Thrombolytics convert plasminogen to plasmin, which degrades fibrin and thrombus. Third-generation thrombolytics include *Reteplase* and *Tenecteplase*, both of which have enhanced fibrinolytic potency and can be given by bolus injection enhancing ease of administration. To prevent reocclusion of the infarct-related artery

ancillary anticoagulant therapy such as Fondaparinux, LMWH or UFH should be given. Absolute contraindications to thrombolytic therapy include intracranial haemorrhage, uncontrolled hypertension or recent closed head or facial trauma. Practitioners should check the list of contraindications issued by the drug manufacturers.

Secondary prevention Beta-Blockers, ACE-inhibitors and Statins

Reduction in post-ACS mortality is achieved with the use of beta-blockers, ACE-I and statins.

Beta-blockers should be commenced as soon as possible after the ACS event. Beta-blockers such as *Bisoprolol* block the effect of catecholamines on adrenergic receptors in the myocardium, reducing myocardial contractility and slowing the heart rate. The beneficial effects are to decrease cardiac output, reduce myocardial oxygen demand and increase diastolic filling time hence augmenting coronary blood flow.

Angiotensin-converting enzyme inhibitors (ACE-I) block the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. ACE-I such as *Ramipril* have been shown to reduce mortality and left ventricle (LV) remodelling post ACS. Patients who cannot tolerate ACE-I can be given angiotensin receptor blockers (ARBs).

Statins such as *Atorvastatin* inhibit HMG CoA reductase production in the liver and lower LDL cholesterol. Unless contraindicated, all patients with ACS should take a statin to lower and then maintain a normal LDL cholesterol level.

Administration of an insulin infusion for patients presenting with hyperglycaemia during or immediately following an episode of ACS has been shown to reduce the risk of further cardiac events or death, even in patients not known to have diabetes.

Adherence and side-effects

Most patients with ACS will be taking at least 5 drugs: aspirin, thienopyridine, ACE-I, beta-blocker and statin. The importance of optimal secondary prevention to ensure long-term survival is evident, but the use of 5 drugs poses a challenge for patient adherence. Patients should be encouraged to persevere with all drugs, but also advised of any risks. Patients taking dual-antiplatelet therapy are advised to be vigilant for evidence of bleeding which will not resolve. Patients taking ACE-I should have renal function monitored regularly and patients taking statins should be advised of the possibility of long-term muscle pain. All patients should be referred for cardiac rehabilitation to optimise lifestyle gains. They should be advised and supported with smoking cessation, weight loss and increase in exercise levels if appropriate.

Acute heart failure

Acute heart failure is a life-threatening condition in which the patient experiences rapid onset of the symptoms associated with heart failure. Rapid assessment and treatment is necessary to ensure the comfort and safety of the patient. Several factors are known to trigger acute heart failure, such as acute coronary syndrome and tachyarrhythmia, which usually require additional treatments.

History

Acute heart failure may occur in response to the sudden onset of an acute cardiovascular event, such as acute coronary syndrome, aortic dissection, tachyarrhythmia or pulmonary embolus. However, many patients with chronic heart failure may experience an episode of acute decompensation, precipitated by new onset of infection, arrhythmia or non-adherence to prescribed medications or fluid and dietary salt restrictions.

Signs and symptoms

Paroxysmal nocturnal dyspnoea, orthopnoea, cough, peripheral oedema and weight gain are common symptoms associated with pulmonary congestion, caused by fluid overload. Dizziness, fatigue and confusion are symptoms associated with low cardiac output. Patients with acute heart failure often feel anxious and distressed.

Clinical signs include tachypnoea, hypoxaemia, use of respiratory accessory muscles and bilateral pulmonary crackles on auscultation. Sputum may appear white or pink and frothy. Hypoperfusion may cause hypotension, diaphoresis, cool extremities and oliguria and if associated with a systolic BP < 90 mmHg, cardiogenic shock is diagnosed. Additional signs include narrow pulse pressure, jugular venous distension, congested hepatomegaly and ascites.

In addition, the patient may experience symptoms and signs associated with the precipitating event, such as sepsis, tachyarrhythmia or acute coronary syndrome.

Assessment and investigations

Rapid assessment and history taking is necessary to establish a diagnosis of acute heart failure and to ascertain the cause of the episode. Patients should be closely monitored during the first hour, with regular observations and continuous pulse oximetry, cardiac monitoring and non-invasive haemodynamic monitoring. A record of urine output and fluid balance should be kept. Investigations should include a 12-lead ECG, chest X-ray and echocardiogram to ascertain the extent of cardiac dysfunction and identify the cause. Blood tests should include natriuretic peptides, such as B-type natriuretic peptides (BNP) and NT pro-BNP, cardiac troponin, urea, creatinine and

electrolytes, as well as liver and thyroid function tests and arterial blood gas sampling. Once the patient is stable, their weight should be recorded.

Treatment

Patients with acute heart failure should be treated in a setting that provides close monitoring and rapid access to resuscitation equipment. The patient should be positioned upright in the high Fowler's position and high flow oxygen should be administered if the patient is hypoxaemic. Patients may be frightened and so reassurance is essential. Opiates may be required for patients in considerable distress but should be administered cautiously as bradycardia, hypotension or respiratory depression may result. Anxiolytics may be necessary to treat patients with delirium.

In patients diagnosed with acute heart failure with a systolic BP > 90 mmHg, intravenous diuretics, nitrates and continuous positive airway pressure (CPAP) can relieve pulmonary congestion and improve respiratory function. However, all three interventions should be administered with close monitoring as they could worsen hypotension and precipitate cardiogenic shock. Inotropic support is indicated in patients with severe hypoperfusion in the absence of hypovolaemia. Cautious administration is again necessary as inotropes can cause sinus tachycardia, myocardial ischaemia and arrhythmias. Ultrafiltration is an alternative intervention in patients with an acute exacerbation of chronic heart failure who no longer respond to diuretic therapy. Patients with acute heart failure may develop AF for which thromboembolic prophylaxis and digoxin are appropriate treatments.

Once haemodynamic stability is restored, patients diagnosed with chronic heart failure should be offered a range of treatments and lifestyle advice to minimise recurrence of symptoms, prevent acute exacerbations and optimise quality of life. ACE-Inhibitors (ACE-I) and beta-blockers have been demonstrated to reduce mortality and morbidity and the introduction of aldosterone inhibitors, such as Spironolactone or Eplerenone, also have proven benefits. Diuretics, such as Furosemide, Bumetanide or Metolazone, may be offered to control fluid retention. Recent data has revealed that a new drug, Sacubitril Valsartan, that combines a neprilysin inhibitor and angiotensin receptor blocker (ARB), may be a more effective alternative to an ACE-I in some patients with a reduced ejection fraction. Cardiac resynchronisation therapy, also known as bi-ventricular pacing, may additionally offer some improvement in symptoms for patients with a symptomatic heart failure.

Patients are encouraged to manage their condition themselves through careful monitoring and lifestyle adjustments. They should be advised to strictly limit salt and water intake to reduce weight and fluid

gains. A cardiac rehabilitation programme provides education and support, as well as a supervised exercise programme, which has been shown to improve patients' exercise capacity, reduce hospital admissions and improve quality of life. Many patients frequently experience anxiety and depression for which self-help groups provide support for patients and their carers in learning to live with this long-term condition.

Aortic aneurysm

An aortic aneurysm is a localised dilatation of the thoracic or abdominal aorta resulting from weakening of all three layers of the arterial wall. An aneurysm is diagnosed when the diameter of the aorta is found to have increased by at least 50%. The most significant complications associated with aortic aneurysm are rupture or dissection, resulting in blood loss, hypotension and cardiac arrest.

History

Aortic aneurysms develop when the elastin fibres within the aorta degenerate as a result of ageing, hypertension or specific connective tissue disorders such as Marfan syndrome. Aortic aneurysms affecting the descending thoracic and abdominal aorta are strongly associated with atherosclerosis and cardiovascular risk factors, such as hypertension, dyslipidaemia, smoking and advancing age, which contribute to weakening of the vessel wall. A pseudoaneurysm (false aneurysm) occurs when blood passes from the lumen through a channel within the intima and medial layers and collects within the adventitia.

Signs and symptoms

Patients with aortic aneurysm are frequently asymptomatic. However, symptoms may occur if the aneurysm is large enough to compress adjacent structures, such as the trachea, bronchus or oesophagus resulting in stridor, hoarseness, dyspnoea, cough or dysphagia. Ascending aortic aneurysms may dilate the aortic valve, resulting in the symptoms associated with aortic regurgitation and heart failure. Rupture of an aortic aneurysm may occur with a slow leak or sudden burst, causing hypotension and tachycardia associated with profound blood loss and may result in cardiac arrest.

Assessment and investigations

Patients presenting with a ruptured aortic aneurysm will require rapid assessment and close monitoring prior to transfer for emergency surgery. Thoracic aortic aneurysm is often an incidental finding from investigations such as chest X-ray, echocardiogram, CT scan or MRI. Once identified, a CT scan will enable identification of the exact location and dimensions of the aneurysm, which will be used to guide the management of the patient. An aortogram may also be used to identify which arterial branches of the aorta are affected.

Treatment

Rapid surgical intervention is the only curative option for patients with ruptured aortic aneurysm. In the absence of rupture or dissection, treatment for patients is guided by the diameter of the aorta. The risk

of rupture significantly increases as the aorta widens beyond 6 cm. Open surgical deployment with a prosthetic graft is recommended once the aortic diameter is more than 6 cm or if rupture has occurred. Thoracic Endovascular Aortic Repair (TEVAR) with a stent graft is an increasingly common alternative intervention. Close monitoring and conservative pharmacological blood pressure management to reduce the risk of rupture is recommended for patients with an aortic diameter of less than 6 cm and for those unsuitable for surgical intervention.

Aortic dissection

Aortic dissection occurs when a tear in the intimal layer of the aorta creates a false channel that permits blood flow into the tunica media. Aortic dissection is a life-threatening condition requiring emergency surgical intervention.

History

Thoracic aortic dissection occurs more frequently in men and is associated with advancing age, hypertension, Marfan syndrome and trauma. A classification system is used to specify the region of the aorta affected by the dissection. Stanford Type A dissection affects the ascending thoracic aorta, the most commonly affected region, which may extend to the aortic root, the aortic arch or the descending thoracic aorta. Stanford Type B dissections affect the descending thoracic aorta and may extend to the abdominal aorta.

Signs and symptoms

Aortic dissection is characterised by a 'tearing' or 'ripping' pain located either between the scapulae, associated with a type B dissection, or in the central chest region, suggesting type A dissection. The location of the pain may spread throughout the chest and back or to the abdomen if the dissection extends beyond the thoracic aorta. An array of additional symptoms, such as limb ischaemia and acute kidney injury, may emerge, dependent upon whether major arteries originating from the aorta are affected. For example, the patient may appear confused or with reduced level of consciousness if the left common carotid artery arising from the aortic arch is affected. Tachycardia and hypertension usually occur, initially due to the sympathetic response to pain or reduced renal perfusion, but will deteriorate if reduced myocardial perfusion or cardiac tamponade, associated with a type A dissection, occur.

Assessment and investigations

Rapid, systematic assessment of the patient with suspected aortic dissection is required to aid diagnosis and selection of an appropriate treatment strategy. Cardiovascular assessment should include cardiac monitoring, regular pulse assessment and blood pressure recordings from both arms, which may be different if the dissection originates in the aortic arch. Acute coronary syndrome should be rapidly ruled out using comprehensive chest pain assessment and serial 12-lead ECGs. It should be noted that ST-segment elevation, usually affecting the inferior leads, may be evident if right coronary arterial perfusion is affected in type A aortic dissection. A urinary catheter should be inserted to facilitate accurate fluid balance monitoring. Serum bloods should include full blood count, urea and electrolytes, troponin,

clotting screen and cross-match prior to surgery. A chest X-ray may reveal a widened mediastinum associated with type A dissection; CT, MRI or transoesophageal echocardiogram will confirm the presence of aortic dissection.

Treatment

Preventing progression of the dissection should be prioritised in the management of both type A and type B aortic dissection, by maintaining the patient's systolic blood pressure between 100–120 mmHg with beta-blockers and intravenous vasodilator infusions such as glyceryl trinitrate (GTN). Emergency cardiac surgery is usually necessary for patients with type A dissection to either repair or replace the damaged intimal layer with a prosthetic graft, although research is on-going into the role of Thoracic Endovascular Aortic Repair (TEVAR) to treat dissection. Conservative medical therapy alone may be recommended for patients with type B dissection, unless complications affecting major arterial branches necessitate urgent endovascular stenting or surgical repair.

Aortic regurgitation

Aortic regurgitation (AR) is reflux of blood from the aorta into the left ventricle (LV) across the leaking aortic valve during diastole. This results in pressure and volume overload in the LV, which hypertrophies to accommodate the regurgitation, the stroke volume increases and the major arteries become visibly pulsatile. As the disease progresses LV end diastolic pressure (LVEDP) rises and the increased LV mass becomes increasingly inefficient with reduced coronary perfusion. Increased LVEDP may also cause mitral regurgitation and subsequent left atrial dilatation, increased pulmonary pressure and symptoms of atrial arrhythmias and left ventricular failure (LVF).

History

AR may be caused by chronic untreated hypertension, abnormalities of the aortic valve cusps (bicuspid aortic valve, endocarditis or rheumatic heart disease) or diseases of the aortic root (Marfan syndrome, syphilis, aneurysm or dissection). Chronic AR may develop over many years and during this period the patient may be asymptomatic. It is only when the compensatory mechanisms fail that LV dysfunction leads to a reduction in left ventricular ejection fraction. In acute AR, due to aortic dissection or infective endocarditis, the LV is of normal size and cannot cope with the increased volume. LVF develops rapidly and raised left atrial and pulmonary capillary pressure leads to catastrophic pulmonary oedema.

Signs and symptoms

In chronic AR, the patient may have an awareness of the heart beat or palpitations on exertion, during stress or when lying on the left side. This may also be associated with a pounding sensation in the head. As the disease progresses and LVF ensues, symptoms of dyspnoea, paroxysmal nocturnal dyspnoea, fatigue and weakness will develop. Clinical signs in AR are due to the hyper-dynamic circulation; a large volume or 'collapsing pulse', bounding peripheral pulses, a widened pulse pressure and a displaced heaving apex beat. There may be an early diastolic murmur, a systolic murmur and bilateral inspiratory crackles with pulmonary oedema. Patients may develop angina due to increased LV mass and reduced coronary perfusion. The 12-lead ECG may show LV hypertrophy, left axis deviation and left ventricular strain pattern.

Acute AR presents with a sudden onset of heart failure and reduced cardiac output. Tachycardia, hypotension, cardiovascular collapse and cardiogenic shock all require urgent intervention.

Assessment and investigations

Acute AR requires urgent assessment and treatment of the patient. Airway and respiratory assessment including rate, depth, breathing pattern and peripheral oxygen monitoring should be undertaken.

Heart and breath sounds, pulse, blood pressure and cardiac rhythm should be monitored for cardiogenic shock, atrial and ventricular arrhythmias and evidence of heart failure. A 12-lead ECG may demonstrate LV hypertrophy and myocardial ischaemia; ACS should be excluded. An echocardiogram will confirm AR as the cause of the patient's symptoms and a chest X-ray will evaluate pulmonary oedema and cardiomegaly. Arterial blood gases will be required, venous samples will assess urea and electrolytes (U&Es), full blood count (FBC), troponin, B-type natriuretic peptides (BNP) and glucose levels. Fluid balance and weight should be monitored and fluid restrictions may be required.

Treatment

In the acute phase, patients may need oxygen therapy and treatment with vasodilators and inotropes. In chronic AR, systolic blood pressure is controlled with ACE inhibitors or calcium channel blockers. Timing of aortic valve/root replacement or repair is crucial and may be performed before the patient becomes symptomatic to avoid development of LV dysfunction.

Aortic stenosis

Aortic stenosis (AS) occurs when the leaflets (cusps) of the aortic valve become stiffened. During ventricular systole, the opening of the valve is significantly impeded, reducing stroke volume and eventually resulting in heart failure.

History

The most common cause of AS is age-related sclerosis, which causes the cusps to stiffen and fuse together, preventing the valve from opening fully during left ventricular systole. Early detection of AS is difficult as the patient will not usually experience symptoms until the disease is in the advanced stages, when the valve orifice has been reduced to approximately one-third of its normal size. Less commonly, AS can occur with a congenital bicuspid aortic valve or as a result of streptococcal infection in childhood (rheumatic fever). AS is also known to be a rare form of congenital heart disease.

Signs and symptoms

AS produces a triad of classic clinical symptoms, usually occurring on exertion: dyspnoea, chest pain, pre-syncope or syncope. The patient may experience fatigue as well as other symptoms caused by heart failure, such as ankle swelling and palpitations, which may be due to atrial or ventricular arrhythmias. AS can cause sudden cardiac death.

Clinical signs include a slow rising, low volume pulse and signs associated with heart failure, including jugular venous distension (JVD) and peripheral oedema. On auscultation, AS will produce an ejection systolic murmur and possibly an ejection systolic click; a soft 2nd heart sound, S3 and bilateral (inspiratory/expiratory) crackles associated with pulmonary oedema. The 12-lead ECG may show evidence of left ventricular hypertrophy, atrial enlargement, left anterior fascicular block or left bundle branch block.

Assessment and investigations

Initial assessment of the patient should prioritise baseline observations, continuous cardiac monitoring, chest pain assessment and 12-lead ECG to rapidly rule out acute coronary syndrome as the cause of the symptoms. The patient should be assessed for the signs of heart failure and a chest X-ray and blood samples taken to assess for renal dysfunction, including estimated glomerular filtration rate (eGFR), electrolyte imbalance, full blood count, troponin and B-type natriuretic peptides (BNP). A fluid balance chart should be commenced immediately and the patient may require a urinary catheter. Once stable, the patient should be weighed daily. An echocardiogram will establish the diagnosis of AS and measure the LV ejection fraction.

An angiogram will assess the severity of the AS by measuring the difference in systolic pressure between the left ventricle (LV) and aorta (gradient).

Treatment

The treatment for hypoxia, dyspnoea, chest pain or anxiety should be prioritised initially with bed rest, oxygen therapy, frusemide and morphine, with an anti-emetic if required. Nitrates should be avoided due to the vasodilator effect that can reduce ventricular preload, which would further decrease cardiac output. Electrolyte imbalance should be corrected to prevent possible arrhythmias. The patient should be encouraged to rest to minimise exertion and prevent symptoms. Most patients with symptomatic AS will require surgical intervention urgently. Aortic valve replacement surgery remains the mainstay of treatment but if the patient is unsuitable for surgery, transcutaneous aortic valve implantation (TAVI) is an effective alternative. Conservative management includes avoidance of strenuous exercise and pharmacological therapy including beta-blockers or calcium channel blockers to reduce myocardial work.

Arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) or dysplasia (ARVD) is a rare, inherited form of cardiomyopathy in which heart failure is caused by fibro-fatty replacement of myocytes, predominantly within the right ventricle (RV). The risk of ventricular arrhythmias is increased, principally on exertion and therefore ARVC is a known cause of sudden cardiac death.

History

ARVC is an autosomal dominant inherited condition in which genetic mutation causes damage to the proteins within the desmosome, the bridge that joins myocytes together. As the desmosome weakens, the myocytes separate, allowing deposition of adipose and fibrous tissue, forming scar tissue. This process is thought to accelerate with strenuous exertion. Structural changes to the RV will initially be minimal, usually affecting the inflow, outflow and apical regions. Later, the fibro-fatty tissue may extend to all regions of the RV, causing dilatation and systolic dysfunction. Some patients may eventually develop left ventricular involvement.

Signs and symptoms

The clinical features of ARVC develop over time, although disease progression is variable among patients and some patients remain asymptomatic. Premature ventricular contractions (PVCs), and non-sustained and sustained VT may occur at any stage of the condition; the first presentation may be cardiac arrest, usually following strenuous activity. ARVC should be considered in patients presenting with right ventricular outflow tract (RVOT) tachycardia (left bundle branch block pattern with a rightward mean QRS axis). Patients may also describe symptoms associated with heart failure or syncope.

Assessments and investigations

Approximately 30–50% of patients with ARVC have a family history of the condition. Currently there is no single test to identify AVRC; genetic testing will only be helpful in some cases. International criteria are used to diagnose AVRC using familial, histological, electrocardiographical and structural data. The 12-lead ECG may reveal QRS prolongation or Epsilon waves. Late potentials may be evident on the signal-averaged ECG. 24-hour Holter monitoring and exercise testing should be used to identify the occurrence of ventricular arrhythmias. An echocardiogram may reveal RV dilatation and reduced RV ejection fraction with normal LV function. Invasive diagnostic tests include electrophysiology studies, right ventriculogram and endomyocardial biopsy.

Treatment

The treatment for ARVC aims to prevent the occurrence of life-threatening arrhythmias and to limit the extent of right ventricular systolic dysfunction. Pharmacological therapy includes anti-arrhythmic agents such as beta blockers or amiodarone to prevent arrhythmias. The patient may be offered radio-frequency ablation and an implantable cardioverter defibrillator (ICD) to prevent or treat ventricular arrhythmias. ACE-inhibitors may be prescribed to minimise systolic dysfunction. Close relatives of the patient should be offered genetic counselling prior to screening for ARVC.

Atrial fibrillation

Atrial fibrillation (AF) is a commonly occurring arrhythmia that may result in acute heart failure or stroke. AF occurs when multiple, rapid re-entry circuits cause the atria to fibrillate at a rate of 300–600 bpm. The AV node protects the ventricles by restricting the conduction of impulses through to the ventricles. This results in an irregular, narrow QRS complex arrhythmia with a ventricular rate between 30 and 180 bpm. AF may be paroxysmal or permanent.

History

AF is the most common sustained arrhythmia affecting individuals over 65 years of age and is frequently idiopathic in origin. Reversible causes of AF include hypoxia, chest infections, excess alcohol or caffeine consumption, electrolyte imbalance, emotional stress, fluid overload or drugs that can induce tachycardia, for example Salbutamol. AF can also be caused by acute exacerbation of heart failure and is strongly associated with conditions that dilate the atria, such as mitral valve regurgitation, dilated cardiomyopathy or hypertension. AF commonly occurs after cardiac surgery.

Signs and symptoms

The patient may present with sudden onset of palpitations, dyspnoea, chest pain, fatigue, pre-syncopal or syncopal symptoms, or other signs associated with heart failure. The patient's pulse will be irregular, weak and thready on palpation. The diagnosis will be made from the cardiac monitor, 12-lead ECG or 24-hour tape that will typically show an irregular rhythm at a rate of 30–180 bpm with a normal duration QRS complex (<100 ms) (unless bundle branch block is present). No discernible P waves will be evident, although fibrillatory waves may be visible (Figure 12.1).

AF is associated with a high risk of stroke due to stasis and coagulation of blood within the fibrillating atria. If sustained for more than 48 hours, thrombus formation will occur, particularly within the left atrial appendage from which emboli could be displaced into the systemic circulation. This risk is increased when sinus rhythm is restored.

Assessment and investigations

Initial systematic assessment of a patient with new onset AF should use the ABCDE approach and include a 12-lead ECG. Continuous

Figure 12.1 Atrial fibrillation (AF) as seen in lead II.

cardiac monitoring, regular observations and fluid balance measurements are necessary to monitor for acute deterioration. Establishing the cause of AF should be prioritised. Serum blood tests should be taken to identify electrolyte imbalance and renal dysfunction and record a clotting screen. Individual risk assessment should be conducted using the 'CHA_2DS_2-VASc' score to establish risk of thromboembolism, offset against the risk of bleeding associated with anti-coagulant therapy using the 'HAS-BLED' score.

Treatment

Emergency treatment will be required for the patient who becomes haemodynamically unstable with AF. This will usually be rapid direct current cardioversion (DCCV) unless the ventricular response is very slow, in which case the patient will require transcutaneous pacing. Beta-blockers or calcium channel blockers are suitable drug treatments to slow the ventricular response rate in fast AF; Digoxin is preferred in patients with heart failure. Amiodarone is recommended where cardioversion is sought, for example post-cardiac surgery. Elective DCCV, radio-frequency and cryoablation are therapeutic options if AF persists.

Anti-coagulation should be considered for all patients with paroxysmal or permanent AF, to reduce the risk of thromboembolic complications such as stroke. During the acute phase, anti-thrombin therapy, such as low molecular weight heparin, should be initiated and continued until therapeutic levels of anti-coagulation are established. Warfarin may be prescribed for this or, alternatively, a non-vitamin K oral anticoagulant (NOAC), such as Rivaroxaban, may be suitable, although not recommended for patients with AF caused by valve disease. Aspirin does not protect against the thromboembolic risk and is therefore not recommended.

Atrial flutter

Atrial flutter is a relatively uncommon arrhythmia that may result in acute heart failure or stroke. Atrial flutter occurs when an ectopic atrial site, usually close to the atrio-ventricular (AV) node, generates regular impulses at a rate of 300/min. The rhythm is the result of either increased automaticity or a rapid macro re-entry circuit in the atria. The atrial flutter completely suppresses the activity of the sino-atrial (SA) node. The ectopic atrial pacemaker fires rapidly and the series of atrial impulses create a waveform with a characteristic saw-tooth appearance called an F wave. The AV node will have a decremental effect on the rapid F wave rate, blocking conduction to the ventricles in a ratio of 2:1, 3:1 or 4:1. This results in a narrow, complex, regular rhythm of 150, 100 or 75 bpm respectively. There may also be variable conduction through the AV node, resulting in an irregular QRS rate. Atrial flutter may be paroxysmal or permanent.

History

Atrial flutter, whilst relatively rare, has many reversible causes including hypoxia, chest infections, excess alcohol or caffeine consumption, electrolyte imbalance, emotional stress, fluid overload or use of drugs that can induce tachycardia, for example Salbutamol. Atrial flutter can occur during acute heart failure and is strongly associated with conditions that dilate the atria, such as mitral valve regurgitation, dilated cardiomyopathy or hypertension. Atrial flutter commonly occurs after cardiac surgery.

Signs and symptoms

A patient with an acute onset of atrial flutter may present in a collapsed state with signs of shock, particularly if the conduction rate is 2:1 or if the patient has pre-existing ventricular dysfunction. A sudden onset of atrial flutter may cause palpitations, anxiety, dyspnoea, chest pain and syncope or signs of heart failure. Atrial dysfunction results in blood stasis and the potential for atrial thrombus, which may embolise resulting in pulmonary embolus or stroke. The diagnosis will be made from the ECG, which will typically show a regular, narrow complex QRS with the characteristic saw-tooth flutter waves known as F waves (Figure 13.1). In Lead II, a typical F wave has an inverted negative deflection reflecting abnormal atrial depolarisation followed by a positive F wave deflection reflecting atrial repolarisation.

Assessment and investigations

Initial systematic assessment of a patient with new onset atrial flutter should use the ABCDE approach and include a 12-lead ECG and SpO_2 monitoring. Continuous cardiac monitoring, regular vital signs and

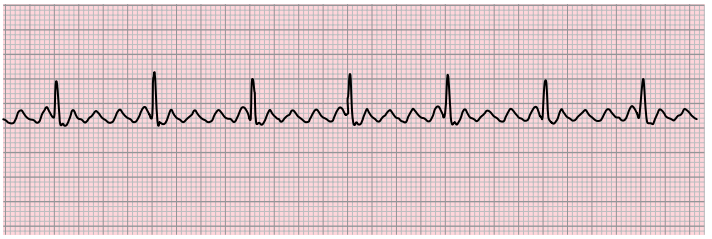

Figure 13.1 Atrial flutter.

fluid balance measurements are necessary to monitor for acute deterioration. Serum blood tests should be taken to identify electrolyte imbalance, renal dysfunction and to record a clotting screen. The risks of thromboembolism offset against the risk of bleeding associated with anti-coagulant therapy should be assessed using 'CHA_2DS_2-VASc' and 'HAS-BLED' risk scores. Sudden resumption of sinus rhythm increases the risk of stroke.

Treatment

The treatment depends on the haemodynamic consequences of the arrhythmia. A ventricular rate of 150 bpm will often cause rapid collapse and deterioration in most patients. Emergency treatment is directed to restoring sinus rhythm using direct current (DC) cardioversion. If the patient has a ventricular rate of less than 150 bpm and is not haemodynamically compromised, acute pharmacological cardioversion using class 1c (flecainide) or class III (Sotalol or Amiodarone) antiarrhythmic drugs can be used. Patients who have been in atrial flutter longer than 48 hours should be anticoagulated and cardioversion delayed until the thromboembolic risk has reduced. Recurrent atrial flutter can be prevented by Sotalol or Amiodarone to control the ventricular rate, although the treatment of choice for recurrence is catheter ablation to permanently interrupt the atrial re-entry circuit.

B

Brugada syndrome

Brugada syndrome is an autosomal dominant ion-channelopathy, which occurs in structurally normal hearts. The condition may only manifest when the patient presents with an aborted sudden cardiac death, but pre-morbid symptoms may include syncope, palpitations and seizures. The most common cardiac arrhythmia is polymorphic ventricular tachycardia (VT), which may deteriorate to ventricular fibrillation. It is a leading cause of sudden cardiac death in healthy individuals.

History

The syndrome was first described in 1992, by the Brugada brothers, as a distinct clinical and electrocardiographic syndrome following investigation of eight patients who had survived an out-of-hospital cardiac arrest and who were found to have characteristic ECG abnormalities. This was subsequently linked to a high incidence of sudden cardiac deaths in the Philippines and Thailand, where syndromes had been respectively described as 'bangungut' (to rise and scream in the night) and 'lai tai' (death during sleeping). In 1998, the mutation of the sodium channel gene 5A (SCN5A) was identified and the hereditary nature of the syndrome was confirmed.

Signs and symptoms

There is a wide phenotype variation and some patients may be asymptomatic and only diagnosed on routine 12-lead ECG examination. Some patients may suffer with palpitations and syncope; the underlying arrhythmia is polymorphic VT. Many patients die during sleep and death may be preceded by chest pain, seizures, loss of bladder control and laboured breathing. The first arrhythmic events tend to occur around 40 years of age, but may occur between 1 and 70 years.

Assessment and investigations

The diagnosis is aided by patient and family history, electrocardiogram and genetic testing. Patients are normally fit and healthy and hence physical examination will be normal. The 12-lead ECG presentation is characterised by down-sloping ST-segment elevation in V_1–V_3 with a right bundle branch block pattern (Figure 14.1). In patients with a 'concealed form' of Brugada Syndrome, the ECG pattern or arrhythmia may only be revealed after provocation during an electrophysiological study, a VT stimulation study or the administration of Ajmaline. Genetic testing may identify the SCN5A gene and help in predictive testing for other family members.

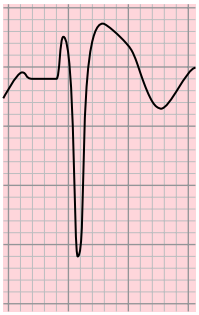

Figure 14.1 Brugada Sign: down-sloping ST elevation with right bundle branch block pattern (V_1).

Treatment

Anti-arrhythmic drug therapy is not useful in Brugada syndrome and the only effective treatment is implantation of an internal implantable cardioverter defibrillator (ICD). Genetic testing and counselling is essential for any family members affected.

C

Cardiac arrest

Cardiac arrest is defined as sudden cessation of effective systemic blood flow due to failure of cardiac contraction. It is rapidly accompanied by absent respiratory effort and loss of consciousness. If not treated, death will occur within minutes.

History

Most sudden unexpected deaths are due to cardiac arrest, which is preceded by cardiac symptom onset. The underlying arrhythmias are ventricular fibrillation or ventricular tachycardia; rarely the presentation may be extreme bradycardia or asystole. Cardiac arrest is usually caused by underlying cardiac conditions such as acute coronary syndrome, aneurysm, cardiomyopathy, electrophysiological abnormalities, infective heart disease or valvular heart disease. Other causes include pulmonary embolism, cerebral or subarachnoid haemorrhage, electrolyte or metabolic disturbances.

Assessment

Ensure it is safe to approach the patient and assess responsiveness by shaking him and shouting in his ear. Open the patient's airway by placing the patient on his back, flexing the neck and extending the head using the 'head tilt – chin lift' method. Rapidly check (no more than 10 seconds) if the patient is breathing by looking for chest movement, listening at the mouth for breath sounds and feeling for air on your cheek. At the same time, check for presence of the carotid pulse. If the patient is unresponsive and there are no other signs of life, help should be sought and basic life support commenced. Apply personal protective clothing as soon as possible and especially if the patient has a known infective condition.

Treatment

The Resuscitation Council (UK) guidance was issued in 2015 and is approved by the National Institute of Health and Care Excellence. The 'Chain of Survival' (Figure 15.1) includes early recognition of warning signs, early activation of emergency services, early basic life support including cardiopulmonary resuscitation (CPR), early defibrillation and early Advanced Cardiac Life Support (ACLS). When a patient is found to be in cardiac arrest, the in-hospital resuscitation team or emergency services should be summoned immediately.

CPR should be commenced, in cycles of 30 regular chest compressions, at a rate of 100–120/min, depressing the sternum by 5–6 cm, followed by 2 effective breaths. As soon as possible, the

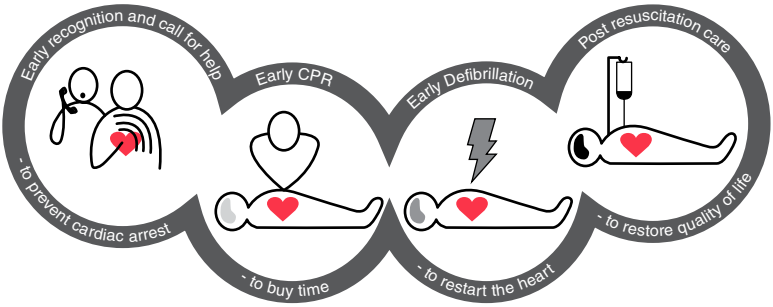

Figure 15.1 The Chain of Survival.

patient should be attached to a defibrillator/monitor to assess cardiac rhythm. If the patient has a 'shockable rhythm' (ventricular tachycardia or ventricular fibrillation) an unsynchronised shock of 150–200 J biphasic (360 J monophasic) should be delivered followed immediately by 2 minutes of CPR. If the patient remains in ventricular tachycardia/ventricular fibrillation (VT/VF), this cycle of CPR and shocks should be repeated. Amiodarone should be administered after the third shock. If the patient has a 'non-shockable rhythm', i.e. asystole or pulseless electrical activity (PEA), continuous CPR should be administered and the rhythm reassessed every 2 minutes.

Vascular access should be established promptly to facilitate administration of adrenaline every 3–5 minutes. Oxygen delivery should be maintained, although the patient's airway may need to be secured using endotracheal intubation or a supraglottic airway.

Treatable causes should be considered using the 4 'H's' (Hypoxia, Hypovolaemia, Hyper/Hypokalaemia and Hypothermia) and 4 'T's' (Thromboembolism, Tension Pneumothorax, Tamponade and Toxins). Percutaneous coronary intervention should be expedited for cardiac causes, even if the patient remains in cardiac arrest.

On return of spontaneous circulation, the patient should be systematically assessed and closely monitored using the ABCDE approach and a 12-lead ECG recorded. Patients may require ventilator support, necessitating transfer to an intensive care setting. Targeted temperature management may be implemented, although this remains disputable.

Cardiac arrhythmias: treatment and interventions

Cardiac arrhythmias can be treated using a variety of medications and devices that can control the rate of the rhythm, address the underlying cause of the arrhythmia or return the heart to a stable rhythm.

Mechanisms of arrhythmias

Anti-arrhythmic drugs are used to treat cardiac arrhythmias that are caused by three mechanisms affecting the action potential of cardiac myocytes: enhanced automaticity, triggered activity and re-entry.

Enhanced automaticity refers to the accelerated activation of depolarisation that can occur in both pacemaker cells and cardiac myocytes at the end of phase 4 of the action potential. Sinus tachycardia can occur when adrenaline enhances the normal automaticity of the sino-atrial (SA) node. Cardiac disease, drugs and low potassium levels may accelerate depolarisation of cardiac myocytes, referred to as enhanced abnormal automaticity.

Triggered activity can occur when the action potential of cardiac myocytes fails to return to the resting membrane potential of –90 mV during phase 3. Early or delayed after-depolarisations can occur when the transmembrane potential oscillates around the threshold potential of approximately –70 mV. Myocardial damage can cause early after-depolarisations that initiate ventricular arrhythmias, including Torsades de Pointes.

Re-entry mechanisms can cause tachyarrhythmias when an ectopic beat causes activation of two pathways within a ring of tissue: one that is refractory, as it has recently depolarised and is slow to repolarise (α), and another pathway that is slow to depolarise (β) but is ready to be activated due to fast repolarisation. If the ectopic beat is conducted slowly down the β pathway, the α pathway may be ready to be activated, conducting the impulse back up to the tissue above. This re-entry circuit results in a circus movement tachycardia, such as supraventricular tachycardia (SVT) or ventricular tachycardia (VT).

Anti-arrhythmic drugs

Anti-arrhythmic drugs modify cardiac conduction and are categorised within the Vaughan Williams classification based on their primary effect on the cardiac action potential. As well as treating arrhythmias, these drugs can be pro-arrhythmic and reduce ventricular contractility and therefore must be administered with caution.

Class I

Class I anti-arrhythmic drugs reduce the rate of sodium entry into the cell during depolarisation (phase 0) to prevent tachyarrhythmias. Drugs in this class should not be offered to patients with structural heart

disease, as they are associated with increased mortality. Administration of these drugs is usually initiated under close cardiac monitoring in a hospital setting:

Class I drugs are further stratified into 3 subtypes:

- Class Ia drugs, such as disopyramide, additionally prolong the refractory period of the action potential, increasing the QT interval.
- Class Ib drugs, such as Lidocaine, shorten the refractory period and have no effect on the QT interval.
- Class Ic agents, such as Flecainide, have minimal effect on the refractory period but severely depress sodium entry into the cell.

Class II

Beta-blockers, or β-adrenergic receptor antagonists, are categorised as Class II anti-arrhythmic drugs. Beta-blockers limit the effect of catecholamines in phase 4 of the cardiac action potential, particularly affecting nodal tissue. Cardioselective beta-blockers include Metoprolol and Bisoprolol. Beta-blockers are effective for ventricular rate control in patients with fast atrial fibrillation due to their depressant effect on atrio-ventricular (AV) nodal conduction. However, they may also cause hypotension, as well as numerous other side-effects such as fatigue, and are not recommended for use in patients with asthma or chronic obstructive pulmonary disease (COPD).

Class III

Class III anti-arrhythmic drugs slow the re-entry of potassium into the cell during phase 3 of the action potential, resulting in prolongation of the refractory period and hence the QT interval. Sotalol and Amiodarone are considered to be 'mixed class', as Sotalol is also a beta-blocker, and amiodarone additionally affects the sodium and calcium channels. Amiodarone is indicated for both atrial and ventricular arrhythmias, even in patients with structural heart disease. However, it is associated with numerous serious side-effects that include pulmonary fibrosis.

Class IV

Class IV anti-arrhythmic drugs are the non-dihydropyridine calcium channel blockers (CCBs), such as Verapamil. These drugs prolong the refractory period of the AV node and reduce myocardial contractility, by slowing the influx of calcium into the cell during phase 2 of the action potential. CCBs may be suitable for patients with atrial arrhythmias and SVTs, although due to their negative inotropic effect, they may cause hypotension and should consequently be administered with caution.

Other drug treatments for arrhythmias

Certain drugs used to treat arrhythmias, such as Digoxin, Adenosine and Isoprenaline are not included this classification, as they do not affect the cardiac action potential.

Digoxin will reduce the ventricular rate in atrial arrhythmias and is often indicated in patients with atrial fibrillation and heart failure. Adenosine causes rapid, transient blockade of the AV node that is useful for treating patients with SVTs caused by re-entry mechanisms. Isoprenaline is a beta-adrenergic receptor agonist administered to increase the rate of depolarisation of the SA node.

Anti-coagulation, using Warfarin or a non-vitamin K oral anti-coagulant (NOAC), such as Rivaroxaban, may be indicated for stroke prevention in patients with atrial arrhythmias.

Therapeutic procedures for cardiac arrhythmias

A range of therapeutic procedures is available to treat patients who experience symptoms associated with cardiac arrhythmias.

Pacing

Cardiac pacing is primarily used to augment cardiac output by increasing heart rate in patients experiencing symptomatic bradyarrhythmia. When the patient is haemodynamically compromised, emergency cardiac pacing can be delivered using transcutaneous pacing controlled by an Automated External Defibrillator (AED) or via a transvenous pacing wire advanced into the right ventricle and connected to an external pulse generator. Epicardial pacing may be suitable for patients immediately following cardiac surgery.

When a permanent pacemaker is required, a small device is inserted into a subpectoral pocket, with one or two electrodes advanced into the right atrium and/or right ventricle to deliver single or dual chamber pacing. The pacemaker is capable of sensing underlying cardiac activity and delivering a small electrical current to trigger depolarisation when required to maintain a safe heart rate. Many permanent pacemakers are rate-responsive to facilitate adjustment of the patient's heart rate based on their level of exertion. Recent advances in technology have led to the development of wireless pacemakers.

Synchronised direct current cardioversion

Patients who become severely haemodynamically unstable due to the sudden onset of tachyarrhythmias may require synchronised direct current cardioversion (DCCV) to restore sinus rhythm. This involves a transthoracic electric shock that is timed by the defibrillator to coincide with the QRS complex, to avoid delivering the shock during ventricular repolarisation (T wave), which can induce the 'R on T' phenomenon that can trigger Torsades de Pointes or ventricular fibrillation. Cardioversion should be conducted while the patient is under sedation with appropriate airway management.

Catheter ablation

Radio-frequency ablation and cryoablation are invasive percutaneous interventions used for symptomatic tachyarrhythmias. The origin of the

arrhythmia must first be established before a catheter is advanced via the femoral circulation to the site where radiofrequency waves or cryotherapy is delivered to destroy the tissue that triggers the arrhythmia. This treatment is particularly useful for arrhythmias caused by a re-entry mechanism such as A-V re-entry tachycardia (AVRT), A-V nodal re-entry tachycardia (AVNRT) and atrial flutter. Ablation may also be administered during cardiac surgery, particularly for atrial fibrillation.

Implantable Cardioverter Defibrillators (ICDs)

Implantable Cardioverter Defibrillators (ICDs) may be offered to patients who have life-threatening ventricular arrhythmias. A small device is implanted in a sub-pectoral pocket, from which electrodes are advanced into the right atrium and right ventricle. The ICD has the same capabilities as a permanent pacemaker, but in addition can detect and respond to tachyarrhythmias. The response is individually programmed within each ICD, usually involving initial anti-tachycardia pacing followed by a series of electrical shocks until sinus rhythm is restored. This may be extremely uncomfortable for the patient, who may lose consciousness during the event.

Cardiac resynchronisation therapy (CRT)

Cardiac resynchronisation therapy (CRT) may be offered to patients with advanced heart failure to optimise left ventricular function. CRT-P refers to the use of biventricular pacing that requires placement of three electrodes. The right atrial and ventricular electrodes facilitate dual chamber, rate-responsive pacing. An additional electrode activates the left ventricle from its position in the coronary sinus, accessed via the right atrium. Stimulation and depolarisation of the three chambers is individually timed to optimise ventricular diastolic and systolic function. A defibrillator function may be added to the device for patients at risk of VT associated with heart failure (CRT-D).

Cardiogenic shock

Cardiogenic shock is a severe form of acute heart failure, diagnosed when the patient shows signs of organ hypoperfusion, such as cyanosis, confusion and oliguria, in the absence of hypovolaemia, with a systolic blood pressure below 90 mmHg.

History

Cardiogenic shock usually occurs immediately following an acute cardiovascular event, such as acute coronary syndrome (ACS), tachyarrhythmia, myocarditis, thoracic aortic dissection or pulmonary embolus.

Signs and symptoms

Patients in cardiogenic shock present with symptoms associated with acute heart failure, including severe dyspnoea, ankle swelling and reduced level of consciousness. Peripheral and central pulse assessment will usually reveal tachycardia and jugular venous distension. Systolic blood pressure will be less than 90 mmHg; pulse pressure and mean arterial pressure are likely to be low, indicating reduced stroke volume and poor organ perfusion. Cardiorespiratory auscultation may reveal pulmonary crackles and third and fourth heart sounds. Signs of peripheral and central cyanosis may be present, such as cool, clammy skin that is mottled in appearance. Peripheral oedema is highly likely to be present.

Assessment and investigations

Patients with suspected cardiogenic shock should undergo rapid assessment and should be cared for in a high dependency environment. Observations should include assessment of airway, respiratory rate, depth and use of accessory muscles alongside continuous pulse oximetry. The patient should be commenced on continuous 3-, 5- or 12-lead cardiac monitoring. Insertion of an arterial line will provide continuous mean arterial pressure monitoring and permit regular arterial blood gas analysis. Central venous cannulation is useful for both invasive haemodynamic monitoring and inotropic drug administration. An echocardiogram should be conducted to establish the extent of ventricular dysfunction. A urinary catheter should be inserted and fluid balance closely monitored. A blood glucose level should be recorded and serum blood samples taken for natriuretic peptides, troponins, urea and electrolytes, lactate, C-reactive protein (CRP), D-dimer, liver function and thyroid function tests, full blood count and a clotting screen. A 12-lead ECG should be recorded promptly to rule out ACS as the cause of cardiogenic shock. If ACS is suspected, patients should have immediate coronary angiography, followed by primary percutaneous coronary intervention (PCI), if indicated.

Treatment

The aim of treatment for patients in cardiogenic shock is to improve organ perfusion by improving cardiac output and blood pressure. Administration of intravenous inotropes such as Dobutamine, and vasopressors such as Norepinephrine, may improve mean arterial pressure but will also induce tachycardia, which may prove detrimental. These drugs may be combined if there is insufficient response or insertion of an intra-aortic balloon pump may provide an alternative means of improving organ perfusion. Mechanical devices, such as the left ventricular assist device, can provide a bridge to cardiac transplantation or provide symptomatic relief for patients with end-stage heart failure.

D

Dilated cardiomyopathy

Dilated cardiomyopathy (DCM) refers to a spectrum of myocardial disorders resulting in ventricular dilatation and systolic impairment. DCM is the most common type of cardiomyopathy and causes significant morbidity and mortality; DCM is a major cause of sudden cardiac death and is also the most frequent cause of heart failure.

History

There are multiple aetiologies for DCM including idiopathic, familial (genetic), viral, toxic, alcoholic or ischaemic. Familial (genetic) DCM is caused by mutations in the structural proteins which comprise the cardiac myocytes. Ischaemic DCM is the result of the remodelling process of the left ventricle in response to injury, with a consequent reduction in ejection fraction. Toxins, such as anti-cancer therapies (anthracyclines), alcohol and infections (viral, bacterial, fungal or parasitic) are also implicated in damage to the contractile processes in the heart. Autoimmune and infiltrative causes, such as systemic lupus erythematosus or amyloidosis, are rare. Pathologically, there is an increase in myocardial mass and a reduction in ventricular wall thickness. The heart becomes globular in shape with diffuse ventricular dilatation, atrial enlargement, thrombus formation in the atrial appendages and development of an intraventricular conduction delay.

Signs and symptoms

Patients with DCM may present with symptoms of heart failure, arrhythmias, conduction defects (bundle branch blocks), thromboembolism or sudden death. Common features are fatigue, breathlessness, chest pain, palpitations and fluid overload. Syncope or palpitations at rest are worrying symptoms as they may predict sudden cardiac death. Onset of symptoms may be slow and insidious or sudden and acute, dependent on the aetiology. Mitral regurgitation is a common feature in DCM and patients may present with a left ventricular heave and a pan-systolic murmur on auscultation.

Assessment and investigations

Careful history taking is essential to establish the aetiology and to identify reversible and secondary causes. Risk factors, such as excessive use of alcohol, past medical history of cancer or recent febrile events, may point to the aetiology. Patients with high risk symptoms, such as syncope or palpitations on exertion, should be treated with a high index of suspicion.

Vital signs should be carried out to evaluate the temperature (infectious causes), heart rate and rhythm (atrial and ventricular arrhythmias), respiratory rate and oxygen saturation (heart failure). Physical examination will include palpation of the heart for apical thrill, left ventricular heave and auscultation of the heart for evidence of mitral regurgitation. A 12-lead ECG should be performed and may reveal widespread T wave and ST-segment changes, arrhythmias (ventricular arrhythmias are common), conduction defects, particularly right bundle branch block (RBBB) or left bundle branch block (LBBB). Continuous monitoring should be commenced to monitor for these abnormalities.

Echocardiography is the cornerstone of diagnosis and will assess ventricular size and function and valvular impairment. Regular echocardiography is utilised to guide and evaluate efficacy of management. Coronary angiography should be undertaken to exclude coronary artery disease. Chest X-ray will demonstrate global dilatation of the heart and may show pulmonary oedema in heart failure.

Treatment

Initial evaluations are tailored to finding the cause, thereafter treatment is aimed at optimising cardiac function. Patients in heart failure are treated with beta-blockers, ACE inhibitors and diuretics. In patients with New York Heart Association (NYHA) III/IV heart failure, cardiac resynchronisation therapy and implantable cardioverter defibrillator (ICDs) are appropriate. In some cases, cardiac transplantation may be a suitable treatment option.

H

Heart blocks

Atrio-ventricular (AV) blocks, commonly referred to as heart blocks, are bradyarrhythmias resulting from AV nodal dysfunction. Interference with AV nodal conduction results in several forms of block, which may cause haemodynamic instability.

History

Heart blocks may be transient or permanent. They can arise from degenerative disease affecting the AV node associated with advancing age or from administration of pharmaceutical agents such as beta-blockers, calcium channel blockers, Digoxin and Amiodarone. Vasovagal episodes, myocardial ischaemia, inflammation or trauma resulting from cardiac surgery, such as transcutaneous aortic valve implantation (TAVI) or valve replacement, may also induce heart block.

Signs and symptoms

Patients may be asymptomatic with heart block, although bradycardia may cause fatigue, dyspnoea, pre-syncope, syncopal symptoms on exertion and hypotension. Assessment of the patient's ECG is necessary to identify and differentiate heart block.

- **1st degree AV block** (Figure 19.1): characterised by PR interval prolongation (>200 ms). QRS duration will be normal. The patient's pulse will be regular, but the rate may be normal or < 60 bpm.
- **2nd degree AV block Mobitz Type I (Wenckebach)** (Figure 19.2): characterised by progressive prolongation of the PR interval and intermittent loss of QRS complex. Pulse and ventricular rate will be irregular and usually < 60 bpm.
- **2nd degree AV Block Mobitz Type II** (Figure 19.3): characterised by a PR interval that is fixed, and often normal, and sudden loss of QRS complex.
- 2:1 block is characterised by an alternating pattern of P, QRS and T followed by a P wave which is not conducted.
- **3rd degree (complete) AV Block** (Figure 19.4): characterised by dissociated atrial and ventricular rhythms. The SA node gives rise to the regular atrial rhythm, which bears no correlation to the ventricular rhythm, which will either be a regular, normal QRS (<100 ms) rhythm at a rate of 40–60 bpm (junctional escape rhythm); or a regular, wide QRS (>100 ms) rhythm at a rate of 20–40 bpm (ventricular escape rhythm).

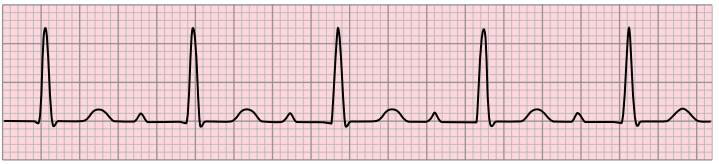

Figure 19.1 1st degree AV block.

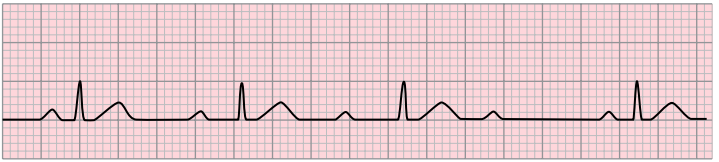

Figure 19.2 2nd degree AV block Mobitz Type I (Wenckebach).

Figure 19.3 2nd degree AV block Mobitz Type II.

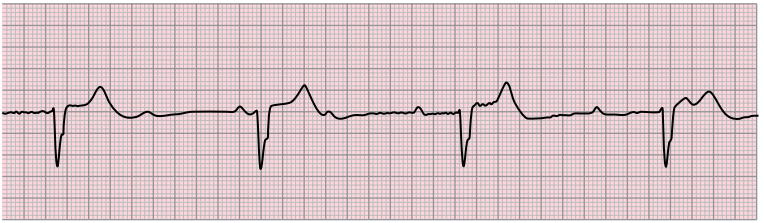

Figure 19.4 3rd degree (complete) AV block.

Assessment and investigations

Patients should be closely monitored for signs of haemodynamic compromise, including respiratory assessment, pulse, blood pressure and urine output. A 12-lead ECG should be recorded to rule out ischaemia as the cause and a history taken from the patient to establish any reversible cause of heart block.

Treatment

Patients who are tolerating heart block well should be closely monitored for signs of haemodynamic instability but may not require immediate intervention. Any reversible cause should be addressed immediately. Emergency treatment will be necessary if the patient shows signs of haemodynamic instability, usually associated with 3rd degree (complete) AV block. Atropine may be effective, particularly during vasovagal episodes, as it transiently inhibits the effect of the vagus nerve on the nodal tissue, but will be short-acting. Emergency transcutaneous pacing can rapidly augment cardiac output by increasing heart rate. However, it is likely to be very uncomfortable for the patient, hence opiate analgesia and/or sedation may be required. Insertion of a temporary transvenous pacing wire will be necessary if the bradyarrhythmia persists. Epicardial pacing may be a suitable alternative for the patient immediately following cardiac surgery. The patient may require a permanent pacemaker if the arrhythmia persists due to an irreversible cause.

Hypertension

Hypertension is known to cause coronary heart disease, stroke, heart failure, chronic kidney disease and peripheral vascular disease. It is defined as the level at which blood pressure (BP) could cause organ damage, currently established as 140/90 mmHg and 150/90 mmHg for patients over 80 years of age. Diagnosis should be made from a series of BP recordings and for treatment purposes is classified as stage 1 (>140/90 mmHg); stage 2 (>160/100 mmHg) and severe hypertension (systolic > 180 mmHg, diastolic > 110 mmHg).

History

The prevalence of hypertension is known to increase with age, although the exact cause cannot be identified in the majority of patients. Family history, insulin resistance, obesity and diabetes are strongly associated with elevated BP. Occasionally, a cause may be identified such as chronic kidney disease, thyroid or endocrine dysfunction.

Signs and symptoms

Patients with hypertension are often asymptomatic, although symptoms may manifest as a result of ensuing organ damage, such as coronary heart disease, stroke or kidney disease.

Assessment and investigations

BP should be recorded from the brachial artery when the patient is resting using either an automated device or, if the patient has an irregular rhythm, a manual sphygmomanometer and stethoscope. If the BP is found to exceed 140/90 mmHg, recordings should be taken on both arms and repeated during the consultation. The diagnosis should be made following ambulatory or home monitoring over the course of several days.

Patients diagnosed with hypertension should have their 10-year cardiovascular risk calculated as well as blood tests to establish creatinine, estimated glomerular filtration rate (eGFR), electrolytes, glucose, total cholesterol and HDL levels. A urine sample should be tested for protein, haematuria and albumin:creatinine ratio. A 12-lead ECG should be recorded and scrutinised for evidence of damage associated with chronic hypertension, such as left ventricular hypertrophy or left bundle branch block. An echocardiogram may be indicated for further investigation. Hypertension may cause retinopathy and hence the fundi should also be examined.

Treatment

Lifestyle modification is an essential element of treatment. Patients should be advised to take regular exercise and increase their dietary intake of fresh fruit and vegetables and reduce salt, saturated fat and

alcohol intake. Cardiovascular risk factors, such as hyperlipidaemia, diabetes, lack of physical exercise and smoking should also be addressed.

Pharmacological therapy is indicated for all patients with stage 2 hypertension or stage 1 hypertension associated with diabetes, renal or cardiovascular disease, evidence of organ damage or a 10-year cardiovascular risk of ≥20%. Patients under the age of 55 years should be offered a once daily ACE-Inhibitor or angiotensin receptor blocker. Older patients, and those of African or Caribbean descent, should be offered a calcium channel blocker. If the response is inadequate, these treatments may be combined or supplemented with a diuretic. Specialist review may be necessary, particularly if the patient is under 40 years of age or has resistant hypertension.

If severe hypertension is found, the patient should be referred to hospital for urgent specialist review. Gradual reduction of BP over 1–2 days using oral medications such as a calcium channel blocker is necessary to avoid the risk of cerebral, renal or cardiac ischaemia, unless a specific indication, such as aortic dissection, demands more rapid BP reduction with intravenous beta-blockers or glyceryl trinitrate (GTN).

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is the most common inherited cardiac disease and is the leading cause of sudden cardiac death in people under the age of 35 years in the UK. A genetic mutation results in thickened myocardium, which reduces the filling capacity of the left ventricle, inhibiting wall compliance and diastolic function, though the heart size remains normal. Syncope or pre-syncope, chest pain, heart failure and life-threatening arrhythmias may occur on exertion, although many patients remain asymptomatic and subsequently unaware of the condition.

History

HCM is caused by a genetic mutation responsible for the abnormal, chaotic arrangement of myofibrils in the ventricles that can cause arrhythmia. Significantly, this differs from the organised pattern of myofibrils seen in left ventricular hypertrophy (LVH). HCM may be identified through genetic screening of families of individuals who have the condition or who have died from sudden cardiac death. The inheritance is usually autosomal dominant.

Signs and symptoms

Patients are frequently asymptomatic with HCM although diastolic dysfunction may cause dyspnoea and other symptoms associated with heart failure. Patients may experience symptoms associated with myocardial ischaemia due to insufficient oxygenation of the enlarged ventricle, even with normal coronary arteries. Palpitations may occur due to atrial or ventricular arrhythmias. Some patients may have left ventricular outflow tract (LVOT) obstruction caused by the abnormal anterior motion of the mitral valve during systole, which may induce syncope or pre-syncopal symptoms on exertion. The first presentation may be cardiac arrest, caused by ventricular arrhythmias, most often occurring during exertion.

Assessments and investigations

Baseline observations may be normal. However, the 12-lead ECG may show increased QRS amplitude in the precordial leads, with non-specific ST-T abnormalities suggestive of LVH and ‘dagger-like’ Q waves in the inferior and lateral leads associated with septal hypertrophy. Cardiac auscultation may reveal a fourth heart sound or double apical pulsation caused by forceful atrial contraction into a stiffened left ventricle. Obstruction of the LVOT may be evidenced by an ejection systolic murmur heard at the left sternal border. A pansystolic murmur may be present reflecting mitral regurgitation. While the chest X-ray is usually normal in patients with HCM, the echocardiogram will provide diagnostic information. Symmetrical or

asymmetrical hypertrophy of the left ventricle will be seen, along with vigorous left ventricular contraction and the systolic anterior motion of the mitral valve and subsequent regurgitation. Analysis of the family pedigree is useful to establish genetic inheritance and should be used to identify family members who may also have the condition.

Treatment

Avoiding strenuous exercise and competitive sports is strongly advised, as the increased myocardial oxygen demand and subsequent ischaemia may induce life-threatening arrhythmias. Beta blockers are usually prescribed to reduce heart rate, which will enhance diastolic function and limit the occurrence of ventricular ectopic beats. Calcium channel blockers can improve ventricular compliance. Implantable cardioverter defibrillator (ICD) implantation is recommended for prevention of cardiac arrest and some patients with LVOT obstruction may benefit from permanent pacing. Patients experiencing recurrent symptoms may be offered myomectomy or percutaneous alcohol ablation to reduce the obstructive element of the septum. Genetic counselling should be offered to all patients and family members should be screened for the condition, regardless of the presence of symptoms.

I

Infective endocarditis

Infective endocarditis (IE) refers to an infection of the endocardium. The condition is relatively uncommon, but can be deadly with a high mortality and morbidity. The pathological process results from endocardial injury followed by transient or persistent bacteraemia allowing bacterial adherence to the damaged surface. Infected vegetations may develop on the heart valves, which may fragment and embolise. Additionally, the heart valve and its supportive structures may become damaged, necessitating surgical replacement.

History

IE usually occurs in the presence of existing structural heart disease (valvular abnormality, prosthetic valves or congenital heart disease) and is characteristically caused by *Staphylococcus* or *Streptococcus*. It may also be due to fungal infection or as a result of drug abuse, which may cause tricuspid valve endocarditis. IE may present insidiously with the patient giving a history of a 'flu-like' illness for several weeks. Alternatively, patients may present acutely as a result of embolic events, sepsis or heart failure.

Signs and symptoms

Symptoms of IE include night sweats, malaise, weight loss and fever. Some patients may present with acute heart failure, caused by valvular regurgitation. Petechial haemorrhages in the skin, Janeway's lesions on the palm of the hands or soles of the feet, splinter haemorrhages under the nail beds or Osler's nodes, which are painful nodules on fingers or toes, probably due to vasculitis, are all extremely rare and only seen in advanced untreated endocarditis. Many patients will have a murmur on acute presentation due to valvular regurgitation.

Assessment and investigations

Careful history taking is essential to establish the diagnosis as the non-specific symptoms may mislead or confuse. Patients in high risk groups (congenital heart disease, prosthetic heart valves) who present with a fever and new heart murmur should be treated with a high index of suspicion.

Vital signs should be carried out to evaluate the temperature, heart rate and rhythm, respiratory rate and oxygen saturation. Urinalysis may reveal proteinuria or microscopic haematuria. Physical examination will include auscultation of the heart for evidence of heart murmurs. A 12-lead Electrocardiogram (ECG) should be performed and may reveal

conduction defects, particularly AV-blocks or bundle branch block, suggesting development of myocardial abscess. Continuous cardiac monitoring should be commenced to observe for these conduction defects.

Physical examination may identify the features of splinter haemorrhages, Janeway's lesions or Osler's nodes. Blood cultures are a pivotal diagnostic tool and at least three blood samples should be taken at 30-minute intervals using meticulous aseptic techniques. The blood cultures will identify any causative micro-organisms although 30% of IE cases may be culture-negative. Serum blood tests will assess white blood cell count, C-reactive protein and ESR to assess for sepsis severity, urea, electrolytes, and creatinine will assess renal function as glomerulonephritis is common in acute IE.

An Echocardiogram will verify the presence of vegetations on heart valves, a Transoesophageal echocardiogram (TOE) provides better resolution and also enables assessment of structural dysfunction. Echocardiograms will evaluate the progress of the vegetations, assess for valve damage and detect abscess formation.

Treatment

In suspected IE, intravenous antibiotics should be commenced after the blood cultures have been retrieved. The majority of patients will require intravenous antibiotic therapy for 4–6 weeks and approximately 50% of patients require cardiac surgery to replace damaged valves. Patients are usually required to restrict physical activity whilst in hospital and consequently patients may become depressed because of the limitations to their lifestyle. IE is a serious condition with an in-hospital mortality rate of 20% and requires specialist cardiology care.

L

Long QT syndrome

Long QT syndrome (LQTS) is an inherited condition affecting the sodium and potassium ion channels of cardiac myocytes resulting in prolonged ventricular repolarisation. It can be identified on the 12-lead Electrocardiogram (ECG) as a prolonged QTc interval. Patients frequently have no symptoms but, in the event of a critically timed premature ventricular contraction (PVC), may experience the sudden onset of palpitations and syncope associated with torsades de pointes. This may deteriorate into ventricular fibrillation and therefore LQTS can potentially cause sudden death.

History

LQTS may be identified in patients with a history of cardiac events such as syncope. It can be an incidental finding on a 12-lead ECG recording or identified during a genetic screening programme. LQTS is classified by the genetic variations affecting the myocyte ion channels identified so far. The most common forms, LQT1, LQT2 and LQT3, are associated with different triggers for arrhythmia: exercise, emotion and acoustic stimuli, and rest or sleep, respectively.

Hypokalaemia, hypomagnesaemia or hypocalcaemia, bradycardia or acute myocardial infarction may cause QT prolongation, even in patients without LQTS. It can also be brought about by prolonged fasting, liquid protein diets and prescribed pharmacological treatments, such as Methadone, or specific drugs from the following groups: tricyclic anti-depressants, anti-psychotic drugs, anti-fungal agents, macrolide or quinolone antibiotics and anti-arrhythmic drugs.

Signs and symptoms

There are usually no physical signs associated with LQTS. Patients are frequently unaware of the condition until the sudden onset of palpitations and syncope, or possibly sudden death, caused by an episode of torsades de pointes. Torsades de pointes is characterised by an irregular, broad QRS tachyarrhythmia, originating in the ventricles (Figure 23.1) triggered by the occurrence of a PVC during the prolonged period of repolarisation, often referred to as the ‘R on T phenomenon’.

Assessments and investigations

In the absence of arrhythmia, the QT interval can be measured on the 12-lead ECG from the beginning of the QRS complex to the end of the T wave. Broadly speaking, the R-R interval should be less than half

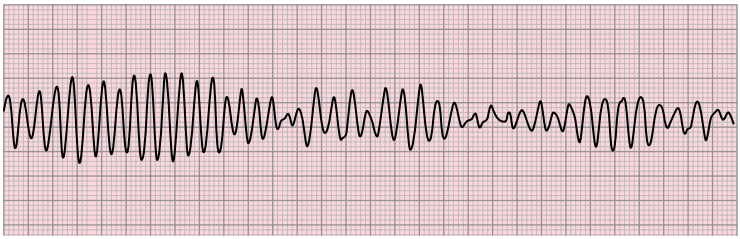

Figure 23.1 Torsades de Pointes.

the QT interval. As the QT interval is inversely proportional to heart rate, the corrected QT interval (QTc) is used for diagnostic purposes, calculated using the equation QT/√R-R interval. The QTc may be considered prolonged if greater than 440 ms in men or 460 ms in women, but often patients with LQTS have a QTc greater than 500 ms. It should be noted that short QT syndrome, another ion channelopathy similar to LQTS and Brugada, is also associated with arrhythmias.

Patients experiencing episodes of torsades de pointes will require close monitoring of respiratory function, pulse, blood pressure and continuous cardiac monitoring. 12-lead ECGs should be recorded in-between spells of the arrhythmia to establish the presence of QT interval prolongation. Previous medical history, including family and drug history, should be taken as well as blood tests, including serum potassium, calcium and magnesium.

Treatment

Torsades de pointes often self-terminates but may deteriorate into ventricular fibrillation, requiring advanced life support. Intravenous magnesium sulphate or isoprenaline may be effective, coupled with correction of electrolyte disturbance. Cardiac pacing may be beneficial to shorten the QT interval to prevent further episodes of torsades de pointes. Possible causative agents should be withheld immediately.

As there is no specific treatment for LQTS, patients are advised to avoid triggers for arrhythmia such as competitive sport, strenuous exercise, emotional distress and drugs that prolong the QT interval. Beta-blockers, cardiac pacing and implantable cardioverter defibrillator (ICD) therapy may be offered to reduce the risk of arrhythmia, although increasingly treatments vary based on the genetic type. Specialist counselling and genetic screening should be offered to the patient and their families.

M

Marfan syndrome

Marfan syndrome is an autosomal dominant genetic abnormality caused by mutation of the FBN-1 gene which encodes for the production of fibrillin, a protein essential for the formation of elastin fibre in connective tissue. Within the body, connective tissue provides scaffolding, anchorage and support for the skeletal, ophthalmic and cardiac systems. Abnormalities in fibrillin-1 cause the tissues to progressively stretch and weaken resulting in the potential for aortic root dissection, aortic regurgitation and mitral valve prolapse. Patients with Marfan syndrome may demonstrate a range of health problems throughout the body.

History

There may be a familial history, but 20–30% of patients present with a new mutation of the gene. Patients may be identified serendipitously when the ophthalmic (dislocation of the lens and myopia) or skeletal abnormalities (joint hypermobility, scoliosis, chest deformity or high arched palate) are identified. Marfan syndrome predominantly affects the mitral and aortic valve due to higher pressure in the left heart. Prolapse of both the mitral and aortic valves is common and may lead to mitral and aortic regurgitation. The aorta may also be affected; aortic root dilatation and dissecting aortic aneurysm are the consequence.

Signs and symptoms

There is a wide phenotype variation and those with milder forms of the disease may never be diagnosed. However, for patients with more severe forms of the condition, serious cardiac abnormality is evident. Sudden cardiac death can occur due to aortic dissection; left ventricular (LV) failure results from mitral regurgitation (MR) or aortic regurgitation. The regurgitant valves cause dilation of the LV and LA chambers predisposing the patient to arrhythmias, particularly atrial fibrillation (AF).

Assessment and investigations

Careful history taking, including familial history of sudden death, is helpful in establishing the diagnosis. Physical examination may uncover the physical features of Marfan syndrome. The Ghent criteria provide a nosology for diagnosis of the syndrome and genetic testing may identify the FBN-1 mutation. Investigations include echocardiogram and magnetic resonance imaging to assess the aortic valve size and

aortic root diameter. A 12-lead ECG may identify AF or LV hypertrophy and cardiac auscultation will reveal a pan-systolic murmur in MR or an early diastolic murmur associated with aortic regurgitation.

Treatment

If Marfan syndrome is diagnosed following genetic testing, yearly follow-up and family screening is recommended. Aortic root dilatation and LV function is measured regularly using echocardiography. Beta-blockers reduce the rate of aortic root dilatation and improve survival, and the angiotensin receptor blocker (ARB) Losartan has been demonstrated to be effective, too. Medical therapy aims for a systolic blood pressure of ≤ 120 mmHg. Prophylactic aortic root and/or ascending aorta graft surgery are undertaken once the aortic root dilates to greater than 5 cm in diameter. Elective repair of aortic dissection is also undertaken to prevent sudden cardiac death. Women with a diameter of ≥ 4.5 mm are advised to avoid pregnancy without prior repair and a Caesarean section delivery may be advised. All patients with Marfan syndrome are advised to avoid exertion at maximum capacity.

Mitral regurgitation

Mitral regurgitation (MR) occurs when the valve cusps fail to fully close during ventricular systole. Leakage of blood through the valve into the left atrium results in reduced stroke volume, atrial dilatation and increased pulmonary capillary pressure, causing symptoms associated with heart failure and, frequently, atrial arrhythmias.

History

Mitral valve prolapse, age related calcification, rheumatic fever, infective endocarditis, aortic stenosis and dilated cardiomyopathy can damage the valve cusps or dilatation of the annulus, causing MR and gradual development of heart failure. The left atrium will dilate to accommodate the additional volume, often causing atrial fibrillation (AF) or flutter. Haemodynamic compensation to maintain systolic function eventually results in left ventricular enlargement. Without intervention, right ventricular (RV) failure will ultimately result from raised pulmonary and RV pressure, RV dilatation and tricuspid valve regurgitation. Acute rupture of the chordae tendineae or papillary muscles will result in severe valvular dysfunction and acute heart failure.

Signs and symptoms

Symptoms of MR arise due to heart failure. Patients may describe weakness, fatigue, breathlessness on exertion, orthopnoea and paroxysmal nocturnal dyspnoea. AF or flutter can arise from left atrial dilatation, which may additionally cause palpitations. The Electrocardiogram (ECG) may show 'p mitrale', indicating left atrial dilatation, and ECG criteria associated with left ventricular chamber enlargement. A pansystolic murmur may be heard on auscultation at the apex, with S3 and gallop rhythm. Bilateral inspiratory/expiratory wheeze and crackles may also be heard, associated with pulmonary oedema. Late signs, such as peripheral oedema, jugular venous distension (JVD) and increased abdominal girth, are associated with RV failure.

Assessment and investigations

Patient assessment should include respiration rate, depth, symmetry, use of accessory muscles and peripheral oxygen saturation levels. Following pulse and blood pressure assessment, cardiac monitoring should be commenced to observe for atrial or ventricular arrhythmias. A 12-lead ECG should be recorded to exclude acute coronary syndrome (ACS) as the cause of heart failure, to identify signs of chamber enlargement and possible myocardial ischaemia. A chest X-ray will identify pulmonary oedema and cardiomegaly if present. An echocardiogram is necessary to confirm MR as the cause of heart

failure. The patient should be examined for signs of peripheral oedema, such as ankle swelling and JVD. Arterial blood gases should be taken as well as venous blood samples for urea and electrolytes (U&Es), full blood count (FBC), troponin, B-type natriuretic peptides (BNP) and glucose levels. A fluid chart should be maintained; a urinary catheter may be required to establish accurate output measurement and patient comfort.

Treatment

If the patient presents with heart failure associated with MR, oxygen therapy, diuretics and nitrates will be required. Morphine may be indicated if the patient is distressed. Supplemental treatment may be necessary for AF or flutter. Once stable, treatment should address the underlying cause where possible and aim to limit disease progression with diuretics and angiotensin-converting-enzyme inhibitors (ACE-I). Surgical repair of the mitral valve or mitral valve replacement will usually be necessary.

Mitral stenosis

Mitral stenosis occurs when calcification and fusion of the cusps reduces the diameter of the open valve. It can occur in patients with a history of rheumatic fever; most remain asymptomatic for several decades until symptoms of dyspnoea emerge. Treatment is dependent upon the severity of the condition, ranging from medical therapy to surgical replacement of the valve and annulus.

History

Mitral stenosis most frequently occurs in patients with a history of rheumatic fever in childhood, although there are other, much rarer causes. The group A β-haemolytic Streptococcus infection causes inflammation, thickening, fusion and calcification of the valvular cusps, which gradually reduces the diameter of the open valve. This limits ventricular diastole and causes a progressive rise in left atrial pressure, resulting in hypertrophy, dilatation and often atrial fibrillation (AF). Pulmonary capillary pressure subsequently increases, leading to pulmonary oedema and eventually pulmonary hypertension. Right ventricular hypertrophy and dilatation will ensue if mitral stenosis is left untreated, eventually causing tricuspid valve regurgitation.

Signs and symptoms

Patients typically experience symptoms once the valve opening has diminished from approximately 5 cm^2 to 2 cm^2, usually decades after the initial infection. The most common symptom is dyspnoea, often coupled with a cough and frothy, blood-tinged sputum associated with pulmonary oedema, caused by the raised left atrial pressure. The severity of these symptoms may worsen with episodes of AF. Eventually, elevated pulmonary pressure will cause peripheral oedema, weakness and fatigue.

The reduction in end diastolic volume causes patients to have a low volume pulse, which will be irregular if AF is present. Jugular venous distension (JVD) may occur with a prominent 'a' wave visible if the patient is in sinus rhythm. Murmurs will be evident on auscultation, usually a loud opening snap heard after the second heart sound followed by a low, rumbling mid-diastolic murmur heard best at the apex. Discolouration of both cheeks, known as malar flush, is associated with severe mitral stenosis.

Assessments and investigations

Baseline observations, cardiorespiratory assessment, chest X-ray, 12-lead Electrocardiogram (ECG) and echocardiogram are necessary to establish the diagnosis of mitral stenosis. Left atrial enlargement may be visible on the chest X-ray and seen on the ECG as a prolonged, notched P wave of > 120 ms duration (known as a bifid P wave or

'p mitrale'). The 12-lead ECG may also suggest right ventricular chamber enlargement in patients with severe mitral stenosis. These findings must be confirmed with an echocardiogram, which will establish the severity of valvular dysfunction and the extent of cardiac remodelling. Transoesophageal echocardiography (TOE) may also be used for more detailed assessment prior to percutaneous or surgical intervention.

Treatment

Symptoms associated with mild to moderate mitral stenosis may be treated with diuretics, alongside treatment for AF if required. Surgical intervention should be considered if pulmonary oedema continues, despite medical therapy or if pulmonary hypertension develops. Percutaneous trans-septal balloon valvotomy involves a balloon catheter, advanced from the femoral vein to the right atrium, where it then punctures the interatrial septum to access the left atrium and the mitral valve. The balloon is inflated to separate the cusps and then swiftly deflated and removed. Surgical valvotomy or mitral valve replacement are alternative therapeutic options that usually require cardiopulmonary bypass.

Myocarditis

Myocarditis is a life-threatening inflammatory disease affecting the myocardium. It can occur as a result of infection or from a non-infectious cause, such as sarcoidosis. The subsequent myocardial inflammation can lead to systolic dysfunction and eventually dilated cardiomyopathy, manifesting as acute heart failure, cardiogenic shock or life-threatening ventricular arrhythmias.

History

Myocarditis is most frequently caused by viral infection such as enteroviruses or Parvovirus, but can also be due to bacterial, fungal, parasitic or protozoal infection (Chagas disease). In addition to sarcoidosis, non-infectious causes include toxins, including cocaine, and autoimmune disease, such as inflammatory bowel disease.

Signs and symptoms

Diagnosis of myocarditis is notoriously difficult due to the array of clinical features associated with it, which may differ with the underlying cause. The patient may present with systemic symptoms associated with either a respiratory or gastrointestinal virus but, as the condition progresses and myocardial dysfunction ensues, chest pain, dyspnoea and other symptoms associated with heart failure may emerge.

Assessment and investigations

Patient assessment may reveal signs associated with infection and heart failure but also acute coronary syndromes (ACS), which must be rapidly ruled out. Taking a detailed history is essential as data derived from the investigations detailed below may imitate ACS. Cardiac monitoring should be commenced due to the high risk of ventricular arrhythmias and fluid balance should be closely observed.

The 12-lead Electrocardiogram (ECG) may reveal non-specific ST-T wave changes, left ventricular hypertrophy, atrial enlargement, left bundle branch block or atrial fibrillation. Cardiac troponin and B-type natriuretic peptides (BNP) are likely to be elevated along with other markers of inflammation. The echocardiogram may show wall-motion abnormalities suggestive of dilated cardiomyopathy. Cardiorespiratory auscultation may reveal signs associated with pulmonary oedema and a 3rd heart sound. Jugular venous distension may also be evident. Cardiac Magnetic Resonance imaging will enable visualisation of myocardial inflammation, oedema, necrosis and fibrosis. Endomyocardial biopsy is the gold standard diagnostic tool to enable identification of the cause of myocarditis.

Treatment

Close monitoring is essential due to the high risk of sudden death and bed rest advised to minimise myocardial exertion and to limit the extent of heart failure. Treatment for patients with myocarditis will focus on correcting arrhythmia and reducing the symptoms associated with heart failure. Drugs that might suppress ventricular contraction, such as calcium antagonists, should be avoided. Currently, no antiviral therapies for myocarditis are available. If active infection has been ruled out from the biopsy, immunosuppression therapy may be offered, particularly where non-cardiac autoimmune disease is the established cause of myocarditis. Patients may require a significant period of convalescence before returning to normal life after myocarditis, although some may not fully recover and may require cardiac transplantation.

P

Pericarditis

Pericarditis is an inflammatory disease of the pericardium. In one-third of cases it will also include inflammation of the myocardium, when it is labelled myopericarditis. Pericarditis generally presents acutely, although when associated with other pathology, the onset may be insidious. In most cases resolution is complete in 4–6 weeks, but in some cases recurrent or chronic pericarditis may develop. Pericarditis may occur following Acute Coronary Syndromes (ACS) and typically the patient may present 4–6 weeks after the acute coronary event.

History

The causes of pericarditis are varied and can be classified as infectious (viral, bacterial, fungal or parasitic) or non-infectious (neoplastic, metabolic, autoimmune or post-ACS). Infectious pericarditis will often present acutely with the patient giving a 2–3 week history of a 'flu-like' illness and the patient may have a fever. However, patients with a malignancy, an autoimmune or metabolic cause may present more insidiously and signs of the primary pathology may be the presenting feature.

Signs and symptoms

Classic presentation includes the following: chest pain, a fever, a pericardial friction rub, 12-lead ECG changes, evidence of a pericardial effusion and raised inflammatory markers. Chest pain is typically sharp, made worse by deep inspiration and improved by sitting up and leaning forwards. The pain is often very severe and incapacitating and the patient may be very anxious. A pericardial friction rub can be sporadic and heard over the left sternal edge with the diaphragm of the stethoscope.

Assessment and investigations

History taking is essential to establish the onset, duration and possible causes and to expedite early treatment. A detailed history of any recent infections, travel abroad or exposure to toxic substances should be carried out. Evaluation of the chest pain: onset, character, quality, duration and the factors which relieve and provoke the pain will inform the diagnosis. Typically the pain is described as continuous, sharp or pleuritic in character and widespread across the precordium. The patient may state that sitting up and leaning forward reduces the pain. A set of vital signs should be carried out to evaluate the temperature, heart rate and rhythm, respiratory rate and oxygen

saturation. Physical examination may include percussion and auscultation of the lungs and heart to rule out other causes of chest pain such as respiratory infections, TB or malignancies; it may also reveal the classical pericardial friction rub. A 12-lead ECG should be performed and may reveal widespread ST-segment elevation without reciprocal ST-segment changes hence differentiating it from ACS. In addition, P-R segment depression may be seen in the acute phase of presentation, and inverted T waves may develop during the resolution phase. An Echocardiogram may establish the presence of a pericardial effusion. Serum blood tests should include full blood count, urea, electrolytes, creatinine and inflammatory markers such as C-reactive protein (CRP).

Treatment

The aim of the treatment is to alleviate the patient's pain and concomitant anxiety as quickly as possible. Opiates will not be effective in pericarditis and the mainstay of medical treatment initially is to give doses of an anti-inflammatory drug either orally or rectally to relieve the acute pain. Continued use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDS) is advocated until the inflammation subsides and Colchicine may be beneficial in the long-term to prevent recurrences. The patient should be advised to rest until the symptoms resolve. Where the cause is due to systemic disease (autoimmune or renal disease, TB) or neoplasms (particularly lung and breast cancer) subsequent therapy is directed by the primary cause. Hospitalisation is only generally indicated for high risk patients or if invasive treatments are required for cardiac tamponade, large pericardial effusions, constrictive pericarditis or where cancer or metabolic disease is undiagnosed but suspected. Patients who are managed conservatively should be advised to restrict physical activity until symptom free.

S

Supraventricular tachycardia

Supraventricular tachycardia (SVT) is a term that describes a tachyarrhythmia arising above the ventricles at a rate greater than 150 bpm. This may include a number of tachyarrhythmias: atrial tachycardia, AV nodal re-entry tachycardia (AVNRT), AV re-entry tachycardia (AVRT), atrial flutter and junctional tachycardia. Atrial flutter and atrial fibrillation are considered separately in other chapters in this book.

History

Paroxysmal SVT is an umbrella term for any rhythm faster than 150 bpm, which originates above the ventricles. The term SVT is used when the exact mechanism cannot be identified from the surface ECG. Atrial tachycardia and A-V nodal re-entry tachycardia (AVNRT) may occur in healthy but susceptible individuals with no apparent underlying heart disease. A-V re-entry tachycardia (AVRT) is a re-entrant tachycardia associated with the Wolff-Parkinson-White (WPW) syndrome. SVTs may be precipitated by increased catecholamine or sympathetic tone, amphetamines and cocaine misuse, acid base or electrolyte imbalance, over exertion, or stimulants such as stress, alcohol or tobacco. SVTs may also be triggered by atrial and ventricular ectopics. The underlying arrhythmogenic mechanism in atrial tachycardia is enhanced automaticity; a re-entry mechanism for AVNRT and AVRT. The re-entry circuit may involve the AV node (AVNRT) or the AV node and an accessory pathway (AVRT) in WPW. The initiation of the tachycardia is generally sudden with the onset often precipitated by a premature atrial ectopic. There may be a brief period of asystole at the termination of the tachycardia. The tachycardia may last from a few seconds to several hours and may be paroxysmal, persistent or permanent.

Signs and symptoms

The tachycardia is accompanied by symptoms of palpitations, anxiety and evidence of reduced perfusion and cardiac output: dizziness, breathlessness and syncope or pre-syncope. The rapid heart rate increases the workload of the heart and also reduces diastolic filling time, hence reducing myocardial perfusion, causing chest pain and possibly precipitating heart failure and cardiogenic shock. Syncope may occur after termination of the arrhythmia due to the brief period of asystole experienced.

Assessment and investigations

Cardiac monitoring or 12-lead ECG recording will enable identification of a regular, narrow QRS complex tachycardia with a rate of between 150 and 250 bpm (Figure 29.1).

In atrial tachycardia, the rhythm arises from rapid firing of an atrial ectopic focus. P waves will be present but abnormal in morphology, R-R intervals are regular and the conduction ratio is 1:1, the ventricular rate is extremely fast, usually in the range of 140–180 bpm but can be as fast as 250 bpm, at which point AV block will develop to reduce the ventricular rate. Atrial tachycardia usually begins and ends suddenly and may occur in short bursts or be present for prolonged periods.

AVNRT is twice as common in women, may occur spontaneously or is triggered by noxious stimulants. It may also terminate suddenly or continue until medical intervention occurs. AVNRT arises due to the presence of a fast and slow conducting pathway within the AV node. In normal sinus rhythm, the impulse proceeds through the AV node, utilising the fast pathway. However, in AVNRT, if an atrial ectopic occurs early, the fast pathway is refractory and the slow pathway transmits the impulse to the ventricles. The impulse then travels backwards up the fast pathway which has recovered its excitability and this initiates a 're-entry tachycardia'. On the ECG, the ventricular rate is 140–250 bpm, and atrial impulses are either hidden within or occur after the QRS due to retrograde conduction. The QRS complex is usually narrow, unless a bundle branch block is present.

In AVRT there is a macro re-entry circuit created by the incomplete separation of the atria from the ventricles during foetal development of the heart. Abnormal collections of myocardial fibres (known as accessory pathways) are invested through the AV groove allowing a large circuit including the AV node, Bundle of His and the accessory pathway to conduct a fast reciprocating tachycardia. Patients with this anatomical abnormality, who also have symptomatic tachycardia, have a syndrome known as Wolff-Parkinson-White (WPW) syndrome. If the accessory pathway (known as the Bundle of Kent) excites the ventricles early during sinus rhythm, the excitation wave depolarises the ventricles abnormally (pre-excitation) and this manifests on the ECG

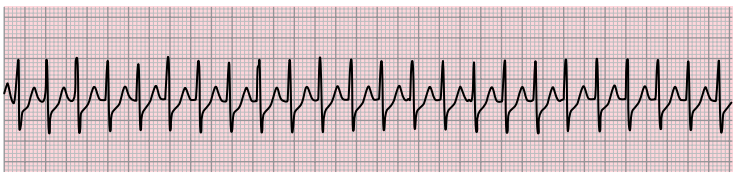

Figure 29.1 Supraventricular tachycardia (SVT).

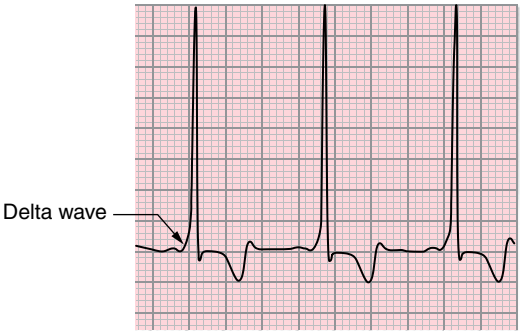

Figure 29.2 WPW pattern.

as a short P-R interval (due to bypass of the AV node) and a wide QRS with a slurred upstroke known as a delta wave (Figure 29.2). If a tachycardia develops, the circuit evolves from the atria to the ventricles via the AV node and enters retrogradely via the accessory pathway. This tachycardia is known as orthodromic AVRT. The tachycardia is fast, 140–180 bpm, with a narrow QRS complex (delta waves are absent), the P waves are seen after the QRS and before the T wave due to retrograde conduction.

Patients should be closely monitored for signs of haemodynamic compromise, including respiratory assessment, pulse, blood pressure and urine output. A lengthy period of tachycardia may cause cardiomyopathy and this may induce polyuria. A 12-lead ECG should be recorded and a history taken from the patient to establish any precipitant causes of the SVT and to enable differentiation of the possible type of SVT.

Treatment

In emergency situations, identification of the type of SVT may be difficult but the treatment is essentially the same. If the patient is haemodynamically stable, vagal procedures, such as the Valsalva manoeuvre may be effective. Examples include blowing into a syringe or facial immersion in cold water. Emergency treatment will be necessary if the patient shows signs of haemodynamic instability such as hypotension, pulmonary oedema or circulatory collapse. Bolus doses of intravenous adenosine will cause transitory AV block due to its short half-life, which generally terminates the SVT. Patients should be advised that the side-effects include flushing, chest pain and a sense of impending doom, but these symptoms are brief and will dispel quickly. An emergency electrical cardioversion under sedation with airway support may be necessary if the adenosine is not successful. Following resolution of the tachycardia, further investigation of causes should be undertaken and a cardiology referral made.

T

Takotsubo cardiomyopathy

Takotsubo cardiomyopathy (TC) is characterised by acute presentation of chest pain and/or dyspnoea due to sudden onset of left ventricular (LV) systolic dysfunction, classically triggered by an emotional or physical stressor such as anger, sadness or acute physical illness. The condition was first described in 1990 and initially it was thought that TC only affected patients of Asian origin. However, since 2003, when a Caucasian patient was noted with the syndrome, the condition is now known to be a worldwide phenomenon. In Japan, a 'tako-tsubo' is a round bottomed, narrow necked pot used to catch octopus and the shape of this pot directly mimics the LV apical ballooning seen at angiography in the presentation of this syndrome. The cause is unknown but it is thought to be due to abnormal responses to catecholamine release resulting in vasospasm and transient myocardial stunning. During coronary angiography, the patient is found to have no coronary artery occlusion, despite the presence of ST-segment elevation on the 12-lead ECG. The exact prevalence of TC is not known but there is a higher prevalence amongst post-menopausal women and hence it is suspected that oestrogens may play a role in the disease. However, TC has been observed in younger women and also in men.

History

The acute phase of TC can be life threatening and is generally triggered by an acute stressor. The onset is sudden and the patient may present in a collapsed state with chest pain and/or dyspnoea of sudden onset, which may be accompanied by arrhythmias, cardiac arrest and cardiogenic shock.

Signs and symptoms

Classically patients with TC present with symptoms similar to acute coronary syndromes (ACS) such as chest pain, dyspnoea, arrhythmias and syncope. Some patients present in cardiogenic shock or cardiac arrest. As the symptoms are identical to ACS, differentiation can only be made using angiography. The coronary arteries are found to be patent but an area of hypokinesia is present in the LV, giving rise to the characteristic 'octopus pot' shape to the LV and the potential for acute heart failure.

Assessment and investigations

The patient is likely to be very distressed on presentation and reassurance is vital. Initial assessment of vital signs should include respiratory rate, oxygen saturation and blood pressure undertaken

frequently in the initial stages. The patient should be attached to a cardiac monitor to assess heart rate and rhythm and a 12-lead ECG performed. The 12-lead ECG will be abnormal and is likely to show ST-segment elevation, particularly in the anterior leads. Importantly, there may no reciprocal ST-segment depression, which differentiates this syndrome from ACS. There may also be a prolonged QT interval, which makes patients vulnerable to ventricular arrhythmias in the recovery period.

Careful history taking is essential as a preceding emotional or physical trigger may be identified. Assessment of chest pain should elicit the duration of onset, precipitating factors, nature and radiation of pain and relieving factors. The patient may be poorly perfused with reduced capillary refill and may present in acute heart failure or cardiogenic shock.

Serum blood tests will be performed including urea and electrolytes, full blood count, clotting screen and serum markers of cardiac damage such as troponin and B-type natriuretic peptides (BNP). An urgent coronary and LV angiogram should be performed within 60 minutes of presentation, which will usually demonstrate patent coronary arteries with regional wall hypokinesia and apical LV ballooning.

Treatment

Acute management is directed towards relief of myocardial ischaemia. Opiates, such as intravenous morphine, will relieve the patient's pain and distress. Antiplatelet therapy is likely to be given in advance of the angiogram but can be discontinued when normal coronary arteries are visualised. However, anticoagulation is used to prevent stroke arising from thrombus associated with the apical dilatation. Intra-aortic balloon pump for LV support may be used if cardiogenic shock develops; diuretics are used for acute pulmonary oedema. ACE-inhibitors are used to support the LV dysfunction; most patients recover normal LV function within weeks. Beta-blockers, which inhibit the sympathetic-adrenal response to stress, may be used as prophylaxis against recurrence. Nearly all patients survive and the prognosis is good.

V

Ventricular tachycardia

Ventricular tachycardia (VT) is a life-threatening arrhythmia frequently associated with Acute Coronary Syndromes (ACS) that may present as cardiac arrest. On the ECG, VT appears as a series of 3 or more premature ventricular contractions (PVCs) that occur either in short salvos that terminate independently or as a sustained arrhythmia, lasting for more than 30 seconds. Monomorphic VT produces a regular tachyarrhythmia with uniform, abnormal QRS complexes that originate in the myocardium below the Bundle of His. VT can cause severe left ventricular dysfunction and may deteriorate into ventricular fibrillation (VF).

History

Patients may experience acute symptoms associated with ACS immediately prior to developing VT. Ventricular scar tissue caused by ischaemic heart disease, cardiomyopathy, myocarditis, congenital abnormalities and systemic disease, such as sarcoidosis, can permit the development of an electrical re-entry mechanism producing VT. VT may also occur in a structurally normal heart through the mechanisms of triggered activity or enhanced automaticity. VT may be due to electrolyte imbalance, particularly hypokalaemia and hypomagnesaemia, as well as the inherited ion channelopathies, such as Long QT or Brugada syndromes.

Signs and symptoms

VT is diagnosed from the ECG, which will reveal a fast, regular rhythm with abnormal but uniform QRS complexes (>100 ms) (Figure 31.1). If P waves are visible, they will not be associated with the QRS. Reduced cardiac output during an episode of sustained VT often results in hypotension, potentially causing symptoms of pre-syncope or syncope, dyspnoea, angina or reduced level of consciousness. Clinical signs include a rapid pulse (100–250 bpm) and cannon 'a' waves in the jugular vein due to atrio-ventricular (AV) dissociation. Signs associated

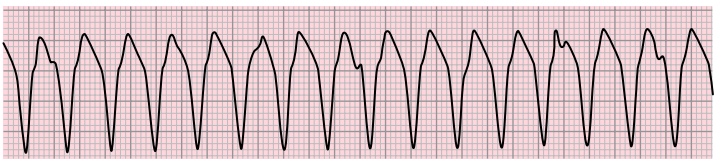

Figure 31.1 Ventricular tachycardia.

with pulmonary oedema may be evident. However, VT may be tolerated well in patients with normal left ventricular systolic function, with few signs of haemodynamic compromise.

Assessments and investigations

Patients should be rapidly and systematically assessed as VT may be life-threatening. If the patient has a pulse, continuous cardiac monitoring and regular respiratory and haemodynamic assessment, including urine output, should be conducted to closely observe for early signs of deterioration. A 12-lead ECG should be recorded and repeated once sinus rhythm has been restored to assess for myocardial ischaemia. Blood samples should include electrolytes and cardiac biomarkers to establish the cause of the arrhythmia. Regular AVPU and GCS scoring will be necessary to assess level of consciousness.

Treatment

Rapid treatment is necessary as the arrhythmia may deteriorate into VF. If the patient has already lost cardiac output (pulseless VT), advanced life support including defibrillation and airway support should be commenced. If the patient shows signs of haemodynamic compromise, such as hypotension or pulmonary oedema, synchronised electrical cardioversion may be indicated. Intravenous anti-arrhythmic drugs are suitable to restore sinus rhythm if the patient is haemodynamically stable. Identification of the cause, such as ischaemia or electrolyte imbalance, is necessary to guide the treatment to prevent recurrence. Primary percutaneous coronary intervention (P-PCI) may be indicated if ACS is suspected. Long term, an internal cardioverter defibrillator and anti-arrhythmic drug therapy should be considered as a means of reducing the risk of sudden cardiac death.

W

Wolff-Parkinson-White syndrome (Pre-excitation syndrome)

Wolff-Parkinson-White syndrome (WPW) is a congenital condition, which affects approximately 0.1–0.3% of the population. During foetal development of the heart, muscle strands or accessory pathways (APs) intersect the atrioventricular groove creating an extra electrical connection between the atria and the ventricles. This results in early excitation and depolarisation of the ventricular tissue. Most APs connect the atrial and ventricular myocardium at the mitral and tricuspid annuli and, as the APs may conduct either anterogradely or retrogradely, this creates a substrate for potential re-entry arrhythmias. In some patients there is a small risk of sudden cardiac death.

History

In WPW, the heart is usually structurally normal, although the APs also occur in association with serious congenital heart disease such as Ebstein's anomaly or transposition of the great vessels. The APs may conduct rapidly or slowly, bypassing the AV node, which has important decremental properties that protect the ventricles against fast atrial rates. If conduction across the AP is rapid, as in atrial fibrillation, a potential for life-threatening ventricular fibrillation (VF) may occur.

Signs and symptoms

The clinical features of WPW are variable, many patients remain asymptomatic, whilst others develop a variety of arrhythmias which may cause dizziness, syncope and palpitations causing them to seek medical assistance; in rare cases the first presentation may be due to cardiac arrest. In some patients, the ECG pattern of WPW is only discovered during routine ECG screening.

The arrhythmias associated with WPW include supraventricular tachycardia (SVT) and atrial fibrillation (AF). In the presence of AF, conduction to the ventricles via the AP causes a rapid, irregular rhythm with a widened QRS complex, which may deteriorate into VF.

Assessments and investigations

A focussed history and a 12-lead ECG form the basis of initial assessment. The 12-lead ECG will reveal a short P-R interval, less than 120 ms (reflecting the bypassing of the AV node) and a wide QRS (>100 ms) with a delta wave (Figure 32.1).

The delta wave is a slurring or widening of the proximal portion of the QRS complex, which reflects the early depolarisation of the

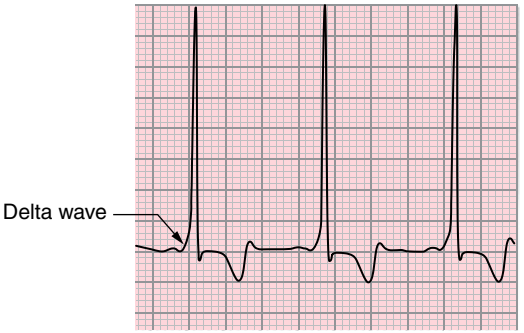

Figure 32.1 Characteristic ECG findings associated with WPW.

ventricular tissue. However, the remainder of the excitation to the ventricles is normal, thus the second portion of the QRS is normal. The QRS is therefore a fusion beat of early depolarisation via the AP and normal depolarisation via the His-Purkinje system. Abnormal ventricular depolarisation may produce QRS complexes of increased amplitude and there may also be ST-segment and T wave abnormalities, which may mimic conditions such as myocardial infarction, bundle branch block and chamber enlargement. Invasive diagnostic tests include electrophysiology studies to map the APs and to test the inducibility of arrhythmias.

Treatment

Emergency treatment for SVT or AF associated with WPW requires careful pharmacological management. Drugs which block AV nodal conduction such as Adenosine are not used, but Flecainide or Amiodarone may be suitable alternatives. Once back in sinus rhythm, the patient's ECG should be examined to rule out WPW as the cause. The long-term treatment for WPW depends on the degree of symptoms and the risk of sudden cardiac death. AP ablation is offered to patients considered at high risk of cardiac arrest.

Foreword

Treatment of patients with cardiovascular diseases has dramatically changed over the past 20 years. Accompanied by an incredible increase in pathophysiological understanding and availability of treatment options, specialized fields of expertise have rapidly evolved.

Electrophysiology is one of these newcomers. Based on the analysis of basic principles of electrical activation in the human heart, the field has developed into sophisticated treatment strategies of device therapy and catheter ablation. The majorities of today's EP patients originate from the mainstream of everyday clinical cardiology and present with endemic, bradycardic, and tachycardic arrhythmias.

With this background, electrophysiology has also arrived in the ER department.

Now it is our obligation to transport our knowledge and expertise for treatment of arrhythmia patients to our cardiology colleagues and specialized ER physicians who encounter emergency situations due to or accompanied by cardiac arrhythmias in a significant number of patients, next to a variety of other medical emergencies.

Dedicated literature on that topic is really scarce. I therefore want to thank the editors and authors of this book to take the challenge, efforts, and work and to bring together a vast amount of EP knowledge and to focus it to the special situation in the ER.

This book should become an integral part of training for young cardiology fellows, and it will be a practical guide and help for all medical staff involved into the management of ER patients.

Christopher Piorkowski
Head of EP Department – University of Dresden

Preface

The book is a practical guide designed for physicians (both emergency physicians and cardiologists) who first evaluate and treat patients with arrhythmias or potentially arrhythmic problems in the emergency setting. It can also be a useful learning tool for students and residents in Cardiology and Emergency Medicine.

In all chapters, every effort was made to provide a brief but comprehensive summary of the topic with both theoretical and practical suggestions, considering the different needs of the specialists involved in the primary care of arrhythmic patients.

The diagnostic pathways and treatment options of patients presenting in the Emergency Department with syncope or arrhythmias, including bradyarrhythmias, atrial fibrillation, and narrow and wide QRS tachycardias, are discussed. In addition, clear advice for the management of patients with cardiac devices and possible dysfunction, electrical storm, or a requirement for urgent surgery are provided.

Practical suggestions are offered for short-term management, e.g., regarding the decision on when to hospitalize the patient and some hints for long-term pharmacological and non-pharmacological treatment.

In the first chapter, an overview of the management of arrhythmic patients, from the emergency physician's point of view, is provided. In the second chapter, some considerations, beyond published guidelines, for the management of syncope are given by a leading expert. An extensive theoretical overview of brady- and tachyarrhythmias are then followed by practical flowcharts in Chaps. 3, 4 and 5, while in the following chapter the differential diagnosis of wide-QRS tachycardias with clear examples are discussed by one of the greatest experts in this field. Chapters 7 and 8 deal with quite rare cardiac conditions, sometimes not so known by emergency physicians and even by cardiologists, who nonetheless in such cases sometimes face difficult decisions. Differently, situations frequently observed in the Emergency Department, but with an arrhythmogenic potential which is not always well defined, are presented in Chaps. 9 and 10. Finally, in the last three chapters, some indications for the management of patients with implanted cardiac devices presenting in Emergency Department or who need urgent surgery are provided, again considering the different skills of the various medical figures involved in the primary care of such patients.

Considering the heterogeneity of the topics, some differences in the chapters' frameworks were necessary. However, the book was conceived to offer quick information and solutions to the single issues, as required in the emergency setting, rather than providing a systematic review.

Management of Arrhythmic Patients in the Emergency Department: General Principles

1

Alessandro Surian and Luca Visintin

Arrhythmic patients are common in the duty of the emergency physician and the cardiology consultant. Both specialists, with their different approach and method, well know the clinical and statistical relevance of arrhythmias.

A wide range of symptoms leading the patient to the emergency department may be related to a cardiac rhythm disorder. They may vary from simple palpitations to a cardiac arrest. Otherwise, the diagnosis of arrhythmia can be made in patients who came to the ED for other diseases.

Emergency physician is the first doctor approaching the patient and must initially define the hemodynamic state induced by the arrhythmia. The need to assure hemodynamic stability must be assumed as the first important target and should not be delayed by any other consideration.

Once a stabilization is obtained, the consultant cardiologist can improve diagnostic and therapeutic definition. A tight cooperation between the two specialists warrants the best patient outcome.

1.1 Triage

Triage of arrhythmic patient must focus on hemodynamic state and time of onset of symptoms and signs. Unstable arrhythmias should be admitted as soon as possible to physician evaluation, while asymptomatic patients may wait longer.

M. Zecchin, G. Sinagra (eds.), *The Arrhythmic Patient in the Emergency Department: A Practical Guide for Cardiologists and Emergency Physicians*,
DOI 10.1007/978-3-319-24328-3_1

Hemodynamic criteria for quick admission are:

- SBP (systolic blood pressure): <90 mmHg
- DBP (diastolic blood pressure): <60 mmHg
- Heart rate per minute: >120 and <50 bpm
- Respiratory rate per minute: >30 and <10
- Body temperature: >39.0 °C and <36.0 °C
- Sat O_2: <90 %

Moreover, chest pain, dyspnea, acute heart failure, acute altered mental status, and signs of shock are evaluated during triage.

Unstable patients should be addressed immediately to the shock room of the ED, while stable patient can wait or be addressed to an examination room provided with ECG for a first evaluation and subsequently be treated when the adequate setting is available [1, 2].

1.2 Emergency Department Physician Approach to the Arrhythmic Patient

Emergency physician's main task is to identify "*hemodynamically unstable*" patients, quickly evaluating parameters like level of consciousness, ventilation, oxygenation, heart rate, and blood pressure (Table 1.1). Clinical evaluation is focused on the investigation of signs of shock (altered mental status, cool and clammy skin, weak and rapid pulse, rapid and shallow breathing, anxiety, lightheadedness, chest pain, decrease of urine, thirst and dry mouth, hypoglycemia, confusion, nausea, lackluster eyes) dyspnea and tachypnea, or oxygen desaturation.

Patient's ECG, blood pressure, and O_2 saturation (sat O_2) should be immediately put under continuous monitoring and intravenous line with blood samples provided. Airways have to be kept patent, breathing assisted, and oxygen given if sat O_2 is below 94 %. A 12-lead ECG should be obtained as soon as possible for a correct diagnostic evaluation of the arrhythmia. Medical history must be gathered.

Table 1.1 First steps

Look for:
shock signs
Chest pain
Respiratory distress
Do:
Monitor the patient, IV line, blood samples
Ensure patent airway and ventilation and give oxygen (if needed)
Support perfusion pressure (use mean arterial pressure as a good index)
12-leads ECG; gather medical history
Treat reversible causes

Should a cardiac arrest occure, advanced life support protocols have to be applied.

Hemodynamic instability, defined as an acute organ failure or a near-cardiac arrest situation, may be due to tachy- or bradyarrhythmia.

In the event of a tachyarrhythmia, an immediate defibrillation or synchronized cardioversion should be done regardless of the arrhythmia mechanism.

In addition, bradyarrhythmias may lead to a severe decrease in cardiac output, causing hemodynamic instability with hypotension, mental dizziness, decreased consciousness level, cyanosis, dyspnea, etc.

A treatment based on atropine, catecholamine, or an electrical stimulation may be helpful or even lifesaver [1, 2].

1.2.1 Tachyarrhythmia

By definition, tachycardia is a heart rate exceeding 100 beats per minute.

By far the most common tachycardia diagnosed in the emergency department is sinus tachycardia.

In the healthy patient, it is a physiological response to physical stress or anxiety. Sinus tachycardia is also a normal condition during the pregnancy. In most other cases, it is due to an underlying pathological condition (e.g., fever, dehydration, anemia and hypoxia, ACS, P.E., hyperthyroidism, high blood pressure, smoking, alcohol, beverages containing caffeine, medication side effects, abuse of recreational drugs, such as cocaine, or imbalance of electrolytes) [3].

"Appropriate" sinus tachycardia offsets an underlying condition, while "inappropriate" sinus tachycardia can be a consequence of deficit of vagal tonus or a hyperactivity of/excessive sensibility to the sympathetic nervous system. During sinus tachycardia heart rate is usually lower than 140–150 bpm, even if, in young people under extreme stimulation, it can exceed 220 bpm. Typically, in sinus tachycardia, the P wave is positive in inferior and lateral leads (as in sinus rhythm). As sympathetic activation increases AV conduction, PR interval is shorter than in sinus rhythm; therefore, with few exceptions, the coexistence of long PR and sinus tachycardia is unlikely, even in patients with I degree AV block during normal sinus rhythm, and usually suggests other mechanisms of tachycardia, as atrial tachycardia or atrial flutter, possibly with 2:1 conduction and a P wave hidden within the QRS complex.

In order to identify if the tachycardia is the main cause of the patient's symptoms, a complete physical examination, blood draw to test metabolic and renal function, emogasanalysis (EGA), 12-lead ECG results and medical history should be performed and any potential reversible causes should be corrected.

Usually tachycardia may be considered as hemodynamically significant when they exceed 150 bpm.

However, it is important to remark that even frequencies lower than 150 bpm may cause hemodynamic compromise, mainly if it is sustained for a prolonged time and/or coexists with an underlying heart disease, leading to chest pain, altered mental status, pulmonary edema, or cardiogenic shock, requiring an emergency electrical cardioversion.

It is advised to perform an effective pre-procedural sedation if the patient is conscious, although hemodynamically unstable.

1.2.1.1 Procedural Sedation/Anesthesia During Cardioversion

Sedative or dissociative drugs, coupled with or analgesics, are used to relieve the patient from unpleasant procedures. Many of these drugs can lead to central nervous system and cardiac and/or respiratory depression. Given the potential risks, regulatory agencies are debating about the medical privileges needed to perform this procedure, particularly about the presence of an anesthesiologist during the procedure.

Recommendations for a safe employ consist of a proper setting (ECG, respiratory rate, sat O2, NIBP monitoring, advance life support trained personnel, devices for life support) and frequent reevaluations (prior to, during, and after procedure); trained staff should choose appropriate drugs and dosing depending on the distinctive features of each patient.

A growing literature highlights the safety of administration of ketamine, midazolam, fentanyl, propofol, and etomidate in the ED [4–6].

- *Equipment and supplies*: oxygen, suction, reversal agents, advanced life support medications and equipment, defibrillator, and CO_2 capnography. An IV line should be set; reversal agents should be available whenever opioids and benzodiazepines are administered.
- *Personnel*: during the procedure, personnel dedicated to patient monitoring should focus only to the sedation and not to other tasks.
- *Training*: the physician should know drug's pharmacology of the agents used and their antagonists. Personnel with experience in Advanced Cardiac Life Support should be present.
- *Drugs*. Electrical cardioversion is a brief but painful procedure. Light sedation is inadequate for a pain-free relaxed patient. Therefore, a moderate to deep sedation and analgesia or general anesthesia is required. In most US and Europe hospitals, emergency physicians are not allowed to provide general anesthesia, so sedation can be the only option if an anesthesiologist is not present. Drugs: midazolam and fentanyl are commonly used, but their long-lasting effects make them not handy or straight dangerous. Instead, for a brief and titratable deep sedation, it makes more sense to employ propofol, etomidate, or methohexital combined with fentanyl. There are contradictory statements from the American Society of Anesthesiologists (ASA) guidelines about authorization for propofol use by emergency physicians. Evidence is accumulating that non-anesthesiologist-administered propofol sedation has a safety and efficacy profile comparable or superior to that provided by benzodiazepines with or without opioids. Medications should be administered gradually, allowing sufficient time between dose and effect assessment. Concurrent administration of sedative and analgesic drugs requires evaluation on dose reduction.
- *Recovery*: observation should be prolonged until there are no more risks for cardiorespiratory depression. Medical institution should set up appropriate discharge criteria [4–6].

1.2.1.2 Cardioversion/Defibrillation

If cardioversion is chosen, set the defibrillator into the synchronized mode. This to avoid shock delivery during ventricular "electric vulnerability" period (apex and descending branch of T wave), a potential trigger of ventricular fibrillation. Defibrillation, used for interruption of pulseless VT, VF, and torsade de pointes synchronization, should be avoided, as QRS complexes may not be identified.

Emergency physician should be trained to recognize the presence of the P wave and distinguish between narrow-complex (supraventricular) tachycardia and wide complex tachycardia, which in condition of urgency should be considered and treated as ventricular tachycardia.

The different types of tachycardia can be treated with different energies:

- As recommended by international guidelines for regular narrow-complex tachycardia, the initial energy cardioversion should be 50–100 J with biphasic defibrillators and 200 J if monophasic (Class IIa, LOE B).
- For irregular narrow-complex tachycardia, the recommended initial biphasic energy is 120–200 J (Class IIa; LOE A).
- Regular wide complex tachycardia may resolve after discharge at 100 J by both biphasic and monophasic defibrillators (Class IIb, LOE C).

Anyway, if the first shock is inadequate to resolve the arrhythmia, increase energy "in a stepwise fashion."

When using monophasic defibrillators, initial energy should be set to 200 J, proceeding in a stepwise fashion in the event of failure.

The irregular wide complex tachycardia should be treated with high-energy unsynchronized shock (i.e., defibrillation), because of the difficulty of the machine to distinguish between the QRS complex and T wave.

Even if there were doubts whether the tachycardia is monomorphic or polymorphic, the shock should not be delayed and a high-energy unsynchronized shock must be delivered.

In the unstable patient (if not hypotensive) presenting with a regular narrow QRS complex tachycardia, *adenosine* is safe to be used while cardiac electrical cardioversion is being set up both for therapeutic (in case of tachycardia involving the AV node as a part of the reentry circuit) and diagnostic (in case of atrial arrhythmias, unmasking atrial activity slowing AV conduction (Class IIb (LOE C)).

If the patient with tachycardia is stable, the emergency physician will have more time for a correct diagnosis and to choose the most appropriate therapy, with the help of a cardiologist if necessary.

After obtaining a complete medical history and a careful physical examination, QRS complex evaluation is needed. QRS duration should be measured in at least two orthogonal derivations: narrow-complex tachycardia (QRS duration <120 ms) should be always considered, by definition, as supraventricular: examples are sinus tachycardia, atrial fibrillation (AF), atrial flutter, AV nodal reentrant tachyarrhythmia (AVNRT), tachyarrhythmia mediated by accessory pathways, atrial tachycardia, multifocal atrial tachycardia (MAT), and junctional tachycardia (rare in adults) .

Based on ECG findings, the regularity of RR intervals and the relationship between P waves and QRS complexes along with the timing of onset of tachycardia may help to differentiate among the various kinds of supraventricular tachyarrhythmia.

If the anamnesis highlights sudden onset of palpitations and its rapid resolution, it is likely to be atrial fibrillation, atrial flutter, AVNRT, atrioventricular reciprocating tachycardia, and atrial tachycardia. Instead, sinus tachycardia, permanent atrial fibrillation, and permanent flutter, together with MAT and premature atrial contractions, show symptoms that arise and resolved more gradually [7].

P waves immediately preceding the QRS complexes address the ED physician's diagnosis to sinus tachycardia, atrial tachycardia, multifocal atrial tachycardia or multiple atrial premature contractions.

P waves following QRS complexes suggest atrioventricular nodal reentrant tachycardia, atrioventricular reciprocating tachycardia, or atrial tachycardia. However, heart rate can be high enough to have T waves overlapping the P waves.

If tachycardia has a narrow QRS complex, vagal maneuvers and, if ineffective, the administration of adenosine at doses of 6–12 mg, (always under cardiac monitoring) may have a dual purpose:

- *Diagnostic*, since the increase of degree of AV block can unmask the nature of the underlying rhythm; a transient slowing of ventricular rate may highlight atrial fibrillation, atrial flutter, and sinus tachycardia, while there might not be any effect on multifocal atrial tachycardia or frequent atrial premature contractions.
- *Therapeutic*, because the increase in parasympathetic tone may slow electrical conduction through the AV node interrupting reentrant arrhythmias involving tissues sensitive to vagal stimulation (AV nodal reentrant tachycardia, AV reciprocating tachycardia, and sometimes atrial tachycardia).

If vagal maneuvers and adenosine are unsuccessful in converting to sinus rhythm or atrial fibrillation and atrial flutter are diagnosed, it is recommended to administer:

- *Diltiazem* (15–20 mg or 0.25 mg/kg IV over 2 min); if needed, after 15 min an additional IV dose of 20–25 mg (0.35 mg/kg) can be administered; the infusion dose is 5–15 mg/h, titrated according to heart rate.
- *Verapamil* (2.5–5 mg IV bolus over 2 min); if no response and non-drug-induced adverse events occur, it is possible to repeat doses of 5–10 mg every 15–30 min up to a total dose of 20 mg.
- *Beta-blockers* (metoprolol, atenolol, propranolol, esmolol, and labetalol).

These drugs are able to convert the reentrant tachycardia by acting on the nodal tissue or slowing the ventricular response in case of other supraventricular arrhythmias [1].

In patients with atrial fibrillation/flutter/tachycardia lasting more than 48 h (or if the onset of the arrhythmia is unknown), electrical or pharmacological cardioversion should not be attempted in absence of adequate anticoagulation in the

preceding 3 weeks. Otherwise, when prompt restoring of sinus rhythm is needed or preferred, cardioversion can be done after excluding the presence of thrombi in the left atrium by transesophageal echocardiography (Class IIa, LOE B) [8].

In most cases the patient with narrow QRS tachycardia is treated in ED, restoring the RS or starting a therapy aimed to control the heart rate, and resigned to be entrusted to the outpatient cardiologist, who will complete the diagnostic process and improve, if necessary, the treatment started in the emergency department.

Handling of wide-QRS complex tachycardia (>120 ms) is different. These tachycardias cannot be treated in PS only but require both an initial cardiac evaluation in the emergency department, including a careful analysis of the ECG and echocardiography, and hospitalization in the specialist department.

1.2.1.3 When should the Cardiology Consultant be called?

Cardiologist called in ED for a patient with a wide-QRS complex tachycardia has a daunting task. In fact, a mistaken diagnostic may lead to disastrous effects in terms of prognosis.

A wide-complex tachycardia can be:

- Ventricular tachycardia.
- Supraventricular tachycardia in a patient with preexisting bundle branch block.
- Tachycardia-dependent bundle branch block (aberrancy).
- Tachycardia caused by drug that have a widening effect on QRS.
- Atrial arrhythmias in the presence of ventricular pre-excitation.

In the diagnostic path of a wide-QRS complex tachycardia, attention must be paid to the clinical examination (variability of the first tone and amplitude variable radial pulse lay for the presence of AV dissociation) and the careful analysis of the ECG [9].

Here is a summary of some general criteria that can help the cardiologist identify the origin of tachycardia (for detailed discussion of the ECG, see Chap. 6):

A. Search if the electrical activity of the atria is present; P waves, independent of QRS, are separated by constant intervals, paying more attention in derivation II and V1, where these waves can be easier to find.

   If some ventricular impulses are not conducted to the atria and the QRS/P ratio is greater than 1, a diagnosis of ventricular tachycardia can be made.

   Small deflections, fitting in a rhythmic manner inside the QRS complexes, suggest the presence of underlying sinus P waves when their rate is lower than the ventricular rate. Hence, a diagnosis of ventriculoatrial dissociation and therefore of ventricular tachycardia can be made. If there is a mathematical relationship between ventricular and atrial electrical activity, a retrograde ventricular-atrial conduction is likely, as it can be found in about 50 % of cases..

   In presence of a clear QRS/P ratio = 1, the diagnosis may be more difficult; it may be expression of atrial tachycardia, sinus rhythm with aberrant conduction, nodal reentrant tachycardia, automatic junctional tachycardia, reciprocating orthodromic tachycardia with aberrant conduction, or ventricular tachycardia with 1:1 retrograde conduction.

B. Search for "concordance" aspect of QRS in the precordial leads. The presence of concordance suggests that the tachycardia has a ventricular origin. Common definitions are "*positive concordance*" if the QRS complex is "R wavelike" from V1 to V6 and "*negative concordance*" in the presence of a "QS-like" morphology from V1 to V6.

   Cardiologists must remember that although a negative concordance is absolutely specific for VT, the positive could, in rare cases, be expression of a pre-excited tachycardia due to a left posterior Kent bundle (pre-excited tachycardia with conduction through ancillary pathway).

C. As stated by Brugada et al., in the diagnostic algorithm of regular wide-QRS complex tachycardia, the presence of RS complexes (R waves followed by S wave) in precordial leads suggests a diagnosis of VT when the interval between the beginning of the R wave and nadir of the S wave is >100 ms [10].

D. The analysis of QRS complexes, in particular in leads V1 and V6, is certainly useful.

In a wide-QRS complex tachycardia with right bundle branch block (positive QRS in V1), morphologies R, Rs, RrĐ, qR in V1 and QS, qR, rS in V6 are suggestive of ventricular tachycardia.

A three-phasic morphology of V1 (rsR' and rSR'), biphasic morphology in V1 (rRĐ), or three-phasic morphologies in V6 (qRs) suggest a supraventricular genesis with aberrant conduction.

In wide-QRS complex tachycardia with left bundle branch block (negative QRS in V1), an initial R wave >30 ms in V1, an interval between the beginning of the QRs complex and nadir of the S wave >60 ms, the presence of a notch in the descending limb of the S wave, and Q wave in V6 (qR aspects, QRS or QS) suggest a ventricular origin of arrhythmia.

Initial R wave <30 ms and an interval between the QRS onset and the S wave nadir <60 ms are suggestive of supraventricular tachycardia with aberrant conduction.

The maneuvers of vagal stimulation can be useful in the diagnosis of wide complex tachycardia, and depending on the response, we can obtain important information:

- If the tachycardia ceases, a supraventricular reentrant tachycardia is likely (but in some cases even the idiopathic ventricular tachycardia is resolved with the vagal stimulation).
- Modifications of the atrioventricular conduction in atrial tachycardia and atrial flutter can be observed.
- In ventricular tachycardia with ventriculoatrial (VA) 1:1 conduction, a variation of VA interval or transient second-degree retrograde VA block may be recorded.

1.2.1.4 Treatment of a Wide-QRS Complex Tachycardia

As mentioned earlier, if the patient gets worse and becomes unstable, staff must be ready to perform an *immediate electrical cardioversion* or to deliver high-energy unsynchronized shock, if ventricular fibrillation emerges or instability is caused by a polymorphic VT.

When diagnostic doubts about the origin of tachycardia are present, it should be treated as if it were of ventricular origin.

In presence of regular and monomorphic complexes, it is reasonable to administer *adenosine*, considered safe, and useful for both diagnosis and treatment purposes (Class IIb, LOE B). Adenosine should not be administered if the patient is unstable or has irregular or polymorphic complexes: in this condition, it could lead to degeneration in VF (Class III, LOE C).

Once diagnosed a ventricular tachycardia, treatment consists of antiarrhythmic drugs such as *procainamide* (Class IIa, LOE B), *amiodarone* (Class IIb, LOE B), or *sotalol* (Class IIb, LOE B) or *electrical cardioversion*.

In patients with known long QT during sinus rhythm, procainamide and sotalol should be avoided.

Procainamide is administered in the initial dose of 10 mg/kg, at rate of 20–50 mg/min. Maximum dose is 17 mg/kg. Maintenance infusion is 1–4 mg/min.

Amiodarone is given 150 mg IV over 10 min; dosing should be repeated to a maximum dose of 2.2 g IV for 24 h.

If an antiarrhythmic drug was already administered without success, it is advisable not to use a second drug without a cardiologist consult (Class III, LOE B) or proceed with electrical cardioversion (Class IIa, LOE C).

Lidocaine is now considered a drug of second choice for the treatment of ventricular tachycardia (dose: 1–1.5 mg/kg IV bolus). Maintenance infusion is 1–4 mg/kg (30–50 mcg/kg per min).

If the wide-QRS complex tachycardia is irregular, the underlying rhythm is likely to be an atrial fibrillation with aberrant conduction. In this case some considerations about the best treatment (rate control or rhythm control) are necessary, in particular:

- Avoid cardioversion if the arrhythmia has been present for more than 48 h (and the patient is stable enough). Consider treatment options with the consultant cardiologist, in particular transesophageal echocardiography to exclude the presence of a thrombus in the left atrium.
- Administer IV *heparin* before cardioversion if not contraindicated.

Irregular polymorphic tachycardia needs an immediate defibrillation. Drugs that may prolong the QT interval should be withdrawn and serum electrolytes corrected.

Myocardial ischemia is the most common cause of polymorphic VT in absence of a prolonged QT interval. In this circumstance amiodarone and sotalol are able to reduce the recurrence of the arrhythmia (Class IIb, LOE C).

1.2.2 Bradycardia

A heart rate below 60 bpm is usually defined as bradycardia. While in young healthy subjects and particularly in athletes it can be a common and non-suspect remark, it can conceal various kinds of diseases.

Usual symptoms of bradycardia are asthenia, fatigue, dyspnea, chest discomfort or pain, pre- or complete loss of consciousness, light-headedness, and decreased level of

consciousness. Signs often noticeable are hypotension and/or orthostatic hypotension, diaphoresis, bradycardia-related (escape) frequent premature ventricular complexes, or other ventricular tachyarrhythmias. All the signs and symptoms are due to the discrepancy between the low heart rate and the metabolic requests of the organism.

Usually symptoms are relevant when lower than 40 bpm or higher in presence of a pre- or coexistent cardiac disease [1, 2, 11–13].

First approach: whatever is the underlying cause, ED physician must define the hemodynamic compensation. If low heart rate is the cause of the symptoms, the patient should be immediately treated with drugs and percutaneous or transvenous pacing. The consultant cardiologist should be called to provide support to the diagnosis and treatment.

If the bradycardia is asymptomatic or the hemodynamic condition is acceptable, the thorough diagnosis can be ruled out with more smoothness.

As soon as possible, a 12-lead ECG should be obtained, with a long stripe in II or V1, to unmask atrial activity, for example, the presence of not-detected 2:1 AV block. A complete physical examination and blood tests for troponin, drugs, electrolytes, and serum creatinine must be performed in the meanwhile. If available, an echocardiogram should be used. Chest X-rays or thoracic echography can help to clear up pulmonary edema or congestive heart failure [1, 2, 11, 12].

Based on the ECG findings, we can discern the following rhythms:

1.2.3 Sinus Bradycardia

It can be a sign of underlying pathologies (e.g., vagal hypertonia, drug effect, hypoxia, ischemia of sinoatrial node due to occlusion of right coronary arteria, etc.).

ECG shows a regular sinus rhythm with heart rate lower than 60 bpm and a constant 1:1 AV conduction with PR interval of 120–200 ms (in the absence of coexistent AV block); P waves are regular, with identical waveform, axis between 0 and 90°.

Symptoms can be absent at rest and may appear only during effort.

Common causes are listed in Table 1.2.

Table 1.2 Common causes of sinus bradycardia

Vagal stimulus	Vomit, abdominal pain (i.e., acute retention of urine, acute abdomen, aortic aneurysm), Valsalva maneuver, carotid sinus hypersensitivity
Drugs	β-blockers, Ca^{++} channel blockers, ivabradine, digoxin, amiodarone, quinidine, and virtually all the antiarrhythmic drugs
Hyperkalemia	Acute or chronic heart failure, ACE-I or K+ savers drugs
Hypothermia	
Hypothyroidism	Autoimmune diseases, inappropriate levothyroxine dosage in known hypothyroidism
Endocranial hypertension	Acute endocranial hemorrhage
Sinoatrial node hypoperfusion	Right coronary ischemia
Sinoatrial sick syndrome	

It is clear from the analysis of the abovementioned causes how crucial it is to find the underlying etiology of the sinus bradycardia [14].

1.2.4 Pitfalls

Not maintaining a high and broad index of suspicion for underlying causes

1.2.5 Low-Rate Atrial Fibrillation

It is characterized by the absence of recognizable P wave, irregular RR intervals, and narrow or wide QRS complexes depending on the previous history of the patient.

Most common causes are drugs (as most antiarrhythmic drugs, digoxin, β-blockers, Ca^{++} antagonists), especially in older patients with reduced renal and/or liver function, vagal hypertonia (mainly in young subjects), or atrioventricular (AV) block. The presence of complete AV block ventricular rate is regular, because of junctional (usually at about 35 bpm) or infrahisian ventricular escape (<30 bpm).

Treatment of symptomatic extreme bradycardia consists in drugs (amines) or transcutaneous or intracardiac transvenous pacing to reach hemodynamic stability.

In elderly patients the most bradyarrhythmias are drug related and will wear off as the involved drugs (e.g., digoxin, β -blocker) wash out; in some cases consider starting with atropine followed by amines [7].

1.2.6 Sinus Node Dysfunction: Sick Sinus Syndrome

Sick sinus syndrome is a condition characterized by a wide spectrum of rhythm disturbances: bradycardia, sinusal arrest, paroxysmal atrial tachycardia, and bradycardia/asystole.

Clinical appearance ranges from asthenia, mental dizziness to syncope, vertigo, and cardiac failure.

Common causes are idiopathic degeneration of sinoatrial node and/or the atrial conduction tissue, right coronary ischemia, and flogistic and infiltrative diseases. More often drugs can be blamed, as beta-blockers, digoxin, Class I and III antiarrhythmic agents, and Ca++ channel blockers.

Tricyclic antidepressant, 4-phosphodyesterase inhibitors and Beta stimulant may induce atrial tachyarrhythmia.

Diagnosis can be reached by anamnesis, ECG, dynamic ECG (Holter, loop recorder), and electrophysiological study (endocavitary or transesophageal).

Depending on the prevalence of tachy- or bradycardia and the underlying cardiac disease, the therapy can vary from drugs to definitive pacing.

Indications for pacemaker implant are symptoms related to bradycardia.

1.2.7 Atrioventricular (AV) Blocks

AV blocks are commonly caused by:

- Lesions of the electrical conduction system of the heart (necrosis, fibrosis, sclerosis)
- Vagal hypertonia (inferior acute myocardial infarction, hypersensitivity of carotidal sinus, vagal maneuvers, abdominal pain, etc.)
- Increase of the refractory period (drugs)

Based on clinical and ECG findings, AV blocks are divided into:

- First-degree AV block (*prolonged* AV conduction *without any AV interruption*)
- Second-degree AV block (*intermittent* AV conduction)
- Third-degree (or complete) AV block (*complete* interruption of AV conduction)

1.2.8 First-Degree AV Block

PR interval is >200 ms with all P waves conducted to the ventricle; it is most commonly iatrogenic in patients treated with β- and Ca + channel blockers and digoxin or can be secondary to vagal hypertonia; less often the cause is an acute coronary syndrome of the right coronary artery involving AV node [15].

1.2.9 Second-Degree AV Block Type I (Wenckebach: Mobitz I)

There is a progressive increase of the PR interval, until a P wave is not followed by a QRS complex. The block is usually located in the AV node ("suprahisian"). Most common causes are drugs (β- and Ca^{++} channel blockers, digoxin) and vagal hypertonia. It can also be secondary to ischemia of the AV branch of the right or the circumflex coronary artery. It can rarely evolve to a higher degree AV block. Therefore therapeutic options are based on the identification of the causes and usually require no more than observation. When symptomatic and if vagal tone is involved, atropine 0.5 mg IV bolus (up to 3 mg in total) can transiently improve clinical status.

1.2.10 Higher Degree AV Blocks (Second-Degree AV Block Type II and Third-Degree AV Block)

Advanced AV blocks are a severe condition, which can quickly evolve into hemodynamic instability and/or cardiac arrest.

1.2.11 Second-Degree AV Block Type II (Mobitz II)

One or more P waves are not followed by a QRS complex without a progressive increase of the PR interval. Causes can be drugs (β- and Ca^{++} channel blockers,

digoxin, and other drugs as lithium) or a damage of the conduction pathways. It can be related to an acute coronary syndrome sometimes involving the left anterior descending coronary or one of its septal branches. It may easily evolve to a third-degree block or asystole, so it should be closely monitored.

1.2.12 Third-Degree AV Block

The ECG in the complete AV block shows a complete dissociation between atrial and ventricular activity with the complete absence of any AV conduction. Depending on the level of the block (suprahisian or infrahisian), the QRS morphology and ventricular rate can be different: in suprahisian block, escape rhythm arises from the AV junction (usually at 35–40 bpm, with narrow QRS complex); in infrahisian block, the rhythm arises from the ventricle; rate is less than 30 bpm with wide QRS complex.

In the presence of acute coronary syndrome, suprahisian blocks are usually secondary to an ischemia of the right coronary artery, while infrahisian blocks are frequently due to a huge ischemia within the interventricular septum due to a stenosis/occlusion of the left anterior descending coronary. Suprahisian blocks, like second-degree AV block type I, can be secondary to ischemia of the AV branch of the right or circumflex coronary artery and are usually more benign and recover spontaneously.

Complete AV block may also be related to drugs reducing AV conduction (β- and Ca^{++} channel blockers or digoxin) or reducing intraventricular conduction (as most antiarrhythmic drugs, leading to infrahisian blocks).

1.2.13 Accelerated Idioventricular Rhythm

In the presence of increased automaticity, ventricular rate may be higher than sinus rate (especially in the presence of sinus bradycardia), despite not exceeding 100/min. It is usually benign and asymptomatic; it can be a sign of reperfusion during acute coronary syndromes and should be treated only in presence of significant symptoms or hemodynamic impairment with drugs increasing sinus rate amines and atrial or ventricular pacing.

1.2.14 Treatment:

Treating an advanced-degree AV block requires fast choices [11–13, 16, 17]:

If hemodynamically unstable (Table 1.3):

- Activate the cardiologist for an IV pacing; discuss with him about the value of a coronarography when acute coronary syndrome is likely.
- As soon as possible, start transcutaneous pacing (with sedation).
- If not available, start drugs: dopamine (2–10 mcg/kg/min) or adrenaline (2–10 mcg/min).

Table 1.3 Unstable bradyarrhythmias

Treatment basic points consist in:
ECG, blood pressure, heart rate, respiratory rate, sat O_2 monitoring, hemodynamic assessment
Drugs: atropine, adrenaline or dopamine, isoproterenol
Guarantee the normal hemodynamic state
Emergency pacing should be considered if the need to maintain hemodynamic stability is imminent. As obvious this can be used only as a temporary means to bring the patient to a more stable solution (e.g., IV pacemaker)

If stable:

Evaluate the patient, and collect medical and drugs history; discuss with the cardiologist the management.

1.2.15 Pitfalls

- Confounding third-degree AV block with other bradyarrhythmias, in particular when similar atrial and ventricular rate are present ("iso-rhythmic dissociation"). It is necessary to evaluate very carefully the presence of the P wave (especially in leads V1 and DII) and the correlation with ventricular activity.
- Know your drugs: Atropine is quite ineffective on infrahisian blocks; amines increase oxygen consumption; isoprenaline–isoproterenol may provoke ventricular tachyarrhythmias, so it should be avoided, if possible, in the presence of ischemia.
- Always check if the transcutaneous pacing is achieving consistent capture by checking the femoral pulse.
- A low heart rate may not always be the cause of symptoms; it can be just a sign of other diseases. For example, sinus bradycardia and hypotension may be due to the vagal response in the presence of aortic dissection or Cushing's reflex during intracranial hypertension; in acute renal failure, elevated serum potassium can lead to significant bradyarrhythmias, while dehydration in prerenal acute renal failure can be the cause of the hypotension.

1.2.16 When Should the Consultant Cardiologist Be Called?

Any hemodynamic instability requires immediate intervention and support by the cardiologist to define the underlying causes and to help in the treatment.

High-degree AV blocks should be admitted to a monitoring-capable structure. Drugs withdrawn and indication to permanent pacemaker implantation have to be defined with the cardiologist [13].

A drug-related bradyarrhythmia may resolve after withdrawing the proarrhythmic treatment and requires amines or only temporary pacing.

Not all bradyarrhythmias need to be admitted into a cardiology ward. In the absence of high-degree AV block, stable patients may be safely admitted into medicine ward or even considered for discharge with an outpatient clinic follow-up program [1, 13, 17].

1.2.17 Definitive Pacemaker Indications

Briefly, indications to permanent pacing, in absence of transient or correctable causes, can be summarized as follows [19]:

Alternating or progressive bundle block (right bundle alternating with left bundle, right bundle + left anterior alternating with left posterior fascicular hemiblock)

Second-degree type II AV block: requires pacing when hemodynamically unstable and when the block is located in His bundle or below, even in asymptomatic patients

Third-degree AV block: indicates pacing in all acquired types, associated with syncope, hemodynamic instability, HR <40 bpm, or RR >3000 ms pauses

In older patients it's often difficult to determine the real cost/benefit ratio of a permanent pacemaker, and the balance between conservative and aggressive therapy should be discussed.

Absence of symptoms, a basal heart rate greater than 40 bpm, and the capacity of substitutive rhythm to increase the rate during physical activity may allow an observational strategy instead of a pacing immediate intervention [17].

1.2.18 A Suggested Algorithm/Pathway for Diagnosis and Treatment

	What to do	**How to do**
All patients	Assess hemodynamic status	Clinical evaluation NIBP, HR, RR, sat O2, body temperature monitoring, IV access
	Identify arrhythmia	ECG
	Identify underlying causes	Medical history, clinical evaluation, ECG, labs, EGA, echocardiography, chest X-ray, expert consulting
	Treat hemodynamic instability	Treat reversible causes; administer appropriate drugs; consider cardioversion or pacing if indicated

Tachyarrhythmia		**What to do**	**How to do**
		Treat instability	Perform immediate cardioversion (with procedural sedation if possible)
		Identify arrhythmia	ECG
	If narrow QRS complex		Manual maneuvers, adenosine if regular, beta-blockers, or Ca++ channel blockers. Consider rhythm control (CVES or drugs) if onset <48 h or rate control ± anticoagulant therapy if >48 h. Consider cardiologist consultant. Admit to ward if poorly tolerated hemodynamic status, severe or evolving underlying pathology, and uncontrolled heart rate regardless initial therapy
	If wide QRS complex		Consider adenosine only if regular monomorphic QRS is present; antiarrhythmic infusion, cardiologist consulting. Admit to ward if evolutive organic cardiopathy, persistence of tachyarrhythmia regardless antiarrhythmic therapy, polymorphic tachycardia, poorly tolerated hemodynamic status

Bradyarrhythmia	**What to do**	**How to do**
	Treat instability	Use atropine, dopamine, adrenaline, or isoprenaline or isoproterenol or perform immediate transthoracic pacing (with procedural sedation if possible). Consult the cardiologist
	Sinus bradycardia	Hemodynamic support, atropine. Identify and treat the underlying causes
	Identify arrhythmia	ECG
	Sick sinus syndrome	Dynamic ECG loop recorder, cardiologist evaluation; consider pacemaker implant
	If First-degree A V block or Second-degree AV block type I	Identify and treat underlying causes. Admit to ward if poorly tolerated hemodynamic status, severe or evolving underlying pathology, uncontrolled heart rate regardless initial therapy
	If high-degree AV blocks (II type II or III)	Be prepared to pace; consult the cardiologist. Admit to a monitoring capable ward

Syncope: First Evaluation and Management in the Emergency Department

2

Franco Giada and Andrea Nordio

2.1 Epidemiology of Syncope

Epidemiological studies conducted in the USA have estimated that 30 % of the general population experience at least one episode of syncope in their lifetime [1], which is responsible for about 1–3 % of admissions to the emergency department (ED) and 1–3 % of hospitalizations [2]. In Italy, syncope accounts for 1–2 % of both admissions to the ED and all hospitalizations [3–7]. About half of the patients attending emergency facilities for syncope are subsequently hospitalized; the mean duration of hospitalization is about 8 days [3–7]. Moreover, in industrialized countries the progressive aging of the population, together with the higher prevalence of syncope among elderly subjects, are likely to increase the impact of syncope on healthcare systems in the near future [6].

2.2 Costs of Syncope

The fact that syncope may be caused by pathological conditions that have a severe prognosis, together with the lack of a diagnostic gold standard, results in frequent hospitalization and the prescription of numerous costly instrumental investigations, which increase healthcare costs. One North American study [8] estimated in 1993 that the mean annual cost per patient hospitalized for syncope was US$4132. In the case of recurrent syncope, this figure rose to US$5281. In the USA the total annual

DOI 10.1007/978-3-319-24328-3_2

cost of syncope amounts to $2.4 billion, similar to that for chronic respiratory diseases and human immunodeficiency virus. In studies conducted in Italy, the mean cost per patient hospitalized for syncope is reported to vary from €1000 to €3000 [9]. These costs are chiefly conditioned by the duration of hospitalization and by the number and type of diagnostic investigations carried out.

Thus, syncope places a considerable burden on healthcare resources. The implementation of an appropriate diagnostic and therapeutic strategy for tackling the problem of syncope in the ED therefore constitutes a challenge from clinical, organizational, and economic standpoints.

2.2.1 Difficulties in the Management of Patients with Syncope in the ED

Syncope is defined as a self-limiting transient loss of consciousness (TLOC), which usually causes falls. The onset of syncope is relatively sudden and the recovery is spontaneous, complete, and rapid. The underlying pathophysiological mechanism is transitory global brain hypoperfusion [10].

The first difficulty encountered in ED in the management of patients who present with TLOC is to distinguish syncope from losses of consciousness (Fig. 2.1) not caused by cerebral hypoperfusion (e.g., epilepsy, metabolic disorders, vertebrobasilar transient ischemic attack, hypoxia), or from conditions with only apparent loss

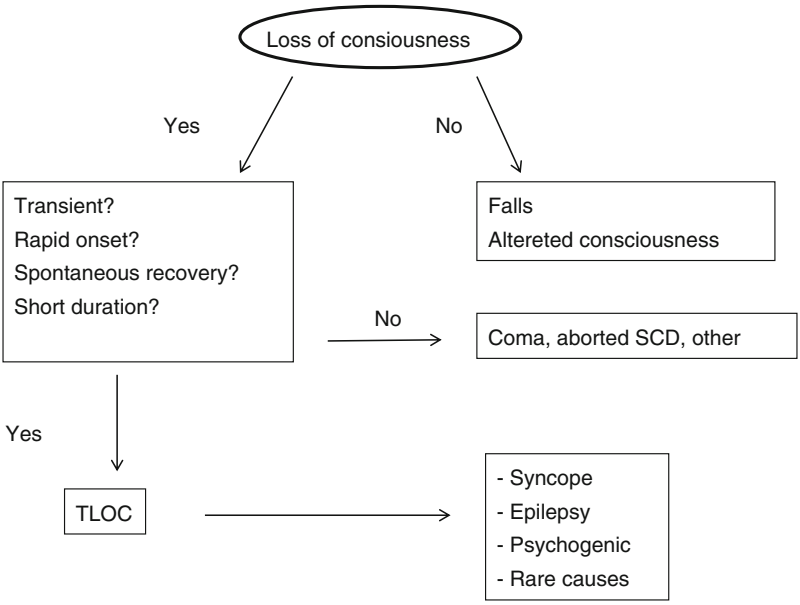

Fig. 2.1 Context of transient loss of consciousness. *SCD* sudden cardiac death, *TLOC* transient loss of consciousness

Table 2.1 Conditions incorrectly diagnosed as syncope

Disorders with partial or complete LOC (without global cerebral hypoperfusion)
Epilepsy
Metabolic disorders including hypoglycemia, hypoxia, hyperventilation with hypocapnia
Intoxication
Vertebrobasilar TIA
Disorders without impairment of consciousness
Cataplexy
Drop attacks
Falls
Functional (psychogenic pseudosyncope)
TIA of carotid origin

LOC loss of consciousness, *TIA* transient ischemic attack

of consciousness (drop attack, cataplexy, psychogenic pseudosyncope, accidental falls in the elderly) [10] (Table 2.1). Moreover from an etiological standpoint, syncope is classified within three main groups: neuromediated or reflex (representing the epidemiologically prevalent cause of syncope), orthostatic, and cardiac (arrhythmic or structural, the second most common cause of syncope). Each of these groups comprises numerous disorders that may manifest in the form of syncope and are not always easy to evaluate (Table 2.2). Finally, the prognostic significance of syncope depends on the underlying pathology, ranging from the generally benign prognosis seen in neuromediated syncope to the more severe prognosis associated with cardiac syncope.

This syncope often raises diagnostic and therapeutic problems which is proved by the diversity of the pathways followed by patients attending the ED. Indeed, data from the literature [4–7] reveal that these patients may be hospitalized in cardiology, neurology, pediatric, geriatric, internal medicine, and orthopedic wards. These patients then undergo, often inappropriately, several instrumental examinations that are costly and have a low diagnostic yield. The result is that hospitalization is prolonged and healthcare costs rise, while a correct diagnosis of the cause of syncope fails to be reached in a high percentage of cases. As the risk of malpractice suits is high in this field, ED physicians often adopt a strategy of "self-defense," which results in an increase of the number of hospitalizations and inappropriate instrumental investigations. Thus, the current management of syncope displays little diagnostic efficacy and considerable economic inefficiency.

The factors underlying these disappointing results can be summed up as follows: insufficient competence and attention on the part of physicians with regard to the differential diagnosis of TLOC, owing to the difficulty of tackling this problem in a multidisciplinary manner; a "defensive" stance prompted by the possible legal implications of a wrong diagnosis; and, in various healthcare institutions, the lack of diagnostic and therapeutic facilities specialized in the management of syncope patients [11, 12].

Table 2.2 Classification of syncope

Neurally mediated syncope
Vasovagal cause
Mediated by emotional distress (fear, pain, instrumentation blood phobia)
Orthostatic stress
Situational
Sneeze, cough
Gastrointestinal stimulation (defecation, abdominal pain, swallowing)
After micturition
After exercise
Postprandial
Others
Carotid sinus syncope
Forms without apparent triggers or atypical presentation
Orthostatic hypotension syncope
Primary autonomic failure
Pure autonomic failure, multiple atrophy, Parkinson disease with autonomic failure
Lewy body dementia
Secondary autonomic failure
Diabetes, amyloidosis, uremia, spinal injuries
Drug-induced orthostatic hypotension
Alcohol, vasodilators, diuretics, antidepressants
Volume depletion
Hemorrhage, diarrhea, vomiting, etc
Cardiovascular syncope
Arrhythmia as primary cause
Bradycardia: sinus node dysfunction, AV conduction system disease, implanted device dysfunction
Tachycardia: supraventricular, ventricular
Drug-induced bradycardia and arrhythmias
Structural disease
Cardiac: valvular diseases, AMI, hypertrophic cardiomyopathy, etc
Others: acute aortic dissection, pulmonary hypertension, pulmonary embolus

2.2.2 The Recommended Management of Syncope in the ED

Most of the direct cost of syncope is attributable to hospitalization. A proper diagnostic evaluation and prognostic stratification of syncope in the ED should limit hospitalization to patients suffering from heart disease, serious neurological diseases, or severe secondary traumas.

In 2009 the European Society of Cardiology developed guidelines on the management of syncope [10]. This document defined what has become the current standard for the management of patients with TLOC and the most valuable diagnostic pathway, and gave recommendations on indications and interpretation of diagnostic tests with indications for hospitalization and treatment.

According to the guidelines, the cornerstone in syncope management in the ED is the initial clinical evaluation, i.e., history, physical examination, recumbent and orthostatic blood pressure measurement, and electrocardiogram (ECG).

Patients should be interrogated about:

- The circumstances (position and activity of the patient, presence of predisposing factors) and symptoms (nausea, dizziness, palpitations) occurring just before the attack
- Manner of fall (slumping or kneeling over), duration, and whether movements were present during LOC (if witnessed)
- Number, frequency of spells, and age at first episode
- Family history of cardiac disease or sudden death, neurological history, metabolic disorders

Consultation by a cardiologist is indicated when a cardiac cause is suspected or ascertained, particularly in cases of:

- Presence of definite heart disease, family history of sudden death, or channelopathy
- Syncope during exertion or in supine position
- Sudden onset of palpitation prior to the syncope

ECG abnormalities such as intraventricular delay with QRS duration >120 ms, Mobitz II second-degree atrioventricular block, sinoatrial pauses >3 s, nonsustained ventricular tachycardia, preexcitation, long or short QT intervals, Brugada pattern, negative precordial T waves suggestive of right ventricular dysplasia, Q waves suggesting previous myocardial infarction, pacemaker/implantable cardioverter-defibrillator malfunction.

Neurological consultation (Fig. 2.2) is indicated for a nonsyncopal TLOC cause (epilepsy, transient ischemic attack, subclavian steal syndrome, psychogenic pseudosyncope), especially in cases of:

- Presence of aura before the event
- Tonic-clonic movements coinciding with the onset of LOC (and not some seconds later) or hemilateral
- Clear automatisms or tongue biting
- Prolonged confusion after the episode
- Family history of seizures, sleepiness or headache after the event

Specific tests such as neurological investigations or blood tests are only indicated for a suspicion of nonsyncopal TLOC.

This strategy requires adequate clinical competence on the part of all of the physicians involved in the management of these patients. Table 2.3 presents the diagnostic criteria that permit a diagnosis of the causes of syncope in the ED by means of initial evaluation, and Table 2.4 lists the clinical features that suggest a diagnosis.

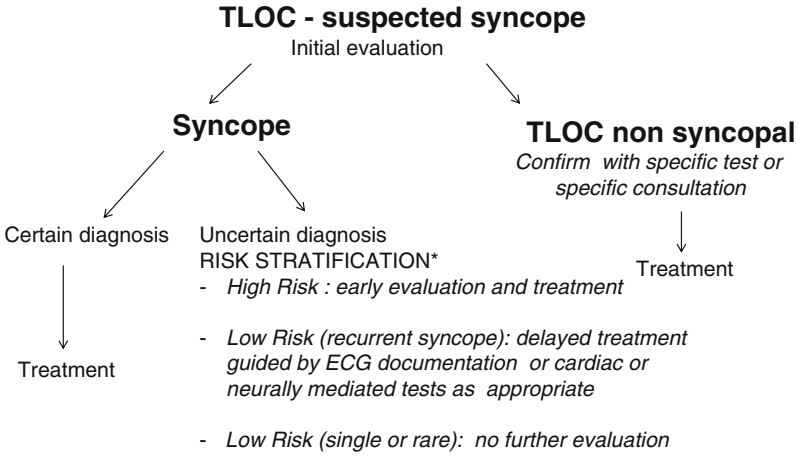

Fig. 2.2 Diagnostic flowchart of patients with suspected T-LOC.*May require laboratory investigations. *ECG* electrocardiographic, *TLOC* transient loss of consciousness

Table 2.3 Diagnostic criteria of causes of syncope with initial evaluation

Vasovagal syncope is diagnosed if syncope is precipitated by emotional distress or orthostatic stress, and is associated with typical prodrome
Situational syncope is diagnosed if syncope occurs during or immediately after specific triggers listed in Table 2.2
Orthostatic syncope is diagnosed when it occurs after standing up and there is documentation of OH
Arrhythmia-related syncope is diagnosed by ECG when there is:
Persistent bradycardia (<40 bpm in awake or repetitive sinoatrial block or sinus pauses >3 s)
Mobitz II or III degree AV block (second or third degree)
Alternating BBB (left and right)
VT or rapid paroxysmal SVT
Polymorphic VT nonsustained and long or short QT interval
PM or ICD malfunction with cardiac pauses
Cardiac ischemia related syncope is diagnosed when syncope presents with ECG evidence of acute ischemia with or without myocardial infarction
Cardiovascular syncope is diagnosed when syncope presents in patients with prolapsing atrial myxoma, severe aortic stenosis, pulmonary hypertension, pulmonary embolus, or acute aortic dissection

AV atrioventricular, *BBB* bundle-branch block, *ECG* electrocardiogram, *PM* pacemaker, *ICD* implantable cardioverter-defibrillator, *OH* orthostatic hypotension, *SVT* supraventricular tachycardia, *VT* ventricular tachycardia, *VVS* vasovagal syncope

The ideal TLOC management should lead, through initial clinical evaluation, to an identification of the nature of the TLOC (syncope or syncope-like conditions) and, in the case of syncope, to an etiological diagnosis and a rapid stratification of patients into three categories (Fig. 2.3):

Table 2.4 Clinical features suggesting a diagnosis at initial evaluation

Neurally mediated syncope
Absence of heart disease
Recurrent syncope history
After sudden unexpected unpleasant sight, sound, smell, pain
Vomiting, nausea during syncope
Prandial or postprandial
After exertion
With head rotation or pressure on carotid sinus
Syncope due to orthostatic hypotension
After standing up
Start or changes of dosage of vasodepressive drugs
Prolonged standing (crowded hot places)
Autonomic neuropathy or Parkinsonism
Standing after exertion
Cardiovascular syncope
Structural heart disease
Family history of channelopathy or USD
Supine or during exertion
ECG findings suggesting arrhythmic syncope:
LBBB or RBBB combined with LA or LP fascicular block
Intraventricular conduction abnormalities (QRS >120 s)
Mobitz I second-degree AV block
Asymptomatic inappropriate sinus bradycardia (<50 bpm)
Nonsustained VT
Preexcited QRS complexes
Long or short QT intervals
Early repolarization
RBBB pattern with ST elevation in leads V1–V3
Q waves suggesting myocardial infarction

USD unexpected sudden death, *LBBB* left bundle-branch block, *RBBB* right bundle-branch block, *LA* left anterior, *LP* left posterior, *VT* ventricular tachycardia

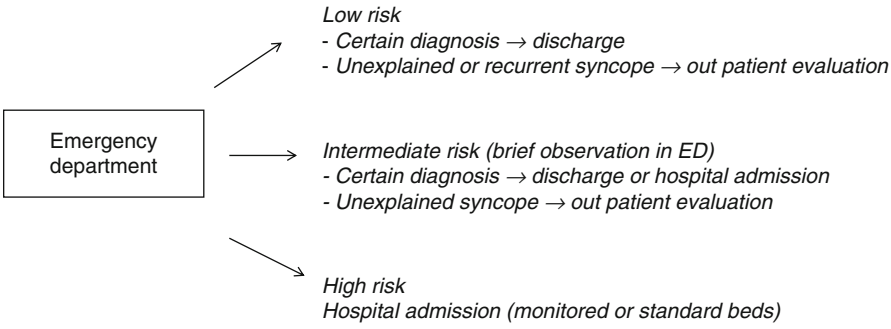

Fig. 2.3 Diagnostic pathway for the management of patients admitted to the ED for syncope

- *Low-risk patients*, who can be handled in the outpatient clinic by the general practitioner or specialist, on an ordinary time schedule, and requiring few, if any, selected examinations [15]; this group includes patients with very likely neurogenic syncope and without injuries
- *Intermediate-risk patients*, who need to be managed within a short time in a specialist outpatient clinic or by means of brief observation in the emergency department, when high risk is not evident but cannot be immediately excluded
- *High-risk patients*, who need to be hospitalized urgently and to immediately undergo appropriate diagnostic and therapeutic procedures. This group includes patients with severe structural or coronary heart disease (heart failure, severe left ventricular dysfunction, previous myocardial infarction), clinical or ECG features suggesting arrhythmic syncope (see above), or important comorbidities (Table 2.5)

Finally, the European guidelines recommend that rapid risk stratification in the ED can be achieved by using the following two scores:

- The OESIL Risk Score [12], which is easy to apply and it includes age >65 years, underlying disease, syncope without prodromes, and an abnormal ECG. A total score of 0 represents 0 % mortality and a score of 1 is associated with <1 % mortality at 1 year. Scores of 3 (mortality of 35 % derivation/29 % validation sets) and 4 (mortality of 57 % and 53 % derivation and validation sets, respectively) carry significantly greater risk.
- The EGSYS Risk Score [13], which shows that the presence of abnormal ECG and/or the presence of structural cardiac disease are the main factors predictive

Table 2.5 Clinical criteria to identify short-term high-risk patients

Severe structural CAD (HF, low LVEF, MI)
Clinical or ECG aspects suggesting arrhythmic syncope
During exertion or supine
Palpitations (during the syncope)
Bifascicular block
Intraventricular conduction abnormalities (QRS >120 ms)
Inadequate sinus bradycardia or SA block in absence of negative chronotropic medications or physical training
Preexcited QRS complex
Prolonged or short QT interval
RBBB pattern with ST elevation (V1–V3 leads)
Negative T waves in right precordial leads, epsilon waves, and ventricular late potentials (ARVC)
Important comorbidities
Anemia (severe)
Electrolyte disturbance

CAD coronary artery disease, *HF* heart failure, *LVEF* left ventricular ejection fraction, *MI* myocardial infarction, *RBBB* right bundle-branch block, *ARVC* arrhythmogenic right ventricular cardiomyopathy

Table 2.6 Risk stratification at initial evaluation in OESIL and EGSYS studies

Study	Risk factors	Score	Endpoints	Results (validation cohort)
OESIL [12]	Abnormal ECG	0–4 (1 point each item)	1 year total mortality	0 % score 0
	Cardiovascular disease (history)			0.6 % score 1
	Lack of prodrome			14 % score 2
	Age >65 years			29 % score 3
EGSYS [13]	Palpitations before syncope (+4)	Sum of + and − points	2 year total mortality	2 % score < 3
	Abnormal ECG and or heart disease (+3)			21 % score ≥3
	Syncope during effort (+3)			
	Syncope while supine (+2)		Cardiac syncope	2 % score < 3
	Predisposing/precipitating factors (−1)			13 % score 3
	Autonomic prodrome (nausea, vomiting) (−1)			33 % score 4
				77 % score > 4

of mortality in 2 years; this score has a very good diagnostic yield in identifying syncope of cardiac origin (Table 2.6).

This strategic course underlines that prognostic stratification and the choice of instrumental investigations selected on the basis of the characteristics of each patient are crucial to the cost-effective management of patients with syncope in the ED [14–17].

Management of Bradyarrhythmias in Emergency

3

Luca Salvatore, Silvia Magnani, Gerardina Lardieri, and Elena Zambon

The sudden appearance in patients of changes in heart rhythm is a situation that requires rapid diagnosis and treatment in emergency departments and intensive care units. The slowdown and block of cardiac impulse conduction form the basis of symptomatic bradycardia.

The prevalence of cardiac bradyarrhythmias and conduction disturbances in outpatients evaluated for the first time is 30–40 %, with an incidence of 3 % for atrioventricular (AV) block and sinus node dysfunction, and 8 % for disorders of intraventricular conduction [1].

Dysfunction of the sinus node has significant clinical implications. Development of concomitant AV block is not uncommon (incidence 8.4 %), as is the presence or appearance of atrial fibrillation (AF), especially in patients already treated with only ventricular pacing (incidence 22 %), with a consequent high risk of systemic thromboembolism [2, 3]. In elderly patients a low heart rate can promote the development or worsening of heart failure, even in the presence of preserved systolic function [4].

The onset of arrhythmias after cardiac and noncardiac surgery, a relatively common occurrence, is a major predictor of morbidity of surgical procedures and is associated with a prolonged hospital stay, although severe bradyarrhythmias requiring treatment occur in less than 1 % of cases. Triggers are generally transient events such as hypoxia, myocardial ischemia, excess catecholamine, or electrolyte disorders [5, 6].

3.1 Anatomy and Pathophysiology

The cardiac impulse begins in the *sinus atrial node*, located in the upper lateral wall of the right atrium near the superior vena cava, vascularized by the right coronary artery (60 %) and the circumflex artery (40 %). The impulse reaches the AV node, which, through the nodal-Hisian system, connects the atria with the ventricles. The nodal-Hisian system is formed by the *AV node* (located in the front part of the Koch triangle, vascularized by the right coronary artery) and the *bundle of His* (vascularized by both the left and right coronary artery). The bundle of His is divided into the *right branch* (vascularized by the anterior descending artery and right coronary artery) and the *left branch*, which in turn is divided into two bundles, the anterior (vascularized by the anterior descending artery) and the posterior (vascularized by the circumflex artery). From here the Purkinje fibers originate, guaranteeing simultaneous activation of the ventricles.

3.2 Bradycardia

A heart rate of less than 60 bpm is usually considered as bradycardia. The usual symptoms of bradycardia are asthenia, fatigue, dyspnea, chest discomfort or pain, prior or complete loss of consciousness, light-headedness, and decreased level of consciousness. Frequent noticeable signs include hypotension and/or orthostatic hypotension, diaphoresis, bradycardia-related (escape) frequent premature ventricular complexes, or other ventricular tachyarrhythmias. Usually the symptoms are relevant when the heart rate is lower than 40 bpm, or higher in the presence of a pre- or coexistent cardiac disease.

Hemodynamically unstable bradycardia may represent a serious life-threatening emergency, with 30-day mortality rates of up to 16 % being reported [7–9]. Bradycardia can be the expression of the dysfunction of *automaticity* or the *conduction* of the electrical impulse, and can be detected at all levels of the conduction system (sinoatrial node, AV node, intraventricular branches).

3.3 Sinus Node Dysfunction

The main manifestations of sinus node dysfunction are *sinus bradycardia* and *sinus arrest*.

Sinus node dysfunction recognizes *intrinsic* causes: degenerative disease, chronic or acute ischemia, infiltrative disease (amyloidosis, hemochromatosis, tumors), inflammatory causes (pericarditis, myocarditis), musculoskeletal disease (Duchenne dystrophy, Friedreich ataxia), vasculitis (systemic lupus erythematosus, scleroderma), and surgical (atrial septal defect correction); and *extrinsic* causes: drugs (amiodarone, flecainide, propafenone, sotalol, chinidina, disopyramide, procainamide), electrolyte disorders (hyperkalemia), endocrinopathies (hypothyroidism), vagal reflex during ischemia, neuromediated syndrome (vasovagal, cough, carotid sinus hypersensitivity), intracranial hypertension, and obstructive jaundice.

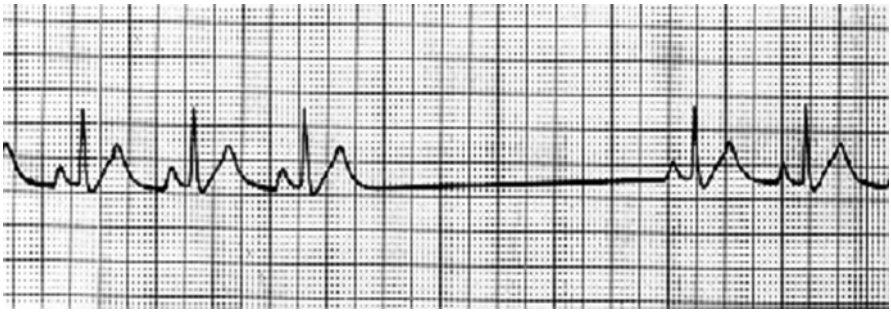

Fig. 3.1 Sinus arrest

3.3.1 Sinus Bradycardia

Sinus bradycardia can be secondary to intrinsic factors such as fibrosis (aging or loss of "pacing cells" [10, 11] resulting from inferior myocardial infarction, or to extrinsic factors such as an increased vagal tone, an abnormal neurocardiogenic reflex, drugs such as β-blockers or Ca^{2+} antagonists, or drugs reducing sympathetic tone such as sympatholytic antihypertensives [12].

The electrocardiogram (ECG) shows a regular sinus rhythm with heart rate lower than 60 bpm and a constant 1:1 AV conduction, with a normal PR interval (120–200 ms); P waves are regular, with the same shape and axis between 0° and 90°.

Symptoms can be absent at rest and may appear only during effort. In general, sinus bradycardia does not require treatment; intravenous atropine can be effective, but is useful only for short-term treatment because of its short half-life; sometimes temporary or permanent pacing may be necessary, favoring atrial over ventricular stimulation [13, 14].

3.3.2 Sinus Arrest

Sinus arrest is the absence of onset of spontaneous atrial impulse. It is generally considered significant when this pause lasts longer than 3 s. The most common causes are tissue fibrosis, ischemia, digoxin intoxication, cerebral ischemia, and excessive vagal tone (Fig. 3.1).

3.4 Atrioventricular Block

Atrioventricular block occurs when the conduction of the atrial impulse to the ventricles slows down or is blocked (paroxysmal or permanently), even though the AV junction is not physiologically refractory.

In the presence of a high atrial rate (e.g., atrial tachycardia or AF), the term AV block is correct only if the ventricular rate is lower than 60 bpm.

There are three anatomical sites of block: (1) above Hisian (inside the AV node), (2) intra-Hisian (inside the His bundle), and (3) infra-Hisian (distal His bundle or bundle branches).

The identification of anatomical site is relevant, as the distal blocks are those with the worst prognosis.

3.4.1 First-Degree AV Block

Every single atrial impulse is followed by a QRS complex, but the PR interval is greater than 200 ms. The block is usually above the AV node, even if there may be a wide QRS complex caused by a coexisting bundle-branch block. In general it is not associated with heart disease, and is usually secondary to increased vagal tone or is drug related (β-blocker or digoxin), although sometimes it can be associated with myocardial ischemia, infiltrative myocardiopathies, myocarditis, Addison disease, or congenital heart disease (septal defect, Ebstein). Prognosis, however, is benign, and no treatment is required. An exception can be the occurrence of a first-degree AV block in aortic valve endocarditis resulting from an abscess of the interventricular septum.

3.4.2 Second-Degree AV Block

Conduction from the atria to the ventricles is intermittent. There are two types of second-degree AV block.

Type I, also known as Mobitz I or Luciani-Wenckebach, involves progressive increase of the PR interval and consequent shortening of the RR interval until a nonconducted P wave develops. The morphology of the QRS complex is normal. The site of the block is usually at or above the AV node [15]. Etiology mainly includes digoxin intoxication, myocardial ischemia (inferior myocardial infarction), excess calcium deposits such as occur in aortic stenosis, or renal insufficiency. It can be also observed in both trained athletes and normal persons during sleep, attributable to increased vagal tone [16–18]. Prognosis is excellent if asymptomatic, while the onset of symptoms such as syncope or heart failure may require the placement of a definitive pacemaker.

Type II (Mobitz II) shows a sudden block of a P wave with a ratio of 3:2, 4:3, and so forth. PP and RR intervals are regular (Fig. 3.2). The block is intra- or infra-Hisian, and tends to progress toward complete AV block with prolonged ventricular pause and syncope [19]. Guidelines favor permanent pacing even in asymptomatic patients with type II block [20].

3.4.3 Atrioventricular Block with 2:1 Conduction

This condition is characterized by an intermittent block with a P/QRS ratio of 2:1, thus having features of both Mobitz I and II. Block can be at any nodal site and

Fig. 3.2 II degree–Mobitz 2 AV block (with intraventricular delay)

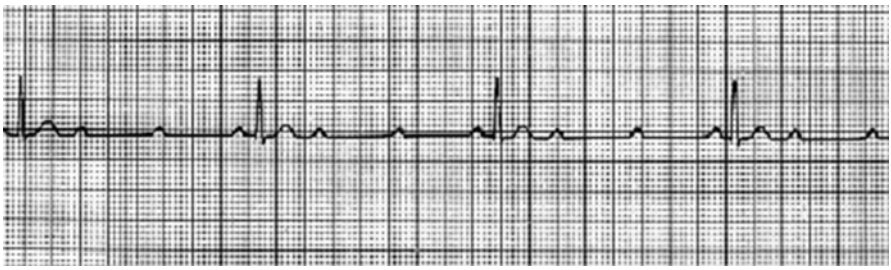

Fig. 3.3 Advanced (3:1) tipo II AV block

intra- or infra-Hisian, the severity depending on the resultant ventricular rate. In an asymptomatic patient a 2:1 block with a coexisting bundle-branch block is an indication for pacing, assuming that the block is infranodal [21].

3.4.4 Advanced AV Block

In advanced AV block, two or more consecutive P waves are blocked with a P/QRS ratio of 3:1, 4:1, and so forth (Fig. 3.3). In everyday practice this term is also used for low-rate permanent AF.

3.4.5 Low-Rate Atrial Fibrillation

The absence of recognizable P wave, irregular RR intervals, and narrow or wide QRS complexes characterizes low-rate AF. Causes are usually drugs (antiarrhythmic, digoxin, β-blockers, Ca^{2+} antagonists), especially in elderly patients with impaired renal and/or liver function, vagal hypertone (young subjects), or impaired AV conduction.

Treatment consists in ensuring hemodynamic normality using drugs (atropine followed by amines) or transcutaneous or transvenous pacing in symptomatic bradycardia.

3.4.6 Third-Degree AV Block

The inability of P waves to conduct to the ventricles (complete block of AV conduction) characterizes third-degree AV block. There is no relationship between P waves and QRS complexes, which are escape beats. Narrow QRS escape rhythms, with regular RR and a frequency between 40 and 60 bpm, are secondary to blocks within the AV node. Wide QRS escape rhythms with frequency between 40 and 20 bpm are secondary to infra-Hisian blocks.

In patients with AF and complete AV block a regular ventricular rate is observed, because of junctional (usually at about 35 bpm) or infra-Hisian escape rhythm.

Third-degree AV block can be secondary to pharmacologic treatments (digoxin, β-blockers, Ca^{2+} antagonists, quinidine, procainamide) or sclerodegenerative phenomena of conduction fibers, or may occur during the acute phase of myocardial infarction. Prognosis is more favorable if associated with inferior myocardial infarction (supra-Hisian block, narrow QRS escape rhythm, and generally spontaneous resolution), while the prognosis is worse in anterior myocardial infarction (infra-Hisian block and wide QRS escape rhythm, generally associated with a wider area and less reversibility of ischemic injury).

Less common causes include infectious diseases (myocarditis, Lyme disease, Chagas disease), rheumatic etiology (Reiter syndrome, scleroderma, rheumatoid arthritis), infiltrative disease (amyloidosis, sarcoidosis, multiple myeloma), electrolyte disorders, and iatrogenic factors (cardiac surgery, radiofrequency ablation) (Fig. 3.4).

3.4.7 Interventricular Block

Left bundle-branch block (LBBB) is a rare finding in the young population, and when present should raise the suspicion of an underlying heart disease. Incidence increases with age [22] and is associated with various causes of heart disease (hypertensive, ischemic, valvular, idiopathic dilated cardiomyopathy). Prognosis depends on the severity of the underlying disease.

Left anterior hemi-block (LAHB), more frequent in the adult male population, is associated with hypertension and ischemic heart disease. Progression to LBBB or complete AV block is uncommon [23].

Left posterior hemi-block (LPHB) is a rare isolated finding because of both the short course and double vascularization of the left posterior fascicle.

Right bundle-branch block (RBBB) as an incidental ECG finding is not often linked to heart disease, but may be associated with systemic hypertension, pulmonary heart disease, or ischemic heart disease.

Bifascicular block commonly indicates the association of an interruption or delay in impulse conduction along both sets of left bundle branch, or along the right branch and one of the two sets of left bundle branch.

RBBB + LAHB, a more common condition, shows a progression to complete AV block in less than 6 % of patients, while RBBB + LPHB, less frequent, has a greater progression toward complete AV block (close to 75 %).

Patients with bifascicular block associated with first-degree AV block (especially infranodal, when the HV interval, documented during invasive electrophysiological evaluation, is >100 ms) have a higher risk for developing complete AV block, and some authors recommend permanent cardiac stimulation [24]. The diagnosis of trifascicular block can be made on surface ECG only in the presence of alternating bundle-branch block (LBBB alternating with RBBB, or RBBB + LAHB alternating with RBBB + LPHB).

3.4.8 Atrioventricular Dissociation

AV dissociation is present when atrial activity is independent from ventricular activity, both occurring at regular rates. AV dissociation is not synonymous with AV block; in fact while patients with AV block also have an AV dissociation, patients with AV dissociation may not have an AV block, for example when an escape junctional (or ventricular) rate is higher than the sinus rate in the absence of retrograde ventricular-atrial conduction.

Elderly patients with degenerative cardiac disease are more likely to have AV dissociation [25].

Treatment depends on the causes, and ranges from antiarrhythmic drug treatment to permanent pacemaker placement.

3.4.9 Conduction Disturbances during Acute Myocardial Infarction

Sinus node dysfunction in the course of myocardial infarction may be secondary to the occlusion of the circumflex artery or the right coronary artery. The bradycardia that follows may favor escape rhythms with narrow QRS, which originate at the junction or in the His bundle and have a heart rate of about 50–60 bpm becoming stable over time, whereas escape rhythms with wide QRS originate from the Purkinje fibers with a heart rate below 40 bpm, are less stable, and may evolve to asystole. The AV block that occurs in the early stages of myocardial infarction is generally secondary to hypervagotonia and is reversible with atropine, while blocks occurring later are frequently related to ischemia of the AV node.

Second-degree type I AV block during inferior myocardial infarction tends to resolve spontaneously within 48 h and does not require invasive treatment unless there is hemodynamic compromise.

Second-degree type II AV block is more likely to progress to complete AV block, and occurs more frequently in anterior myocardial infarction, although it can also occur in inferior myocardial infarction because of occlusion of a large posterior descending artery.

Complete AV block, which is present in 8–13 % of patients with myocardial infarction, occurs in both inferior and anterior myocardial infarction, and can be preceded by fascicular blocks or bundle-branch block with second-degree AV block.

It is associated with a higher incidence of ventricular fibrillation/tachycardia, pulmonary edema, and in-hospital mortality [26].

3.4.10 Cardiac Arrest and Sudden Cardiac Death

The incidence of sudden cardiac death (occuring within 1 h from the onset of cardiac symptoms) is variable, depending on the varying prevalence of coronary disease in different countries [27]. In the USA there are 300,000 cardiac deaths annually, with a total annual incidence of 1 in 1,000 individuals [28].

Ventricular fibrillation is the first rhythm detected in 75–80 % of cases, while in the remaining 20–25 % extreme bradycardia or pulseless electrical activity are causes of cardiac arrest.

Bradyarrhythmic cardiac arrest is secondary to the inability of cardiac automatism to emerge and replace the sinus node or normal function of the AV junction.

Cardiac arrest is more common in advanced cardiac disease, generally as a consequence of extracellular potassium accumulation (secondary to hypoxemia, acidosis, shock, or renal insufficiency), which reduces myocellular automatism.

Pulseless electrical activity is an electrical stable cardiac rhythm in the absence of any effective myocardial contraction. The *primary form* is generally the terminal event of a severe cardiopathy or expression of acute myocardial ischemia, and the *secondary form* is a severe expression of a sudden failure in venous return, such as in pulmonary embolism, cardiac tamponade, or acute cardiac prosthetic valve dysfunction.

Reversible causes such as hypovolemia, hypoxia, cardiac tamponade, pneumothorax, acidosis, and hyperkalemia must be detected and corrected. Pharmacological support involves the use of intravenous epinephrine or atropine (the latter, however, is not effective in infra-Hisian AV block).

External cardiac pacing can be useful, although "asystolic" patients still have a poorer prognosis, regardless of the effectiveness of the stimulation [29].

3.5 Treatment

Sinus node dysfunction generally does not require treatment if asymptomatic. When needed, parasympatholytic drugs (atropine 0.5 mg intravenously, repeatable) can acutely increase the automaticity of the sinus node and improve sinus atrial conduction. Sympathomimetic drugs (theophylline per os) are less frequently used for long-term treatment because of their low efficacy and frequent side effects.

If there is any hemodynamic compromise, such as during an inferior myocardial infarction with right ventricle involvement, temporary endocardial pacing is preferred.

The presence of low cardiac output or heart failure, secondary to bradycardia, should be treated with permanent cardiac stimulation, preferably of the right atrium, to allow the spontaneous maintenance of AV conduction and avoid ventricular stimulation.

Supra-Hisian II AV block generally acutely responds to vagolytic drugs. As mentioned earlier, these drugs should be used with caution in suspected infra-Hisian blocks, which can be exacerbated by the increased cardiac rate and supra-Hisian conduction.

Sympathomimetic drugs such as isoproterenol, which are able to increase the automatism of ventricular "pacemaker subsidiary," can be used in the short term regardless of the level of AV block, in particular when it is likely that the block can be transient or if a temporary pacemaker cannot be immediately applied.

In third-degree AV block vagolytic drugs are not particularly effective, especially in the presence of infra-Hisian block, while sympathomimetic drugs provide valuable support in the acute phase while awaiting a permanent pacemaker.

3.5.1 Temporary Pacemaker

Temporary cardiac pacing is used acutely for critically ill patients who require immediate treatment, and sometimes in noncritical situations when patients are at high risk of developing advanced blocks or cardiac arrest.

An intracardiac approach is usually preferred, generally through the internal jugular vein, the subclavian vein, or the femoral vein.

Transcutaneous pacing, despite not having shown a significant benefit in patients with cardiac arrest [29], may be beneficial for the treatment of severe bradycardia as a "bridge" to a permanent pacemaker.

The main indication remains hemodynamically unstable acute myocardial infarction (Table 3.1). Drug treatment with digitalis, quinidine, class 1C antiarrhythmics, β-blockers, and some calcium antagonists can inhibit sinus node automatism up to the development of severe bradycardia, requiring, if associated with signs and symptoms of hemodynamic compromise, temporary pacing to allow pharmacological washout in safety [30].

Hypervagotonia can occur in carotid sinus hypersensitivity, in pharyngeal or gastroesophageal handling during intubation and/or endoscopy, and with parasympathomimetic or sympatholytic drugs. It is associated with three types of clinical response: the first, or cardioinhibitory, with hemodynamically significant bradyarrhythmia; the second, vasodepressor, with hypotension by peripheral vasodilation; and the third, which is a combination of the first two forms. Sometimes temporary pacing can be useful in intensive care, although these clinical situations are easily reversible with atropine [31].

Myocarditis can require temporary pacing because of transient involvement of the ventricular conduction system.

Complications of temporary pacing include capture failure caused by electrode dislocation (25 %), ventricular tachyarrhythmia related to local irritation of the electrode (10 %), pericarditis (5 %), and cardiac tamponade secondary to right atrium perforation (1 %).

Complications related to central venous access are air embolism (1 %), arterial trauma (1.2 %), pneumothorax (1 %), phlebitis (5.1 %), venous thrombosis (18-34 %), and bacteremia (50 %), although infection of the electrode is low [31].

Table 3.1 Therapeutic approach in conduction disturbances

Sinus atrial dysfunction	Asymptomatic patient: observation Symptomatic patient: atropine 0.5 mg iv repeatable up to 2 mg temporary/ permanent pacemaker
AV block	First-degree AV block: observation Second-degree AV block Type I asymptomatic: observation symptomatic – atropine 0.5 mg iv repeatable up to 2 mg Type II asymptomatic (advanced or Mobitz 2) or symptomatic → pacemaker implantation narrow QRS → atropine, if ineffective → pacemaker wide QRS → PM implantation Third-degree AV block a/symptomatic: narrow QRS → atropine, if ineffective → pacemaker wide QRS → PM implantation
AV block during myocardial infarction	Inferior myocardial infarction First-degree AV block → observation Second-degree AV block: Type I → atropine, if ineffective → temporary pacemaker Type II → temporary pacemaker Third-degree AV block → atropine, if ineffective → temporary pacemaker Anterior myocardial infarction: First-degree AV block → observation Second-degree AV block Type I atropine, if ineffective → temporary pacemaker Type II → temporary pacemaker Third-degree AV block → temporary pacemaker

3.5.2 Permanent Pacemaker

Sinus node dysfunction is a major reason for pacemaker implantation (about 46 % of implanted devices) [32] and has a long natural history with a good prognosis in the early stages, although with the progress of the disease and the appearance of symptoms the prognosis becomes less favorable [33].

Atrial pacing is preferable to ventricular pacing alone, although the advantage is reduced in the presence of thromboembolic events or the occurrence of AF [14, 34].

AV block is the second leading cause of pacemaker implantation. Permanent cardiac pacing has improved survival in patients with complete or advanced AV block, particularly if associated with symptoms (syncope or hemodynamic compromise) or in the presence of heart disease [35].

Asymptomatic first- and second-degree (type I) AV blocks do not require permanent cardiac pacing.

Symptomatic or second-degree AV block with slow escape rhythm (type I) and asymptomatic type II block are class II indications for permanent pacemaker implantation.

Complete or advanced AV block (both asymptomatic and symptomatic) and second-degree (type II) AV block, regardless of the level of block, are class I indications for a permanent pacemaker.

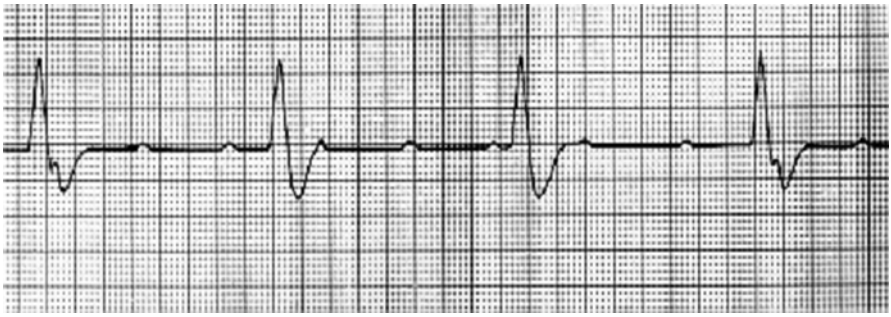

Fig. 3.4 III degree AV block with wide QRS (infra-hisian) escape

Care should be taken in cases of reversible AV block.

Survival in patients with complete AV block not treated with pacemaker implantation is 60 % at 1 year and 30 % at 5 years [35]. Patients treated with permanent pacemakers have been shown to have a 1-year survival comparable with that of the general population [36].

European and American guidelines for Pacemaker implantation [37, 38]
Class I indications
Sinus node dysfunction
Symptomatic sinus bradycardia or chronotropic incompetence
AV block
Second-degree AV block type II
Advanced AV block during sinus rhythm or AF
Complete AV block
Intraventricular block
Trifascicular block (RBBB alternating with LBBB, RBBB + LAHB alternating with RBBB + LPHB)
Bifascicular block (LBBB, RBBB + LAHB, RBBB + LPHB) and second-degree type II or third-degree AV block

Supraventricular Arrhythmias in Emergency

4

Elisabetta Bianco, Marco Bobbo, and Davide Stolfo

The term "supraventricular tachycardia" refers to arrhythmias requiring atrial or atrioventricular nodal tissue, or both, for their initiation and maintenance. Supraventricular tachycardias are often recurrent, occasionally persistent, and a frequent cause of visits to emergency departments (ED) [1].

The following chapter is organized in two main sections dedicated to physician working in ER and cardiologist in order to discuss arguments related to each specific expertise so that patients can receive assessment and treatment personalized on global clinical condition, not only on arrhythmia, in the ED.

4.1 What Physicians Working in ED Should Know

- Timing and modality to treat arrhythmias depends on patient's hemodynamic condition.
- Hemodynamic instability imposes emergent treatment with electrical cardioversion before diagnosis.
- In case of hemodynamic stability it is possible to think about diagnosis and choose best treatment.
- Hemodynamic instability depends on heart rate and on patients' features as age, underlying cardiomyopathy or chronic therapies, electrolyte disturbance, hyperthyroidism, hyperthermia, and drugs intoxication rather than on the type of arrhythmia [2, 3].

DOI 10.1007/978-3-319-24328-3_4

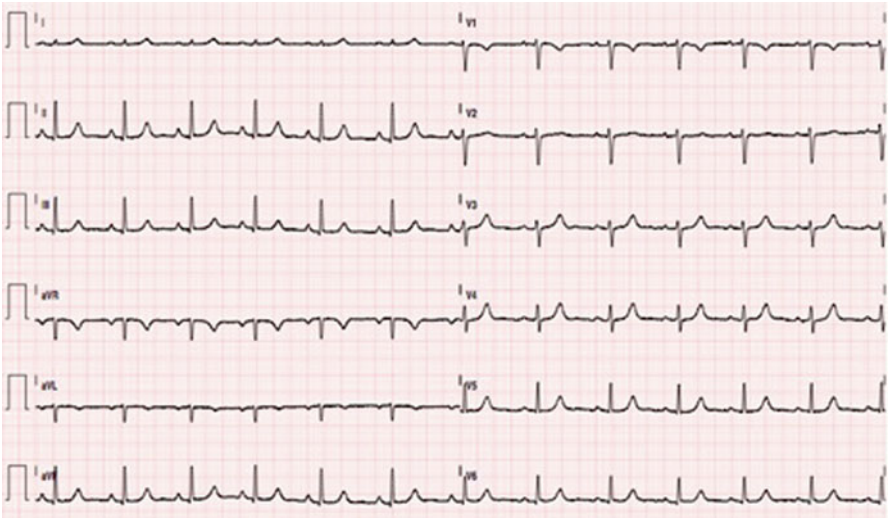

Fig. 4.1 ECG in normal sinus rhythm; with usual setting (paper speed 25 mm/s) 1 mm equals with 40 ms interval

Supraventricular arrhythmias are [4]:

1. Sinus tachycardia
2. Atrial flutter (typical or atypical)
3. Atrial fibrillation (AF)
4. Atrioventricular nodal reentrant tachycardia (AVNRT)
5. Atrioventricular reciprocating tachycardia (AVRT)
6. Atrial/junctional tachycardia (AT)

ECG during arrhythmias differs from normal ECG observed in sinus rhythm. So, first of all, normal ECG must be known [5, 6] (Fig. 4.1):

- Each QRS complex is preceded by a *P wave* with a rate between 60 and 100 bpm with the exception of newborns and infants in whom normal HR is higher (150–230 bpm in newborn) [7].
- P wave is positive in leads I–II and aVL–aVF and in precordial leads from V2–3 to V6, is negative in aVR and can be negative in III, and is biphasic in V1–V2; P wave lasts 120 ms (3 mm).
- Between P wave and QRS complex, there is an isoelectric region (flat line on ECG) which lasts 120–200 ms: the *PR interval.*
- *QRS is narrow* (<110 ms).

While approaching a patient with symptomatic supraventricular tachycardia, physicians must evaluate the patient's clinical status to identify potential reversible causes of tachycardia and to assess the degree of instability and understand if it is related to the tachycardia itself.

Arterial blood pressure, oxygen saturation, electrolyte, and hemoglobin must be evaluated; ECG monitoring and intravenous access must be established.

If possible a 12-lead ECG should be performed during the arrhythmia (and after its interruption) [2].

4.1.1 Patients in Unstable Condition

If the patient demonstrates rate-related cardiovascular compromise with signs and symptoms such as acute altered mental status, ischemic chest discomfort, acute heart failure, hypotension, or other signs of shock suspected to be due to a tachyarrhythmia, proceed to immediate synchronized electrical cardioversion (after sedation of the patient if conscious); provide oxygen if oxygen saturation is below 94 % [2]:

- Narrow regular tachycardia → biphasic synchronized direct current shock 50–100 J
- Narrow irregular tachycardia → biphasic synchronized direct current shock 120–200 J
- Wide regular tachycardia → biphasic synchronized direct current shock 100 J
- Wide irregular tachycardia → biphasic NOT synchronized direct current shock 200 J

If there's no response to the first shock, it may be reasonable to increase the dose in a stepwise fashion.

Cardioversion with monophasic waveforms should begin at 200 J and increase in stepwise fashion if not successful [2].

In newborn, use 0.5 → 2 J/kg [3].

Heparin (low molecular weight or unfractionated heparin) should be administered before cardioversion in case of atrial flutter or atrial tachycardia and after it, depending on patients' features (CHA_2DS_2VASc – HAS BLED) [8].

In patients with implanted pacemaker or defibrillator pads, it should be positioned 8 cm from the device battery; anteroposterior paddle positioning and biphasic energy are recommended [2, 4, 8].

4.1.2 Patients in Stable Condition

The initial assessment should:

1. Distinguish between narrow and wide complex tachycardia.
2. Determine whether the rhythm is irregular or regular (<10 % of variation in cycle length).
3. Consider the rapidity of onset.
4. Identify sinus tachycardia (the theoretical upper rate is 220bpm minus the patient's age in years).

Supraventricular tachycardias have narrow QRS in 90 % of cases. Wide QRS complex could be due to pre-excitation through an accessory pathway or to bundle-branch block or to pacemaker stimulation. Previous ECG and ECG after termination of tachycardia can help to make the diagnosis.

While considering the patient's history, the clinician should assess the duration and frequency of episodes, the mode of onset, and possible triggers (including the intake of alcohol, caffeine or other drugs) as well as previous cardiac or other diseases or previous ECGs.

Supraventricular tachycardias have a sudden onset and termination, in contrast to sinus tachycardias or atrial tachycardias, which accelerate and decelerate gradually; however, some patients do not perceive the sudden onset of supraventricular tachycardia; furthermore, sometimes, they describe sudden onset and gradual offset due to reactive sinus tachycardia after termination of paroxysmal SVT. It may be misdiagnosed as panic disorder [5, 9].

Physical examination during episodes may reveal the "frog sign" which is a prominent jugular venous A waves due to atrial contraction against the closed tricuspid valve. After sinus rhythm is restored, physical examination is usually normal, but a careful examination is warranted to rule out evidence of structural heart disease [11, 12].

4.1.3 Management

4.1.3.1 Narrow QRS

If narrow QRS is present, atrioventricular conduction is certainly entirely through atrioventricular node. That's why maneuvers that increase vagal tone and block atrioventricular conduction are safe: they can interrupt tachycardias depending on AV node conduction (TRNAV or orthodromic TRAV) and can slow down those which don't depend on AV node conduction (atrial flutter or atrial fibrillation). They also interrupt focal tachycardia due to enhanced automaticity.

Physicians have these possibilities:

- *Vagal maneuvers* (Valsalva, carotid sinus massage, facial immersion in cold water, and bearing down). The efficacy is about 25 % [13]. Remember that carotid sinus massage is contraindicated in case of carotid stenosis.
- *Adenosine:* very short-acting endogenous nucleotide (<10 s). It blocks atrioventricular nodal conduction and terminates most of atrioventricular nodal reentrant tachycardias and atrioventricular reciprocating tachycardias as well as up to 80 % of atrial tachycardias [14–16]. Since it may also have proarrhythmic effect (atrial fibrillation in 12 % of patients), it must be administered under ECG monitoring with an accessible defibrillator.

  Common side effects include chest tightness, flushing, and a sense of dread. Avoid in asthmatic patients since it can produce bronchospasm; patients with autonomic failure and with cardiac transplant or patient chronically treated with

antiarrhythmic drugs are more sensitive to adenosine [17]; that's why doses must be halved.

Way of administration and doses: 0.1–0.2 mg/kg (usually 6–12 mg) through peripheral vein; start with 6 mg in a rapid flush immediately followed by 20 ml of saline flush. If there is no effect, try again with 12 mg. Same dose for newborn.

- *Verapamil-diltiazem*: Intravenous verapamil and diltiazem are effective in interrupting tachycardias or can slow down AV conduction, but can cause hypotension thus are not recommended as first choice in the emergency setting [18]. They are contraindicated in heart failure and in newborn because of risk of cardiac arrest or atrioventricular dissociation [3, 19].
- *Electrical cardioversion*: best choice for atrial fibrillation and atrial flutter (typical o atypical) with onset within 48 h or in anticoagulated patients [8]. Biphasic synchronized shock (50 → 200 J; 0.5 → 2 J/kg in infants) is recommended in sedated patient. Before cardioversion, a heparin bolus is recommended in all patients not yet anticoagulated. If there is no efficacy or there is arrhythmia recurrence, pharmacological therapy can be added.

Remember that:

- Sinus tachycardia is usually reactive to other causes so identification and treatment of them are required. No specific drug treatment is usually necessary.
- Atrial fibrillation and atrial flutter can give rise to endocardial thrombus which can cause stroke or thromboembolism: the risk is higher after 48 h of persistent tachycardia and in patients with some specific features ($CHA_2DS_2VASc > 1$). For this reason, anticoagulation (for at leat 3 weeks) is mandatory before cardioversion (or, in alternative, perform trans-esophageous echo to rule out intracardiac thrombi); in case of arrhythmias lasting more than 48 h or non-datable; nevertheless, heparin administration before cardioversion is preferable in all patients. For more details, see specific guidelines [16, 19–21].
- Patients with uncomplicated tachycardias and without cardiomyopathy can be discharged after sinus rhythm restoration; cardiological evaluation can be postponed.
- Sodium channel blockers increase both pacing threshold and the energy required to defibrillation [22, 23].
- Being genetic setting unknown, the effect of an antiarrhythmic drug given for the first time is *never* predictable. That's why administration of antiarrhythmic medications for the first time must be done under ECG monitoring lasting for at least the drug's half-time; after discharge, if chronic therapy is set up, ECG must be checked at the steady state (five half-times) (Fig. 4.2).

4.1.3.2 Wide QRS

Wide QRS can be due to preexisting or frequency-dependent bundle-branch block or to conduction over an accessory pathway. Nevertheless, the majority of wide QRS complex tachycardia has ventricular origin. If the patient is in stable hemodynamic condition, it is better to refer him/her to a specialist for diagnosis and treatment.

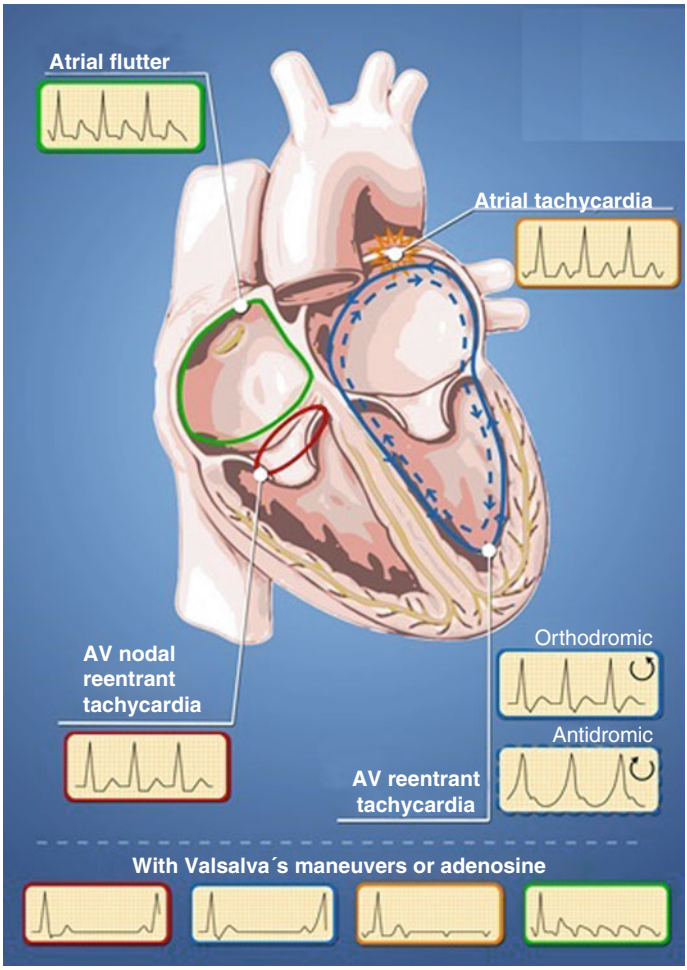

Fig. 4.2 Supraventricular tachycardias (Data from Delacrétaz [12])

4.2 What Cardiologists Should Know

Cardiologist should evaluate all patients with hemodynamic instability related to tachycardias after their stabilization with cardioversion in order to exclude or confirm the presence of cardiomyopathy, to decide the best medical treatment, and to decide for hospitalization or discharge and follow-up.

Non-urgent cardiological examination within few weeks can be reserved to uncomplicated tachycardias, in absence of cardiomyopathy, especially in case of preexisting diagnosis.

Cardiologist should know mechanisms underlying arrhythmias and modality of action of antiarrhythmic drugs in order to choose and combine them, to maximize

efficacy and minimize proarrhythmic and side effects [22, 23], and to remove precipitating features as ischemia and electrolyte imbalance.

For this reason, the next part of the chapter is dedicated to pharmacology of antiarrhythmic drugs and basic electrophysiology.

At the end of the chapter, a scheme of therapies for each arrhythmia is provided.

4.2.1 Basic Electrophysiologic Principles

Every heart contraction is driven by inversion of cell potential from negative to positive. At the cell membrane site, this potential variation from negative to positive (depolarization) and back to negative (repolarization) is called action potential (AP). This is possible thanks to the activation in sequence of different channels driving ion currents (I) inward and outward the cell; every channel is designed to allow passage of its own specific ion and to do it only during a specific phase of AP (some channels open only at negative potential, other at positive). Potassium (K^+) is mainly inside the cell, while sodium (Na^+) is outside and calcium (Ca^{++}) is both outside and stored inside the cell; sodium and calcium are linked to one another. To generate cell depolarization, a specific potential threshold must be reached.

Action potential has been divided in five phases:

- 0 → Depolarization
- 1 → Fast repolarization
- 2 → Plateau
- 3 → Terminal repolarization
- 4 → Resting

During the first phase of action potential, cell membrane is depolarized, and no external stimulus can modify it (absolute refractoriness); during repolarization, external factors can excite the cell with "extra-AP" (relative refractoriness).

Propagation of action potential from a cell to another is called conduction and is characterized by a speed and a safety factor.

Action potential has different morphologies in different tissues (sinus node, AV node, atrioventricular cells). This is due to different kinds of channels and explains the heterogeneous effects of antiarrhythmic drugs on each cardiac tissue.

For example, AV node cell depolarization is mainly calcium mediated, while atrial and ventricular depolarization is sodium mediated; automaticity of sinus node is due to specific channels (HCN) which are permeable to both sodium and potassium and open only at very negative potentials (hyperpolarization).

Function alteration of ion channels (pathological, heart rate or drug mediated) or modifications of ion concentrations modify action potential in terms of duration, velocity of depolarization, or repolarization and determine abnormal rhythm propagation [5, 21].

4.2.2 Mechanisms of Arrhythmias

Arrhythmias are divided into focal and reentrant.

4.2.2.1 Focal

Focal supraventricular tachycardias are defined as an activation starting rhythmically from a small area in atria or AV junction and spreading out centrifugally. Focus can be single or multiple. Mechanism underlying focal tachycardias is automaticity, triggered activity, and micro-reentrant.

- *Triggered activity*: abnormal fluctuations of action potential occurring after or during the repolarization (phase 2–3 or 4 of action potential), which are able to depolarize cell membrane to the depolarization threshold; differently from automatic foci, they are linked to the previous action potential. Three kinds of triggered activities are known (Fig. 4.3):

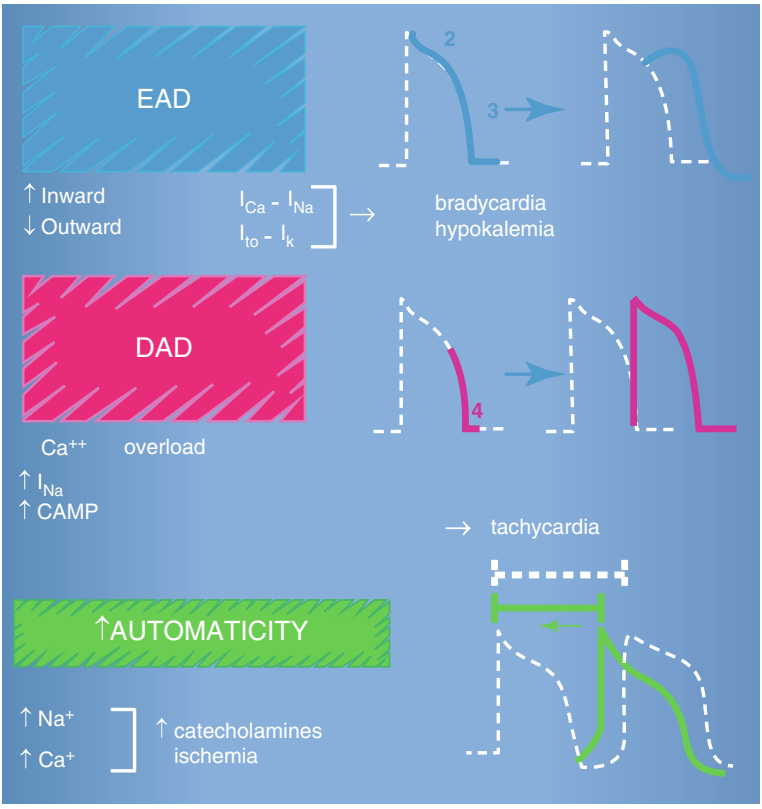

Fig. 4.3 Effects of early after depolarization (EAD), delayed after depolarization (DAD), and automaticity on action potential

(a) *Early after depolarization (EAD)* → occurring during repolarization (phases 2–3 of action potential), due to decreased potassium conductance (typically bradycardia, hypokalemia, or class III antiarrhythmic drugs). They are suppressed by factors that increase potassium outward current (*overdrive – tachycardias*, *K+ channels activators*) or suppress sodium/calcium inward currents (e.g., *magnesium*).
(b) *Delayed after depolarization (DAD)* → occurring during diastolic phase of action potential (phase 4) as consequence of Ca^{++} intracellular overload and Ca^{++} sparks due to increase of I_{Na} (ischemia or digoxin intoxication) or cAMP after beta-stimulation (tachycardia). They are suppressed by *beta-blockers*, *calcium channel blockers*, *vagal stimulation*, or *adenosine*.
(c) *Enhanced automaticity:* positive ionic influx (mostly inward calcium current) during phase 4 (diastolic) depolarization (normal automaticity is driven by sodium current while pathological by calcium). Beta-adrenergic stimulation enhances calcium current and facilitates these arrhythmias. Automatic tachycardias are the most common kind of focal arrhythmias and are characterized by sudden onset with a "warm-up" period. *Vagal stimulation*, *adenosine*, *beta-blockers*, or *calcium channel blockers* may suppress them.

Focal tachycardias are:

- *Atrial tachycardias* → P wave is generally visible with a morphology different from sinus one; 1:1 AV ratio is expected; heart rate can be very variable.
- *Inappropriate sinus tachycardia* → normal P wave morphology; 1:1 AV ratio; heart rate > 100 bpm not related to physiological needs.
- *Junctional tachycardia* → QRS not preceded by P; P wave can be visible after QRS, with morphology typical of AV junction origin (negative in DII–DIII and aVF, positive in V1 or not visible); similar to nodal or atrioventricular reentrant tachycardias; typical of infants.
- *Polymorphic atrial tachycardia/atrial fibrillation* → recurrent paroxysms of polymorphic premature beats starting with warm-up and degenerating in disorganized atrial activity; P wave is polymorphic and not always visible (during AF, sometime P is visible only in V1–V2 due to organization of atrial activity around tricuspid annulus).

4.2.2.2 Reentry

Reentry is a self-perpetuating circuit in which, during a single cardiac cycle, areas still depolarized and areas repolarized coexist. Reentry can be functional or anatomical. If the reentry circuit is >2–3 cm, it's classified as a macro-reentrant; if the reentry circuit is <2–3 cm, instead it's classified as micro (focal tachycardia) [25].

To have a reentry, the following features are required: unidirectional conduction (one way block usually due to extra beat), areas of different conduction rate (short and fast), and shortening of refractory period. Common triggers of reentry

are sympathetic or parasympathetic stimulation, premature beats, and myocardial ischemia.

Wave length (WL) is the product of conduction velocity (CV) and refractory period (RP); WL is theoretical and is always shorter than the real one, so there is an excitable gap (EG) inside the circuit. Reentry has a wave front, a tail, and an excitable gap between them. Excitable gap is necessary to perpetuate reentry.

Factors eliminating the excitable gap block the reentrant circuit making the wave front crash on the tail. There are two ways to obtain it: to *increase the refractory period* (with potassium current blockers or sodium current blockers with slow kinetics) or to *increase the conduction velocity*. In addiction to drugs, the excitable gap can be suppressed stimulating the circuit at a rate just faster than the arrhythmia (overdrive pacing), possible in patients with dual chamber (or atrial) pacemakers.

Ablation can eliminate reentrant circuits by targeting areas of slow conduction that sustain circuit (called isthmus of the tachycardia) and blocking them (creating a permanent lesion with bidirectional block). When ablation lesion is incomplete, it can create an area of slower conduction that is potentially proarrhythmic.

Sometimes, the degree of increase of refractory period brought by drugs is not enough to interrupt tachycardia even at therapeutic concentration: this is more frequent in large anatomic circuit and with drugs that slow down propagation velocity as INa^+ blockers. In this situation arrhythmia became more stable and resistant to therapies. Examples are AVNRT slow/slow or permanent junctional reciprocating tachycardia (PJRT) after calcium or beta-blockers or transformation of atrial fibrillation (small circuit) in atrial flutter (large circuit) after flecainide or propafenone administration.

Reentrant tachycardias are:

- *Atrial flutter (typical and atypical)* → organized atrial rhythm; typical flutter is characterized by negative/positive sawtooth waves (F wave) in leads II, III, and aVF and positive in V_1; in atypical flutter, F waves have different axis depending on circuit; atrial heart rate is between 250 and 350 bpm (but can vary in patient previously treated with ablation or in patients taking antiarrhythmic drugs). In typical atrial flutter, circuit is counterclockwise around tricuspid annulus; slow conduction is between tricuspid annulus and inferior vena cava and conduction block along the crista terminalis and Eustachian ridge.
- *Post-incisional atrial tachycardia* → organized atrial activity due to reentrant around a scar; typical of patients with a history of cardiac surgery or catheter ablation.
- *AVNRT* → P wave arising from junction (negative in DII–DIII and aVF, positive in V1) with RP <PR; two limbs are slow and fast nodal pathways. Reentrant circuit is most of the time down through slow pathway and back through fast pathway (slow/fast), and P wave is visible as a pseudo-r′ in V1 or a pseudo-s′ in inferior leads (P can be not visible); in atypical AVNRT, circuit is down through slow or fast pathway and back through slow (slow/slow, fast/slow), and P wave is separated from QRS; RP >PR). The circuit is inside the AV node so that the

onset of atrioventricular block during tachycardia doesn't interrupt it (AVNRT can have 2:1 AV ratio).

- *AVRT* → reentrant circuit across AV node and accessory truck. It's called orthodromic when it passes from the atrium to the ventricle through AV node and back from the ventricle to the atrium through accessory pathway (RP >PR); it's called antidromic when anterograde wave front is through accessory pathway. The atria and ventricles are part of the circuit, and AV dissociation is not possible without interrupting tachycardia. Presence of pre-excitation is not diagnostic of AVRT (accessory pathway can be a "bystander" during AVNRT or atrial tachycardia, meaning that ventricles are partially or totally activated through the accessory pathway, which nevertheless is not part of the reentry circuit causing the arrhythmia). Evidence of tachycardia cycle length (=RR) augmentation of more than 35 ms (more and less 1 mm with 25 mm/s paper speed) in case of ipsilateral bundle brunch block is diagnostic of AVRT [24], because the ipsilateral block causes a lengthening of the circuit.
- *Permanent junctional reciprocating tachycardia (PJRT) – Mahaim tachycardia* → are rare AVRT through accessory pathway with particular features. PJRT is due to a septal accessory path with only retrograde conduction and decremental properties; it determines incessant narrow QRS tachycardia. Mahaim pathway is an accessory path with decremental properties generally right sided (from anterolateral atrial portion of tricuspid annulus to right ventricle or right bundle); in sinus rhythm, there is typically little or no pre-excitation; during antidromic tachycardia, the QRS is wide (150 ms), with left bundle block morphology, transition after V4.

4.2.3 Antiarrhythmic Drugs

Antiarrhythmic drugs are channel or receptor blockers. They bind specific sites on protein and modify its function with an affinity that varies on the ion channel state (open-inactivated-resting). Furthermore each drug has a specific rate of recovering from block which is a constant time ($T_{recovery}$).

This is why antiarrhythmic drugs that bind open channel, untie during resting state, and have long $T_{recovery}$ (as flecainide – 11 s) reach the steady state earlier having greater effect when a higher percentage of cells are depolarized as during ischemia or high heart rates (direct use dependence). Those drugs that, instead, own affinity for inactivated/resting channels (amiodarone or lidocaine) and own a very short $T_{recovery}$ (lidocaine – 0.1 s) have a greater effect (anti- and proarrhythmic!) under the condition that prolong action potential duration (as bradycardia-hypokalemia) and on rapidly driven tissue (ventricular tachycardia).

Antiarrhythmic drugs have been divided in four classes according to their main effect on action potential (Vaughan Williams classification) [25, 26]. However mostly all of them share properties among multiple classes (quinidine below to I°

class but have also III° class properties). Moreover, ivabradine, digoxin, and adenosine don't belong to any of the four classes (Table 4.1) (Fig. 4.4):

- INa+blockers (I class): shorten action potential, reduce propagation velocity, and act on refractoriness depending on kinetics (flecainide increase relative refractory period; lidocaine no); suppress EAD; reduce inotropism.
- Ica++ blockers (class IV): reduce propagation velocity; suppress abnormal automaticity, EAD, and DAD; reduce inotropism. All have direct use dependence.
- IK+ (class III): lengthening of action potential and of absolute refractory period. Increase inotropism. Have inverse use dependence. Proarrhythmic trough induction of EAD (during hypokalemia/bradycardia)

Key Messages

Remember that:

- *Electrolytes MUST be known, and their alterations MUST be correct before administering any antiarrhythmic drug!*
- Effect of antiarrhythmic drugs can be very different (and very dangerous) among patients with altered function of ion channels (channelopathies, myocardial ischemia) or variants of metabolic capacity or concomitant therapies [27–29]. Therefore, in patients with supraventricular arrhythmias and altered basal ECG (conduction disturbance, repolarization abnormalities), it is important to exclude those abnormalities and choose the correct therapy. When a channelopathy is suspected, further evaluation must be organized [30]; the decision about hospitalization or delayed ambulatory evaluation depends on the risk of arrhythmic death (arrhythmic instabilities, predisposing factors).
- Being genetic setting usually unknown, the *effect of an antiarrhythmic drug given for the first time is never predictable* [31]. That's why the first administration of any antiarrhythmic medications should be done under ECG monitoring lasting for at least the drug's half-time; after discharge, if chronic therapy is set up, ECG must be checked at steady state (five half-times).
- Ic are *effective on accessory pathway*.
- Ic are *poorly effective on atrial macro-reentrant tachycardias (flutter o post-incisional)*; they slow atrial cycle length without interrupting tachycardia; if AV nodal conduction is enhanced (e.g., during exercise), they can promote 1:1 AV conduction. For this reason it's better to associate an AV blocker (Ca^{++} or Na^{+} blocker) to a Ic drug. Vernakalant is not effective on atrial flutter.
- Ic *have a marked negative inotropic effect*; if administered in rapid bolus, it causes broad hypotension even in people without cardiomyopathy so they must be administered under arterial pressure monitoring.
- *Calcium-blockers are dangerous in newborn* because of risk of cardiac arrest and are contraindicated in this setting [3, 19].
- *In newborn and children, beta-blockers are highly effective* especially if combined with amiodarone [32, 33]. Procainamide has also been demonstrated to be more effective than amiodarone in sinus rhythm conversion of pediatric SVT [34].

Table 4.1 The effects, doses, side effects, and contraindications of antiarrhythmic drugs

CLASS	DRUG		INTRAVENOUS	MAINTENANCE (day)	$T_{1/2}$	ELIMINATION	SIDE EFFECTS	CONTRAINDICATIONS

Different colors identify the four classes of Vaughan Williams classification; in *black* drugs not belonging to any class. Drugs without indications for supraventricular tachycardias are only mentioned

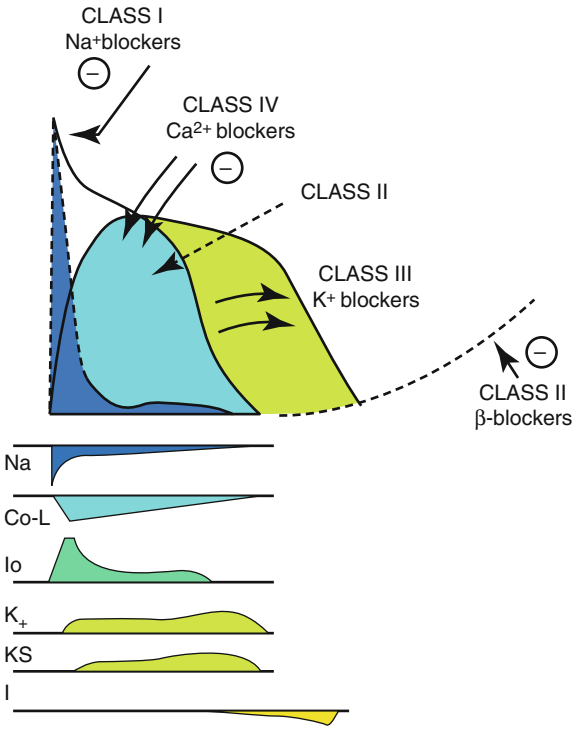

Fig. 4.4 Major effects of antiarrhythmic drugs on action potential

- *Newborn and children aren't* "small adults": they have different metabolism that MUST be known (usually they are better metabolizer than old people); drug's doses must be setup on body weight.
- Amiodarone is effective on different substrates due to its multiple antiarrhythmic affect (class from I to IV).
- *Risk of EAD due to a drug that blocks IK is reduced by addition of a INa/ICa blocker* (as quinidine + verapamil).
- *Supraventricular tachycardias can be associated with troponin level and/or ST abnormalities that rise in absence of coronary artery disease* [35, 36]. Suspicion of coronary syndrome must be based on risk factors, symptoms, ECG, or echocardiographic alteration.
- *Catheter ablation is safe and highly effective in curing supraventricular arrhythmias permanently*. It is a reasonable option of antiarrhythmic therapies in most of tachycardias and must be considered and proposed to patients [4, 37, 38] (Fig. 4.5).

Atrial Flutter and Fibrillation in the Emergency Setting

5

Ermanno Dametto, Martino Cinquetti, Federica Del Bianco, and Matteo Cassin

5.1 Focus on the Topic

Atrial fibrillation (AF) is a supraventricular arrhythmia characterised by uncoordinated atrial activation which determines on the electrocardiogram (ECG) the presence of fibrillatory waves of different timing, shape and amplitude, associated with an irregular and frequently rapid ventricular response (Fig. 5.1). It is the most frequent arrhythmia with a prevalence of 1.5–2 % in the general population [1], increasing with age and is the most frequent cause of arrhythmic access to the emergency department (ED), 1.5 % in "FIRE" and 3.1 % in "HERMES-AF" registries [2, 3] and hospitalisation (3.3 % in "FIRE" registry [2]).

European (ESC 2010) [4] and US (AHA/ACC/HRS 2014) [5] guidelines (GL) classify AF as *first diagnosed* or *recurrent*. Recurrent AF episodes are defined as *paroxysmal* if they terminate spontaneously (AHA/ACC/HRS 2014 GL [5] include also AF treated with cardioversion within 7 days), *persistent* (lasting longer than 7 days), *long-lasting persistent* (continuous for more than 12 months with intention of rhythm control strategy) or *permanent* (further attempts to restore and/or maintain sinus rhythm excluded).

AF may be asymptomatic, so the patient may be referred to the ED by a general physician for an occasional finding of irregular heart rhythm, or symptomatic. Symptoms described on arrival at the ED are most frequently palpitations (69.2 %), followed by dyspnoea (27.5 %), congestive heart failure (10.9 %), fatigue (105), angina (9 %), pulmonary oedema (4.5 %), syncope (3.3 %), transitory ischaemic attack (TIA) or stroke (2.2 %) [2]. Apart from acute symptoms, atrial fibrillation

DOI 10.1007/978-3-319-24328-3_5

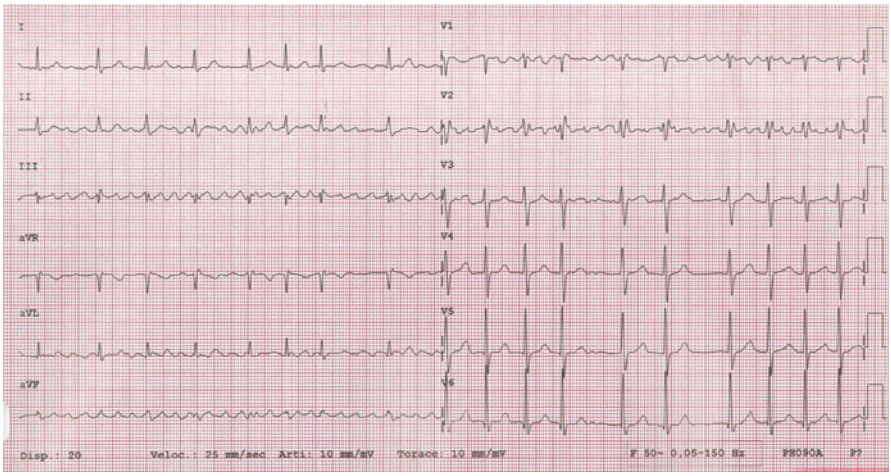

Fig. 5.1 *Atrial fibrillation* with moderately fast ventricular response (about 100 bpm). RR intervals are irregular and coarse F waves are visible

causes a fivefold risk of stroke, a threefold risk of heart failure and doubles dementia and mortality [5]. Furthermore, it reduces the quality of life [6]. For stroke, risk stratification and treatment of *nonvalvular* and *valvular AF* are distinguished. Valvular AF carries a very high thromboembolic risk if not anticoagulated: in patients with mitral stenosis and AF it is about 20 times over patients not affected by AF. Definition of valvular AF is not univocal; according to the AHA/ACC/HRS 2014 Guidelines, it is defined as AF associated with rheumatic mitral stenosis, a mechanical or bioprosthetic heart valve or mitral valve repair [5].

Atrial flutter (*AFL*) is less common (about 10 % of ED admissions for AF or AFL were due to AFL in the "FIRE" registry [2]) but shares similar clinical features and treatment with AF. It is a macroreentrant atrial arrhythmia with regular atrial activation and shows electrocardiographically continuous atrial activity in at least one lead which may have various morphologies depending on the location of the circuit. The ventricular rate is usually regular due to a fixed atrioventricular (AV) conduction rate, mostly 2:1 with a frequency of 120–150 bpm (Fig. 5.2), but may be slower or irregular due to a variable AV conduction rate.

Both arrhythmias are usually associated with cardiovascular pathologies, mostly hypertension (64 %) but also coronary artery disease (32 %), heart failure (32 %), valvular hear disease (26 %) and cardiomyopathy (10 %). Chronic obstructive pulmonary disease (COPD) may be associated in 13 % of the patients and thyroid disease in 9 %. In about 10 %, none of these comorbidities are found, and the arrhythmia is called "lone atrial fibrillation" (or flutter), if the patient is younger than 65 years old [7].

Acute diseases may be associated with AF/AFL like myocardial infarction, pulmonary embolism, pneumonia, severe infections, alcohol abuse, drug toxicity, hypothermia and electrolyte abnormalities [8].

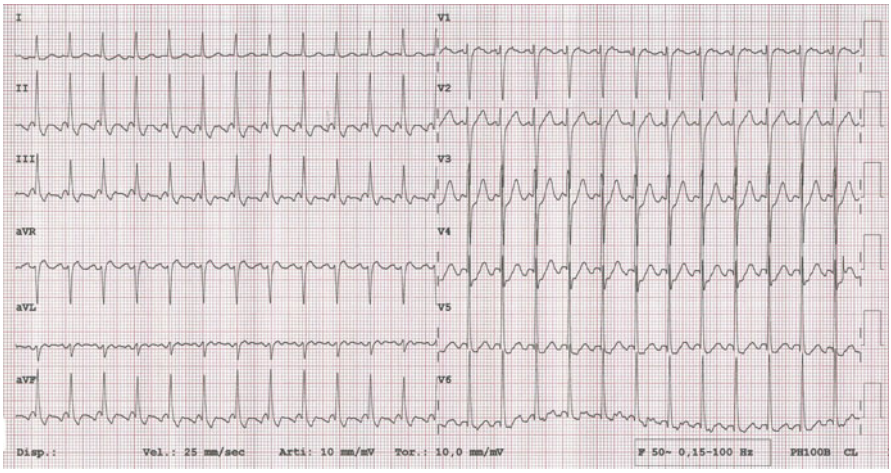

Fig. 5.2 *Atrial flutter with 2:1 AV conduction and quite rapid ventricular rate* of 150 bpm. Regular RR intervals

5.2 What Physicians Working in ED Should Know

The ED physician has several tasks:

1. *Rule out severe clinical instability*

Altered mental status, hypotension, pulmonary oedema and ongoing ischemia necessitate acute electrical cardioversion (ECV) once diagnosis of AF/AFL is confirmed and is thought to be the primary cause [9], at least if there is no prompt response to rate control therapy [4, 5, 10].

2. *Diagnosis of the arrhythmia*

The pulse presents irregular in case of AF but is usually regular in case of flutter. Electrocardiographic diagnosis of AF is usually easy for the irregular RR intervals and f waves. Atrial flutter appears usually as a regular arrhythmia due to fixed conduction rate, mostly 2:1 with ventricular rates around 120–150 bpm, but may be less or conduction may be variable. When rapid conduction is present, the flutter waves may not be so evident. In these cases and if the patient is stable, we recommend to perform a continuous 12-lead ECG registration during carotid sinus massage (after exclusion of any carotid bruit) or adenosine infusion (6, 12 or 18 mg bolus followed by 20 ml saline solution flush) to clear up differential diagnosis with other supraventricular arrhythmias and to record the flutter wave morphology, which helps the cardiologist to define the long-term therapeutic approach (e.g. radiofrequency ablation). *Typical atrial flutter* (also called *cavotricuspid isthmus-dependent atrial flutter*) is a macroreentrant circuit posterior to the tricuspid annulus, crossing the

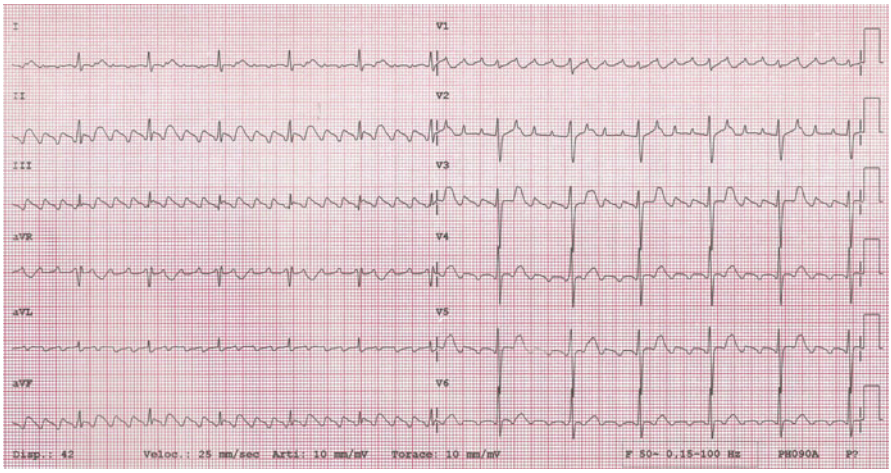

Fig. 5.3 *Typical atrial flutter with counterclockwise atrial activation (common atrial flutter)* with 4:1 AV conduction, 70 bpm. Atrial flutter waves are clearly seen: negative in inferior leads and positive in V1

isthmus between the inferior vena cava orifice and tricuspid annulus. Activation sequence is more frequently counterclockwise (downwards the right atrial free wall and upwards the interatrial septum), and in this case, the arrhythmia is called *common atrial flutter* or *counterclockwise AFL* (Fig. 5.3). Less common is *clockwise typical atrial flutter*, also called *reverse AFL* (Fig. 5.4). On ECG, the former shows classical "sawtooth" flutter waves with negative polarity in inferior leads and positive in V1, and the latter shows flutter waves with positive polarity in the inferior leads and negative in V1. Atypical flutters (noncavotricuspid isthmus dependent) show flutter waves with other morphologies (Fig. 5.5) [5].

In patients with AFL treated with flecainide or propafenone sometimes rapid 1:1 AV conduction is favoured due to flutter wave slowing. This phenomenon is frequently accompained by conduction aberrancy and QRS widening (Fig. 5.6).

In patients with Wolff–Parkinson–White Syndrome, a *pre-excited AF* (Fig. 5.7) is characterised by irregular RR intervals with various degrees of QRS widening (various degrees of fusion between accessory pathway and nodal conduction). In case of fast conduction properties of the accessory pathway, ventricular rate can be extremely high, possibly leading to severe haemodynamic consequences or even to ventricular fibrillation. *Pre-excited AFL* appears as a wide QRS tachycardia.

3. *Clinical history and physical examination for evaluation of concomitant heart disease and comorbidities*

A complete medical history including previous cardiac and noncardiac diseases, history of former AF, medication use and drug or alcohol abuse should be obtained. Onset of the current AF episode should be carefully defined as it is a crucial point for decision making, in particular, it has to be cleared if onset is within or more than

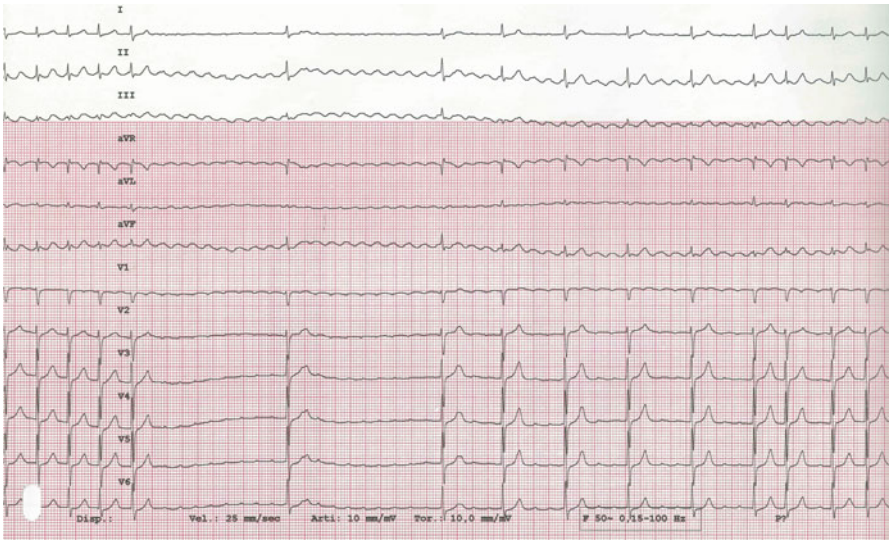

Fig. 5.4 *Typical atrial flutter with clockwise atrial activation (reverse atrial flutter) during adenosine injection*. Initially 2:1 AV conduction, 150 bpm and masked flutter waves. A marked conduction slowing follows, unmasking flutter waves: positive in inferior leads and negative in V1. Diagnosis was confirmed by electrophysiological study

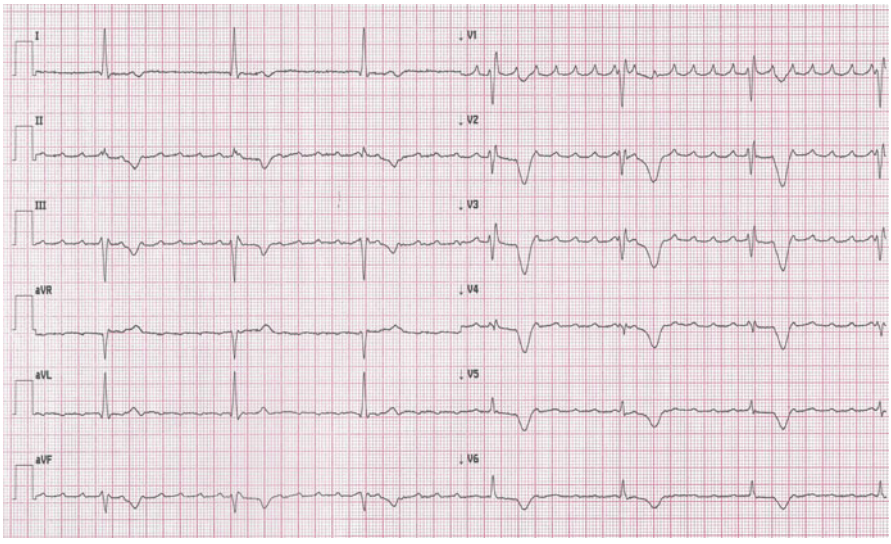

Fig. 5.5 *Atypical atrial flutter:* flutter waves are positive in inferior leads and in V1

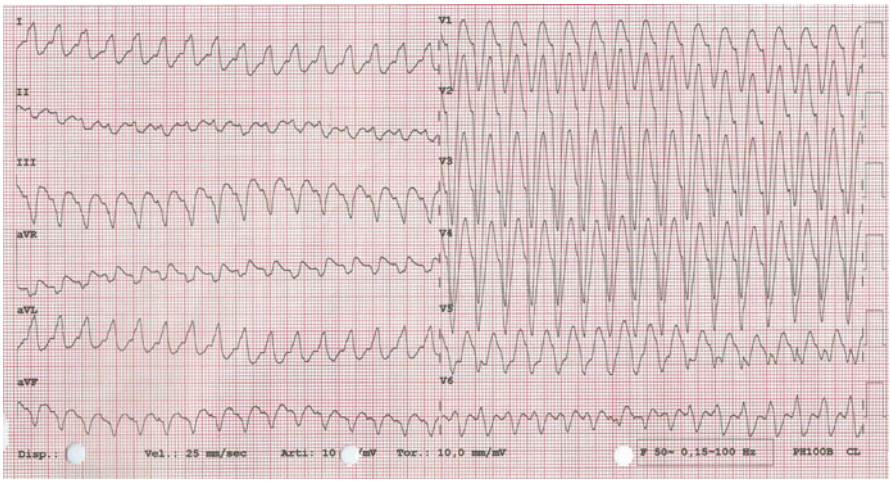

Fig. 5.6 *Atrial flutter with 1:1 AV conduction and aberrancy* 190 bpm (during i.v. flecainide infusion). Flutter waves are not visible. Resembles a wide QRS tachycardia

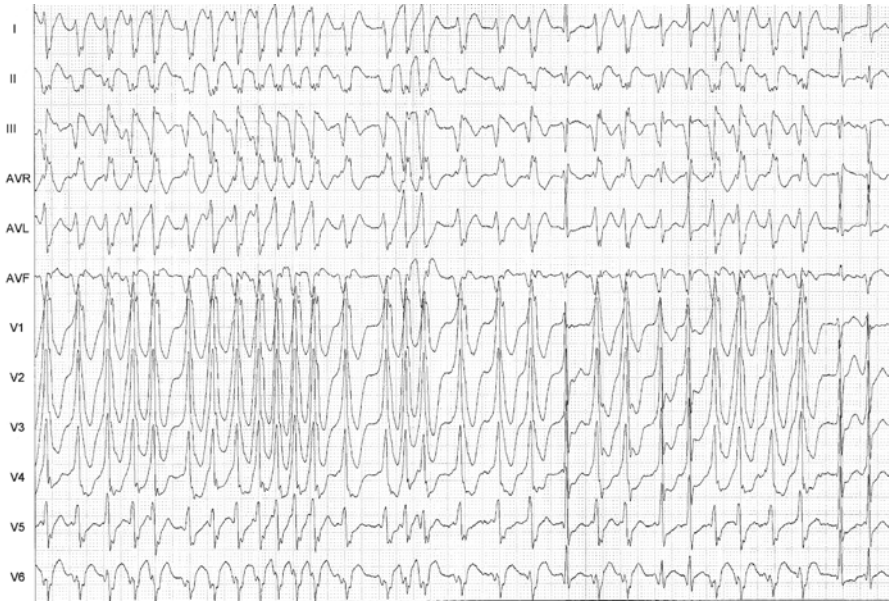

Fig. 5.7 *Pre-excited atrial fibrillation with fast AV conduction*, at times near 300 bpm. Bizarre wide QRS morphology with irregular RR intervals. In between, there are a few beats with normal QRS, conducted through the AV node

48 h (time within acute cardioversion without previous anticoagulation can be considered). Frequently, AF presents as continuous palpitations with acute onset. In this case, onset definition is easy. Other times, palpitations are perceived intermittently

or other symptoms dominate as dyspnoea or fatigue which can be vague. In these cases, it can be of help if patients are used to evaluate daily their pulse (often evaluated together with arterial pressure in the hypertensive). If onset of AF cannot be clearly dated, the arrhythmia should be regarded as *"AF of undefined onset"*.

Physical examination should initially be aimed to vital signs like blood pressure, pulse frequency, signs of pulmonary or peripheral congestion and oxygen saturation. Cardiac assessment should include evaluation of heart sounds and murmurs and a careful evaluation of both arterial and jugular pulse (to assess the rhythm and possible AV dissociation).

Laboratory tests should be tailored to patient's presentation. A complete blood count, serum electrolytes, renal and hepatic function tests, coagulation status and thyroid-stimulating hormone should be routinely obtained. Brain natriuretic peptide, troponin I or T, C-reactive protein and D-dimer test help ruling out heart failure, myocardial ischemia, concomitant inflammatory or infectious disease and pulmonary embolism if these conditions are suspected.

Thyroid disease is not uncommon in AF patients and overt hyperthyroidism is associated in about 4 % of AF patients [11]. Thyroid-stimulating hormone is a reliable screening tool which can be applied in some EDs and may help in decision making (choosing rate control strategy or defining contraindication for amiodarone use [12].

An urgent echocardiogram should be performed in haemodynamically compromised patients [4]. Alternatively, a focused ultrasonography performed by the ED physician can determine underlying cardiac condition like structural heart disease, pericardial effusion and pulmonary embolism, or clarify causes of shock or hypotension and guide resuscitation by volume repletion measuring the inferior vena cava diameter. Ultrasound competence is not uniformly available among ED physicians, but a focused examination of the heart may help guiding therapy in AF management [13]. However, a complete echocardiographic examination should be performed as part of initial evaluation [4, 5, 14] as soon as possible, even on outpatient basis in stable patients.

4. *Symptom relief by cardioversion (electrical or pharmacological) or rate control*

Unstable patients In patients with haemodynamic compromise like hypotension, pulmonary oedema or ongoing myocardial ischemia thought to result mainly from acute AF or AFL, electrical cardioversion is indicated [9], especially if it does not respond promptly to pharmacological rate control measures [4, 5, 10].

Anticoagulation with low molecular weight heparin (LMWH) or unfractionated heparin (UFH) should be initiated as soon as possible. Do not delay ECV if the patient is extremely unstable [9]. In the author's opinion if the patient is hypotensive, ECV is preferable, whereas if pulmonary oedema or myocardial ischaemia is present, rate control should be tried first.

Atrial fibrillation can be an epiphenomenon of an "alternative" primary diagnosis, and in these cases, mortality rate is high (11 % in the study of Atzema et al. [15]). Patients may present with vague symptoms. Scheuermeyer et al. [16] reported

on a series of patients with underlying medical illness like sepsis, acute coronary syndrome (ACS), decompensated heart failure, pulmonary embolism, obstructive pulmonary disease exacerbation, acute renal failure and gastrointestinal bleedings. Those who underwent immediate rate or rhythm control attempts suffered a much higher complication rate (40.7 %) than those who did not (7.1 %) and were unlikely to achieve success. So it is more advisable to delay rhythm management strategies and manage these patients first correcting the primary acute disease, administrating intravenous fluids guided by bedside echocardiography (to assess volume status) and performing frequent reassessments while waiting for confirmatory diagnostic tests [16].

Stable patients with recent-onset AF (<48 h) There is still controversy on optimal management of these patients, being rate and rhythm control the two alternative strategies without clear-cut evidence favouring one or the other. *Rate control strategy* in the ED consists of pharmacological control of ventricular rate and anticoagulation treatment if indicated. With *rhythm control strategy*, the patient is cardioverted to sinus rhythm (SR) either pharmacologically or electrically, usually discharged from the ED and followed as outpatient afterwards. A delayed cardioversion (CV) after at least 3 weeks of adequate anticoagulation can be planned in some patients if the initial rate control strategy is not well tolerated.

Although several trials on AF patients like the AFFIRM [17] did not find significant differences on the main clinical outcomes between rate and rhythm control, the latter seems the preferred strategy worldwide in the long treatment of AF [18, 19]. General indications for preference of either strategy are listed in Italian guidelines on AF management [20]: rhythm control strategy should be the option for (1) patients with first AF episode (taking into account also age and comorbidities) and (2) for patients with recurrent AF with high probability of long-term sinus rhythm maintenance, or in whom rate control proved uneffective or if AF determines negative haemodynamic effects. Rate control strategy is preferred for (1) patients refractory to antiarrhythmic therapy, with frequent AF relapses non-candidable to AF ablation or not candidable to rhythm control strategy because of age or underlying heart disease and (2) for older asymptomatic patients with persistent AF or older patients with recurrent AF, heart failure and poor ventricular function.

As far as ED practice concerns, there is a considerable variability among different countries: rate control strategy is largely favoured in the USA (74 %), while in Canada, most patients undergo cardioversion (66 %). The UK and Australia adopt rate or rhythm control in equal proportions [21].

In our clinic, rhythm control is generally the preferred management strategy.

The theoretical advantages of an aggressive rhythm control approach are rapid discharge without hospital admission, immediate resumption of normal activities, potential avoidance of medications and minimization of healthcare resources and costs. In addition, with rate control strategy, many patients can derive physical and psychological inconvenience maintaining the arrhythmia and drugs after discharge [22].

A recent review of five studies involving 1593 cases undergoing ED cardioversion [23] demonstrated that success rate was high (around 90 %), with a discharge rate of about 90 % and a complication rate generally lower than 5 %, exceptionally leading

to hospital admission. Thromboembolic complication rate was very low (0.06 %). So in selected patients with recent-onset AF, ED physicians should feel comfortable with this approach which should ideally be standardised by a local ED protocol and include timely and appropriate follow-up. The first description of an ED protocol dealing with recent-onset AF or flutter was the "Ottawa Aggressive Protocol" [24]. Excluding patients presenting with AF onset >48 h or of unknown duration and those with other primary diagnosis necessitating admission, it involved sequential pharmacologic and, when indicated, electrical cardioversion by the emergency physician. It allowed discharge of 96.8 % of the 660 enrolled patients, 93.3 % of those in sinus rhythm, after a median length of stay of 4.9 h overall. Adverse outcomes, mainly transient hypotension, occurred in 7.6 % and only 3.2 % of patients required hospitalisation. No patient died or suffered a stroke. Despite these encouraging results, limited data help guide emergency physicians on which AF patients can be safely managed as outpatients (see below). An interesting implementation of an ED cardioversion protocol for acute AF patients after exclusion of high-risk features was described by Bellone et al. [13]; their workup included morphological echocardiographic investigation before treatment by certified emergency physicians, which has the potential of improving the risk stratification and the therapeutical choice.

Another management strategy consists in conservative "wait-and-watch approach" which relies on the known discrete likelihood of spontaneous cardioversion of recent-onset AF (from 20 % up to 68 % in the study of Danias et al. [25]); early (<24 h) presentation is the best predictor of spontaneous cardioversion. Patients may be discharged on rate control medication and anticoagulation if appropriate and scheduled for return visit to ED to permit CV within the 48 h period [26] from symptom onset if AF persists, or may be admitted to an ED observation unit, reassessed after some hours and eventually cardioverted if AF persists [27]. This strategy can be applied following the patient's preference but may be an option if ED is overcrowded.

Stable patients with AF onset >48 h or with AF of uncertain onset If the patient has properly been anticoagulated for at least the preceeding 3 weeks, acute cardioversion can be considered as an alternative to rate control. On the contrary, in non-anticoagulated patients, rate control is generally the most appropriate strategy. In the acute setting, the target ventricular rate should usually be 80–100 bpm [4]. Once rhythm control is achieved and anticoagulation started, the patient can be considered for discharge and referred to a cardiologist or a general practitioner. If adequate rate control is not achieved, the patient is still symptomatic or if new ventricular dysfunction is to be detected, cardioversion should be considered: the patient must be fully anticoagulated independently of the thromboembolic risk (start with UFH or LMWH for immediate action and bridge then with vitamin K antagonists; novel anticoagulants may be used as alternative), then undergo a transoesophageal echocardiogram (TEE) to exclude intracardiac thrombi and finally electrically cardioverted. Anticoagulation should be continued at least 4 weeks or indefinitely, according on the thromboembolic risk profile. If thrombosis is detected, the patient should undergo another TEE after at least 3 weeks of effective anticoagulation and if it has resolved undergo ECV thereafter [4, 5, 10].

According to the Canadian Guidelines 2014 [10], the TEE-based CV approach should also be applied for a AF patients presenting <48 h after AF onset if high-risk features like valvular AF or stroke/TIA in the last 6 months are present.

5. *Antithrombotic therapy*

It is generally believed that antithrombotic therapy is the mainstay of AF management in any care setting, as from this therapy, most of prognostic benefit in terms of morbidity (stroke prevention) and mortality has to be gained. Nevertheless, it is still much underprescribed, usually in less than 55 % of AF patients, as results from studies are conducted in different settings. EDs constitute excellent opportunities to start thromboprophylaxis in the absence of contraindications and help filling this gap [3]. Treatment options include LMWH or UFH, vitamin K antagonists (VKAs) and novel oral anticoagulants (NOACs).

Immediate anticoagulation can be obtained with unfractionated heparin (i.v. bolus of 80 UI/kg followed by continuous i.v. infusion adjusted to an activated partial thromboplastin time of twice the control value (initially 18 UI/kg/h)) [28] or LMWH (most popular being enoxaparin 100 UI/kg BID) based on ACUTE II [29] ad ACE trials [30]. Heparin therapy is generally used as bridging with VKAs which have a delayed onset of action which takes some days.

At present, three NOACs have been tested for AF cardioversion (prospectively or in post hoc analysis) [31–33]:

Dabigatran 150 mg twice daily (TD) if creatinine clearance > 50 ml/min, 110 mg TD if CrCl between 30 and 50. In the USA, the FDA approved 150 mg TD if CrCl >30 and 75 mg TD if ClCr 30–15. Do not use in association with dronedarone; reduce dose if concomitant verapamil is used.
Rivaroxaban 20 mg once daily or 15 mg if CrCl 49–30 ml/min.
Apixaban 5 mg TD or 2.5 mg TD if two or more risk factors for bleeding: age <80 years, weight <60 kg, creatinine >1.5 mg/dl.
Time to peak action is around 3 h for all three.

Valvular AF carries a very high risk per se and must always be treated with VKAs. NOACs were not tested or resulted inferior to VKAs in this setting [5, 34].

For patients with nonvalvular AF, a number of risk stratification schemes have been proposed, the mostly recommended [1, 5] being the CHA2DS2-VASc scoring system [35] (Table 5.1). As chronic therapy, anticoagulation is not indicated for score = 0, indicated for score ≥2, recommended for score = 1 by European guidelines [4], while US guidelines [5] indicate alternatively oral anticoagulants, aspirin or no antithrombotic treatment (Class IIb). We favour oral anticoagulation for patients with score = 1 unless at risk of bleeding.

Any type of AF (paroxysmal, persistent, permanent) carries a similar risk of stroke, so anticoagulation should be chosen regardless of AF type. Atrial flutter has shown to have similar thromboembolic risk as AF and should be managed the same way.

All patients with AF >48 h duration (including those with CHA2DS2-VASc score = 0) candidate to cardioversion must be adequately anticoagulated for at least

Table 5.1 CHA2DS2-VASc scoring system

Acronym	Risk parameter	CHA2DS2VASc score	Stroke rate (%/year)
C	Cardiac failure or dysfunction	0	0
H	Hypertension	1	1.3
A (2)	Age >75	2	2.2
D	Diabetes	3	3.2
S (2)	Stroke/TIA or thromboembolism	4	4
V	Vascular disease	5	6.7
A	Age 65–74	6	9.8
Sc	Sex category (female)	7	9.6
		8	6.7
		9	15.2

Based on Lip et al. [35]
One point is assigned to each parameter except for Age >75 and Stroke whom 2 points are assigned

the three preceding weeks before the procedure, unless intraatrial thrombus has been ruled out by TEE or in case of rare emergency situations and continued on anticoagulation for at least 4 weeks afterwards. Lifelong anticoagulation is indicated for patients at high risk of stroke or AF recurrence.

For patients with AF onset <48 h, current guidelines [4, 5, 10] indicate cardioversion without previous anticoagulation, as former studies demonstrated low embolic complications (0.8 % stroke at 30 days in the study of Weigner et al. [36]). Some concern has raised as it was demonstrated that 4–14 % of these patients had an intraatrial thrombus on transoesophageal echocardiography [37, 38], and ESC 2010 guidelines [4] recommend to start anticoagulation with UFH or LMWH before cardioversion even for AF lasting <48 h. In high-risk patients, heparin therapy has to be followed by long-term oral anticoagulation (class I recommendation), while in patients with no risk factors, heparin therapy may be considered only pericardioversion (IIb, level C recommendation), but this latter recommendation is not evidence based. The 2014 AHA/ACC/HRS guidelines [5] make similar recommendations on use of peri- and postcardioversion antithrombotic therapy, adding the option to use NOACs for the purpose (Class I recommendation). In this context, also a recent European Expert Consensus [28] agrees with the use of NOACs with a class IIa recommendation. A recent large cohort study [39] on 7660 cardioversions of AF lasting <48 h supports the recommendation of prolonged anticoagulation in high-risk patients after CV: without anticoagulation, thromboembolic risk resulted 0.7 % at 30 days. Risk factors were age, heart failure, diabetes, and female gender (elements of CHA2DS2-VASc score system). Patients without risk factors experienced a very low complication rate of 0.2 %, whereas those with multiple risk factors had a thromboembolic risk approaching 10 %.

For patients with AF lasting >48 h or of unknown origin with no risk factors (CHA2DS2-VASc = 0), anticoagulation is not advised unless a delayed cardioversion is planned.

6. *Decision for cardiologist consultation or hospitalisation*

Consultation with a cardiologist should be requested for:

- Unstable patients (hypotension, angina, heart failure)
- Patients with known significant cardiac disease
- If significant underlying heat disease is suggested by objective findings, laboratory data or diagnostic testing
- If rate or rhythm control has not been achieved
- If cardiovascular complications have occurred as consequence of antiarrhythmic or rate control therapy
- If cardioversion preceded by TEE is the choice
- If Brugada pattern emerges on ECG after pharmacological cardioversion

Most of these patients will also require hospitalisation, as well as patients with concomitant acute illness (sepsis, pneumonia, pulmonary embolism, etc.).

5.3 What Cardiologists Should Know

"Pill-in-the-pocket approach": useful treatment strategy for patients with no or minimal heart disease, no conduction disturbances and infrequent but prolonged and well tolerated AF recurrences. Patients have to take orally 200–300 mg flecainide or 450–600 mg propafenone (the higher dosage for weight >70 kg). This approach should be prescribed by a cardiologist after full diagnostic workup (and therefore in the author's opinion avoided in first diagnosed AF) and must first be tested in the ED for safety and efficacy before it can be used at home. If this strategy is the choice, the cardiologist should specify this indication on his written evaluation of the patient so that instructions can be promptly be followed in the ED for the first test treatment. In the original article by Alboni et al., [40] rapid 1:1 flutter complicated only 1 case (0.6 %), so ESC 2010 guidelines [4] recommend this strategy as it was described, but AHA/AC/HRS 2014 [5] and CCS 2010 [41] guidelines recommend addition of beta blocker or nondihydropyridine calcium channel blocker to avoid this side effect. This strategy should not be used for patients with AFL.

Patients already on chronic antiarrhythmic therapy may present to the ED with relapsing acute onset AF. If cardioversion is judged to be the choice, we suggest electrical CV as first choice. Alternatively, pharmacological cardioversion (PCV) with the same antiarrhythmic agent administered intravenously at reduced dose can be performed although there is little evidence in literature. In our centre, it has been common practice for more than a decade to use flecainide or propafenone half dose bolus (1 mg/kg in 10 min) on top of chronic therapy with the same agents or intravenous amiodarone with conventional dosages and infusion rates on top of chronic amiodarone therapy, after checking for contraindications. We have not yet experienced significant side effects. Patients are discharged on the same antiarrhythmic agent, even at higher dose, as single or few AF relapses should not be interpreted as treatment failures if the antiarrhythmic burden is lowered on medication. We advise

in general against the use of different antiarrhythmic drugs on top of chronic antiarrhythmic drug therapy although limited experience on intravenous ibutilide in patients taking amiodarone, propafenone or flecainide seems safe [42, 43].

Coronary artery disease and atrial fibrillation are often associated diseases [7] and share common risk factors. AF may complicate myocardial infarction in about 18 % [44] and is frequently associated with severe LV damage and heart failure. Fast ventricular rate contributes to increased myocardial damage and heart failure, requiring prompt treatment. Adequate rate control can be obtained preferably by administration of beta blockers (uniformly class I recommendation by ESC 2010, AHA/ACC/HRS 2014, ESC 2012 STEMI guidelines [4, 5, 45]) or in alternative nondihydropyridine calcium antagonists (class IIa in ESC 2010; class IIb in AHA/HRS/ACC 2014; class I in ESC STEMI 2012), in patients who do not display HF or haemodynamic instability. In patients with associated severe left ventricular dysfunction, or signs and symptoms of heart failure, rate control is more safely achieved with i.v. amiodarone or i.v. digoxin (class I in ESC STEMI 2012 [45]; Class IIb in AHA/ACC/HRS 2014 [5]), also in association [45]. Urgent electrical cardioversion should be considered in patients presenting with atrial fibrillation and intractable ischaemia or haemodynamic instability [45].

Pharmacologic cardioversion should be considered if ischemic trigger has resolved with amiodarone being the agent of choice [45].

A still yet unsolved issue is the significance of two common findings, *mildly elevated troponin I (TnI) levels or ST depression* on ECG in the absence of overt acute coronary syndromes (ACS). It is common practice in the EDs to check troponin levels in patients presenting with AF even after excluding primary diagnosis of acute coronary syndrome (76 % of 662 patients in the study of Gupta et al. [46]). The prevalence of mildly positive TnI tests in acute AF patients without evident ACS varies from 9 [47] to 44 % [46]. Troponin I elevation predicts increased the risk of death [48, 49] or MI [46, 48] in the long term. This seems true in the acute setting for minor TnI elevations (detectable but subthreshold) as well as for positive TnI tests (with the higher the value the higher the risk [48]), but also in more chronic AF settings [49]). Troponin elevation is associated with older age, CAD risk factors, known CAD disease, creatinine elevation and ventricular rate but not with angina or ischemic ST depression [46, 28].

It is known that TnI elevations can occur also in the absence of significant coronary stenoses probably because of supply–demand mismatch or atrial–ventricular stretch [46]. Moreover, it has to be taken into account that troponin levels may be elevated for other reasons in acute AF patients (79 % in the study of Meshkat et al. [50] including demand-related rise in 36 %, congestive heart failure in 29 %, renal failure in 17 %, sepsis in 14 % and pneumonia in 2 %).

TnI elevation leads to increased prescription of diagnostic tests for CAD which demonstrated mild diagnostic yield (absent in the study of Gupta et al. [46], useful leading to threefold coronary revascularisation rate and better outcome in the study of Conti et al. [47]). Although these studies confirm that biomarkers seem useful for improving risk prediction in AF, the link between AF and coronary artery disease needs additional investigation.

ECG changes suggesting ischemia (ST segment depression) even in the absence of angina or troponin elevations are also frequent. The positive predictive value for

significant CAD varies from 31 [51] to 50 % [52]. Pradhan et al. [51] observed a strong correlation between grade of ST depression and ventricular rate. In their series, the percentages of positive results for diagnostic tests for CAD did not differ significantly between patients with (31 %) or without (21 %) ST depression during AF, so in conclusion, they stated that ST depression during AF is a prevalently rate-related phenomenon.

Absence of ECG changes resulted highly reassuring in the study of Tsigkas et al. [52] (only 4 % prevalence of CAD). In the series of Androulakis et al. [53], the prevalence of ST depression during fast FA was 32.5 %, and non-invasive diagnostic tests performed quite well in identifying patients with CAD.

So what to do in the presence of TnI elevation or new "ischemic" ECG changes during rapid AF?

- *Negative TnI* and *no ECG changes* do not require further investigation.
- *Mildly positive TnI values or ECG changes* should be evaluated in a polyparametric context which accounts for risk factors and cardiac comorbidities.
  - *Lower-risk* patients may be discharged after 12-24 h in an observation unit if stable and troponin descending, possibly after an echocardiogram and non-invasive provocative test for CAD (otherwise these tests should be arranged shortly after as outpatients).
  - *Higher-risk* patients should be admitted.

Heart failure (HF) and AF are strongly associated diseases and can interact to promote their perpetuation as onset of AF can worsen symptoms in patients with HF. These patients should be managed according to clinical severity. If markedly compromised (pulmonary oedema), they should be cardioverted if there is no prompt response to rate control (amiodarone or digoxin are agents of choice) [4]. If clinical presentation is less severe and AF duration is less than 48 h, pharmacological cardioversion with amiodarone or ECV can be considered as alternative to rate control strategy. For rate control purposes, cautious use of beta blockers in patients with systolic heart failure (or diltiazem if HF with preserved EF) can be considered (AHA/ACC/HRS 2014 class I recommendation) [5].

Conversely, worsened HF can promote a rapid ventricular response in permanent AF. These patients usually do not respond to cardioversion and rate control is as well more difficult to achieve. The mainstay of therapy in this setting should be aimed to optimise HF treatment.

Patients may present with newly detected HF in the presence of AF with a rapid ventricular response. These should be presumed to have a rate-related cardiomyopathy, with the arrhythmia being a potentially reversible cause of HF [54]. In this situation, two options can be considered: (1) rate control and re-evaluation for EF improvement and (2) rhythm control, which common practice is to initiate amiodarone and cardiovert in the patient electrically at least 3 weeks later [54]. In our clinic, we try to pursue a more rapid rhythm control strategy for patients with suspected tachycardiomyopathy which consists in performing TEE after clinical stabilisation with HF medications, rate control and anticoagulation. If no thrombus is

detected, the patient receives a 24 h amiodarone infusion after which ECV is performed and followed by oral loading dose of amiodarone.

AF in Pre-excitation If very rapid and unstable, urgent ECV should be performed [4, 5, 9]. If heart rate is not too high and the arrhythmia is well tolerated, it can be cardioverted with intravenous flecainide, propafenone, ibutilide and procainamide. The same agents are effective of rate control [4, 5, 20]. Drugs acting on the AV node, like calcium channel blockers, digitalis and adenosine, are contraindicated, because conduction over the accessory pathway is favoured and the rate transmission to the ventricle may become very rapid potentially inducing ventricular fibrillation. Amiodarone has recently been defined as harmful in the AHA/ACC/HRS 2014 guidelines [5], whereas ESC guidelines 2010 [4] recommend it class I for rate control. Beta blockers are contraindicated according to ESC guidelines 2010 [4] but might be used with caution according to the AHA/ACC/HRS 2014 guidelines [5].

5.4 A Possible Algorithm/Pathway for Diagnosis and Treatment

The management of patients with AF depends on their clinical presentation which may be unstable (Fig 5.8), stable with AF onset < 48 hours (Fig. 5.9) or stable with AF onset > 48 hours/undefined onset (Fig 5.10).

If cardioversion is the choice, check potassium levels (unless emergent ECV is necessary) and correct it if necessary proceeding. If patient is on chronic digoxin therapy, plasma level should be checked (ECV is contraindicated in case of intoxication).

In general, ECV is more effective than pharmacological cardioversion (PCV) and requires less time, but greater organisational efforts.

SR is achieved in about 90 % with ECV and 70 % with PCV [55]. If PCV fails, ECV restores SR in the majority of cases. On the contrary, if AF relapses immediately (IRAF) after ECV, the use of an antiarrhythmic agent before repeat CVE enhances the probability of maintaining SR. If AF does not convert to sinus rhythm with ECV (no or a maximum single sinus beat achieved, as defined by ESC 2010 guidelines [4]), the patient can be pretreated with ibutilide (1 mg over 10 min) which lowers defibrillation threshold and facilitates greatly achievement of SR on repeat ECV [56].

Pharmacologic cardioversion is little effective after 7 days of AF onset; therefore, in this case, ECV is preferred.

Atrial flutter poorly responds to antiarrhythmic drugs except for ibutilide; therefore, ECV should be first choice. If propafenone or flecainide are used for AFL conversion, slowing of atrial rate occurs, which sometimes can conduct faster to the ventricles (from usual 2:1 to 1:1 conduction), often with conduction aberrancy (Fig. 5.6). The result is a very rapid, frequently untolerated arrhythmia which should be electrically cardioverted. So if these agents are used for treatment of AFL, co-administration of rate control drugs is advised. The same phenomenon may occur when flecainide or propafenone is used for conversion of AF, as in some cases AF

organizes into AFL ("IC flutter"). In rare cases of patients treated with these agents, an electrocardiographic "Brugada pattern" may become evident (coved-type ST elevation in at least one lead from V1 to V3). These patients should undergo cardiologic consultation before eventual discharge.

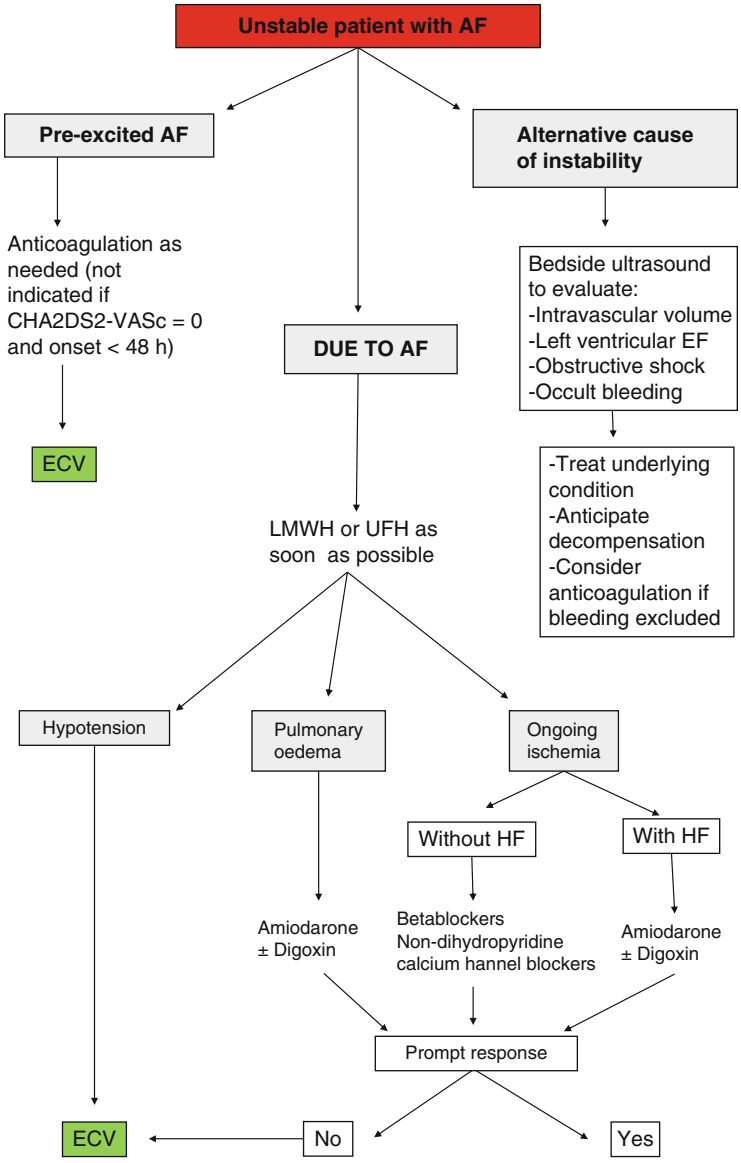

Fig. 5.8 Algorithm for management of patients with unstable AF

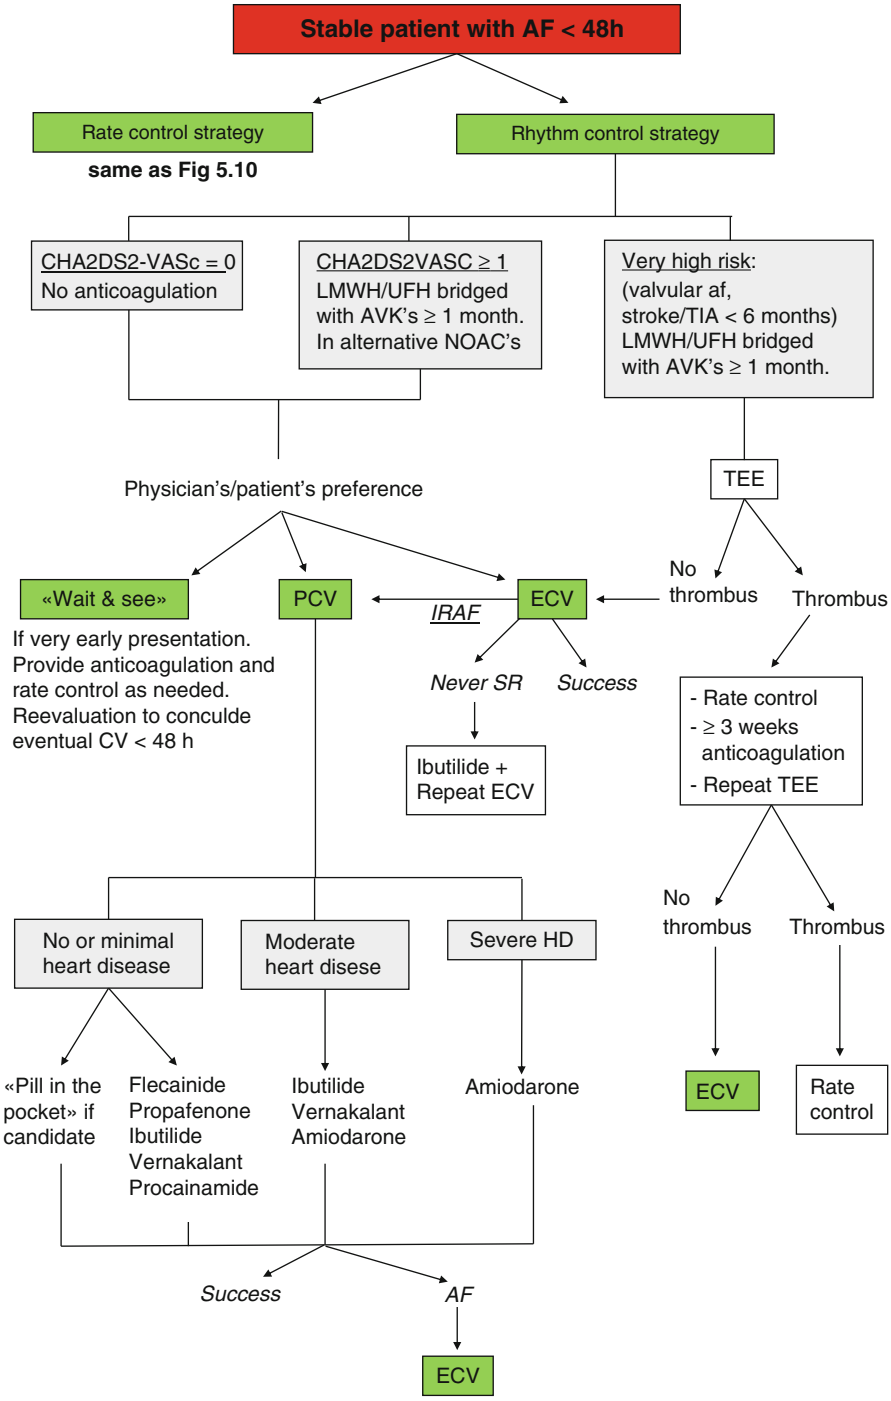

Fig. 5.9 Algorithm for management of patients with stable AF presenting <48 h from onset

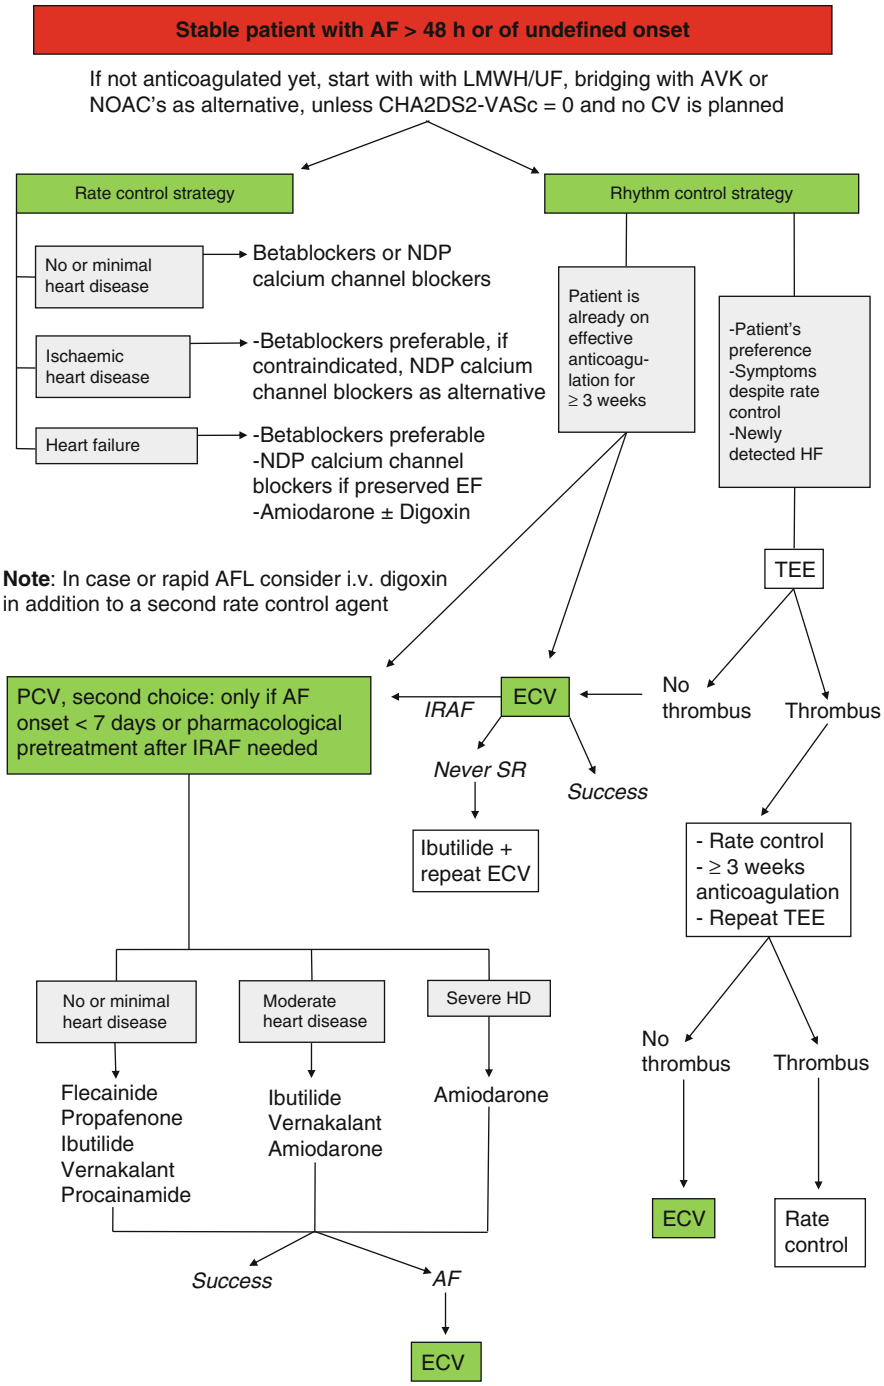

Fig. 5.10 Algorithm for management of patients with stable AF presenting >48 h from onset

A patient who has undergone pharmacological cardioversion should be monitored for a period afterwards (usually half of the drugs elimination's half life) to rule out bradycardia, AV block or ventricular proarrhythmia or hypotension, before discharge. If a patient has been electrically cardioverted, at least 3 h of monitoring is needed [4].

5.4.1 Electrical Cardioversion

Sedation can be provided by different professionals, based on competence, organisation and therapy used. Emergency physicians are involved in the great majority throughout the world for AF cardioversion in the ED. Less often, cardiologists or anaesthesiologists supervise the procedure [21].

A number of medications can be used, like benzodiazepines, narcotics and propofol, alone or in combination. *Midazolam*, a benzodiazepine with a short half-life is gaining increased diffusion because of its pharmacodynamics, wide therapeutic range and availability of a reversal agent (flumazenil). In the two major series [57, 58], adequate sedation was achieved in nearly all patients and no serious complications were observed. Usually, initial bolus doses of 0.01–01 mg/kg are used (the higher ones when the agent is used alone), which may be followed by repeated boli. Mean total dosage used throughout major studies on the use of midazolam as single agent was around 10 mg [59]. *Propofol* is another popular agent for sedation as it has an even more rapid onset of action and washout. On the other hand, it has a greater potential for hypotension and respiratory depression. It is used at dosages of 1–2.5 mg/kg [60].

The procedure can be performed with older monophasic or newer biphasic defibrillators. The latter are more effective with lower energy requirements [61]. The device is connected to the body by a couple of adhesive pads or a couple of handheld paddles.

Four pad positions are currently used: anterolateral, anteroposterior, anterior–left infrascapular and anterior–right infrascapular. They are equally effective to treat atrial or ventricular arrhythmias [62]. If paddles are used (anterolateral position), the operator should press firmly, the optimal force being 8 kg. If the patient has an implantable cardioverter defibrillator (or a pacemaker), anteroposterior or anterolateral locations are acceptable and the nearest pad or paddle should be positioned at least 8 cm away from the device [63]. After the procedure, the device should be interrogated and evaluated to ensure normal function [4]. The DC shock must be synchronised to the R wave to avoid the risk of inducing ventricular fibrillation.

The recommended initial biphasic energy dose for ECV of adult atrial fibrillation is 120–200 Joules (J), whereas for atrial flutter, 50–100 J is usually sufficient. If CV fails, energy should be stepwise increased or the position of the pads changed. For monophasic defibrillators, cardioversion should start at 200 J (100 J for AFL) [10, 62, 63].

Complications They are more often related to arrhythmias, usually transient asystole or bradycardia (0.9 % in the acute CV setting of the Fin CV study [39]).

Pre-cardioversion antiarrhythmic therapy, rate control therapy or slow ventricular rate did not predict bradyarrhythmias, whereas older age, female sex or unsuccessful CV did.

Thromboembolic complications are rare but not negligible if patients are adequately stratified and treated.

Ventricular arrhythmias are exceptional as are episodes of pulmonary oedema.

Complications can rarely be related to sedation like hypotension and prolonged respiratory arrest but are managed with conventional support (fluids and manual ventilation) in the great majority.

5.4.2 Drugs for Rhythm and Rate Control

- Note1: not all drugs or formulations for i.v. or oral use are available in all countries.
- Note 2: for rate and rhythm control drugs, dosages and infusion protocols usually vary between the different guidelines [1, 4, 5, 10, 20, 41]. If there is agreement between sources (or with little variations), one protocol is reported, which also corresponds to the author's practice. If there are marked differences, alternative protocols are mentioned.

5.4.2.1 Rhythm Control Drugs

Flecainide Sodium channel blocker with quite rapid action restores SR in 67–92 % in 6 h. Dosage: 2 mg/kg i.v. over 10 min. Ideal agent for patients with no or minimal heart disease. Avoid in patients with ischaemic heart disease, left ventricular dysfunction, intraventricular conduction delay or Brugada Syndrome. Risks are ventricular proarrhythmia, AV block and electromechanical dissociation. When used for conversion of AFL, 1:1 conduction may ensue with rapid ventricular rate if no rate control agent has been associated. In some countries (USA), approved only for oral use. In this case, 200–300 mg is administered orally (the same dose as the "pill-in-the-pocket" approach), AHA/ACC/HRS 2014 [5] and CCS 2010 [64] guidelines recommending administration of a beta blocker or calcium channel blocker before.

Propafenone Similar properties, indications and efficacy as for flecainide. Dosage: 2 mg/kg i.v. over 10 min. Avoid also in severe COPD because of its weak noncompetitive beta blocking property. In the USA available orally only: administrate 450–600 mg preceded by AV node-blocking agent as above.

Procainamide Sodium channel blocker. Dosage: 15–17 mg/kg i.v. over 1 h with conversion rate around 60 %. Very popular in Canada. Recommended for AF conversion in stable patients in CCS guidelines 2010 [64]. Causes transient hypotension in 5 %.

Amiodarone Multichannel blocker, also with beta- and calcium channel blocking activity if used intravenously. Prolongs prevalently refractoriness in chronic use. Dosage: 5 mg/kg in 1 h, then 50 mg/h for 24 h (ESC 2010 [4]) or 150 mg in 10 min, then 1 mg/min for 6 h, then 0.5 mg/min for 18 h (AHA/ACC/HRS 2014 [5]).

Amiodarone should be diluted in 5 % glucose solution (otherwise there is a risk of crystallisation of the solution). It restores SR with delayed action but similar efficacy as flecainide and propafenone at 12–24 h. It has also significant rate-slowing properties. It is the agent of choice for patients with severe heart disease for both purposes of cardioversion and rate control. Contraindicated in hyperthyroidism, avoid if possible in patients with severe COPD and hypothyroidism. Most common acute side effects are hypotension (especially if infusion is too fast) and phlebitis (the longer the infusion lasts, the more probable).

Ibutilide Rapid-acting agent, prolongs repolarisation. Dosage: 1 mg i.v. over 10 min, if unsuccessful, repeat after 10 min same dose. AF conversion rate is around 50 % with time to conversion about 30 min. Best available conversion agent for AFL. It carries a considerable risk of QTc prolongation and torsades de pointes (4 %). Patients should be monitored for a minimum of 4 h after. Some authors suggest pretreatment with 1–2 g $MgSO_4$ to lower the proarrhythmic risk. Contraindicated if patients are hypotensive, have manifest congestive heart failure, have very low EF (<30 %) and hypokalemic or if QTc >440 ms. Pretreatment with 1 mg over 10 min facilitates great ECV in patients who failed it before.

Dofetilide Prolongs repolarization. Has been mostly studied in the setting of persistent AF. A response may take days or weeks, and therefore it is not an ideal agent in the ED setting. Mentioned and recommended class I only in 2014 AHA/ACC/HRS guidelines [5]. Dosages: 500 mcg BID if creatinine clearance (CrCl) >60, 250 mcg BID if 40–60, 125 mg BID if 20–40. Do not use if CrCl under 20 ml/min. Do not initiate treatment out of hospital (risk of torsades de pointes).

Vernakalant Fast-acting atrial selective multichannel blocker with conversion rate around 50 % and median time to conversion about 10 min. Dosage: 3 mg/kg i.v. over 10 min, followed, if unsuccessful, by second infusion of 2 mg/kg i.v. over 10 min after 15. Contraindicated in hypotensive patients (<100 mmHg), NYHA 3–4 heart failure, FE <35 %, ACS in the last 30 days, severe aortic stenosis and QTc >440 ms.

5.4.2.2 Rate Control Drugs

Beta blockers Very effective, first choice in acute coronary syndrome or heart failure patients (avoid or use with extreme caution in acute decompensation). Do not use in severe COPD and pre-excitation syndrome. Metoprolol, atenolol and propranolol can be used intravenously and orally and are therefore the most useful for acute and chronic treatment. Esmolol is available intravenously only and is frequently used in the intensive care setting. Other beta blockers like bisoprolol or carvedilol are available for oral administration only and can be used if rate control is not too urgent and for chronic therapy.

- Metoprolol: 2.5–5 mg i.v. in 2 min every 5 min up to three doses (max 15 mg), oral maintenance dose 50–200 mg/day
- Atenolol: 2.5 mg i.v. at a rate of 1 mg/min to be repeated at intervals of 5 min up to a maximum of 10 mg
- Propranolol 1 mg i.v. over 1 min up to three doses at 2 min intervals, oral maintenance dose 30–160 mg/day
- Esmolol 0.5 mg/kg i.v. bolus over 1 min, then 50–300 mcg/kg/min i.v.

Nondihydropyridine (NDP) and Calcium Channel Blockers (Diltiazem, Verapamil) Very effective, diltiazem is the less inotropic negative and hypotensive of the two. Avoid in heart failure patients (with the exception of HF with preserved systolic function if not acutelly decompensated) and pre-excitation syndrome.

- Verapamil: 0.075–0.15 mg/kg i.v. bolus over 2 min, may repeat 10 mg bolus after 30 min if uneffective, then 0.005 mg/kg/min infusion [5]. Oral maintenance dose 160–360 mg/day
- Diltiazem 0.25 mg/kg i.v. bolus over 2 min, may give a second dose of 0.35 mg/kg, then 5–15 mg/h infusion. Oral maintenance dose 180–360 mg/day

Amiodarone Usually second-line agent. It is well tolerated in critically ill patients where it can be the first choice.

Digoxin Usually a second-line agent with moderate and delayed efficacy on rate control. When used intravenously, onset of action takes 1 h and peak rate-slowing activity is reached at 6 h. It is first-line agent in patients with acute heart failure. Due to its vagomimetic activity, it tends to transform atrial flutter in fibrillation (about 25 %, personal observation) so it turns out very helpful in rate control for flutter, which is harder to achieve than for AF. In the author's practice, digoxin is used as first-line agent, associated with another rate control drug when fixed. 2:1 AV conduction with rapid ventricular rate is present. Avoid in moderate or severe renal failure due to risk of intoxication.

Dosage 0.25–0.5 mg i.v. with repeat dosing, maximum 1.5 mg/24 h. Oral maintenance dose 0.0625–0.25 mg/day

5.5 Indications for Hospitalisation, Follow-Up and Referral

Hospitalisation should be in general considered for patients with AF and severe symptoms (heart failure, severe angina, syncope), when a significant heart disease is suspected, important comorbidities are present, symptoms are not properly controlled (failed cardioversion or rate control) or if complications occur during first approach treatment.

Decision algorithms like RED-AF [65] and AFFORD [66] have recently developed for predicting 30 days adverse events in AF patients presenting to ED with AF. Nomograms contain many clinical predictors and points are assigned to each predictor. Adverse events vary from ED return visit for recurrent AF to death, through different grades of severity. The AFFORD [66] model fared well in risk prediction and in the identification of patients at very low risk which the authors stated could be safely discharged after cardioversion or adequate rate control, but these were only 17 % of the total. This still poses the problem of the acceptable risk threshold for indicating hospitalisation (e.g. is it worth to hospitalise a patient to avoid return visit for AF relapse? Is stroke preventable by hospitalisation if patient is properly anticoagulated also at home?). Furthermore, the same authors

admit that the effect of hospitalising ED patients with acute AF on short-term adverse events remains unanswered [65] (RED-AF). Uncertainties on hospitalisation criteria are still reflected by the wide discrepancy of the discharge rate after successful CV: 85 % in Canada, 76 % in Australasia, 48 % in the USA and 27 % in the UK [21].

In the absence of obvious severe presentation or comorbidities, careful individual judgement on high-risk features should be performed to guide this decision.

It should be stressed that new-onset AF carries a worse prognosis [7, 18]. In the study of Miyasaka et al. [67], hazard ratio for mortality risk was 9.6 within the first 4 months and 1.7 thereafter, compared with age- and gender-matched general population. The main reason is thought to be that AF complicates underlying conditions with poor prognosis like cardiovascular diseases or malignancies. As a consequence, patients with first episode should undergo a rapid medical workup which can be done of course during hospitalisation, but alternatively, if there is no clinical instability, on outpatient basis. In order to favour the latter strategy, diagnostic pathways which include evaluation by cardiologist and other professionals as well as diagnostic testings should be defined locally and be easily accessible, which is unfortunately not always the case and gives reason for the high percentage of hospitalisation of AF patients in some countries [23].

Follow-up of AF patients should be individualised and take into account symptomatic status, comorbidities (which should be followed up as specifically needed), antiarrhythmic treatment, thromboprophylaxis and complications. Visits should be usually performed by the primary care physician or a cardiologist.

Asymptomatic patients in sinus rhythm without medications and comorbidities do not need a structured follow-up, and a periodic self-check of pulse regularity should be recommended.

Patients on antiarrhythmic or on rate control medications should get an ECG 1 week after beginning or up-titration of therapy to check for efficacy and proarrhythmic complications and a visit every 6–12 months.

At every follow-up visit, the following issues should be reassessed:

- Effectiveness of symptom control either while pursuing rate or rhythm control strategy
- Need for antithrombotic therapy, re-evaluation of risks and benefits
- Optimization of therapy for comorbidities
- Lifestyle counselling and check for adequate compliance

Furthermore, in relation to individual therapy, there may be a need for periodical lab tests (e.g. thyroid function for patients on amiodarone, liver function for patients on dronedarone, blood count and renal function for patients using novel anticoagulants, etc.).

Echocardiography should be performed as recommended for underlying structural heart disease or in case of worsening symptoms despite apparent achievement of rate or rhythm control. Holter recording may be needed for assessment of

adequate rate control or if proarrhythmia is suspected. An exercise stress test can help to adjust rate control medications in active patients with permanent AF who complain uncontrolled palpitations during exercise.

Referral to a cardiologist *is generally indicated for patients with a first AF episode.* A possible exception is older patients with asymptomatic AF with adequate rate control. Basic screening examinations like laboratory tests, thyroid function and echocardiography should be arranged before referral. Other reasons for referral to a cardiologist are inadequate rhythm control strategy (ineffective or not tolerated antiarrhythmic medications), ineffective rate control strategy (inadequate rate control or poor quality of life despite adequate rate control) and evaluation for radiofrequency ablation.

Wide QRS Complex Tachycardia in the Emergency Setting

6

Giuseppe Oreto, Francesco Luzza, Gaetano Satullo, Antonino Donato, Vincenzo Carbone, and Maria Pia Calabrò

6.1 Wide QRS Complex Tachycardia

A wide QRS complex tachycardia can be (1) ventricular tachycardia (VT); (2) supraventricular tachycardia (SVT) with bundle branch block that may be either preexisting or due to aberrant conduction, namely, tachycardia-dependent abnormal intraventricular conduction; a further possibility is the effect of some antiarrhythmic drugs that slow down intraventricular conduction, resulting in marked QRS complex widening; and (3) supraventricular tachycardia with conduction of impulses to the ventricles over an accessory pathway (preexcited tachycardia).

In the presence of wide QRS tachycardia, the correct diagnosis is of paramount importance, since the treatment commonly used in SVT is different from that of VT, and some drugs useful in the former (e.g., verapamil) are harmful in the latter [1–3].

The origin of a wide QRS complex tachycardia can be reliably identified using a "holistic" approach, namely, taking into account all of the available items: no single criterion is able to provide a simple and quick solution of the problem in all cases. The available ECG signs are, without any exception, suggestive of ectopy, namely, ventricular origin of the impulses; SVT with aberrant conduction may only be diagnosed by excluding all of the items favoring VT. The recognition of ventricular or supraventricular origin of wide QRS complex tachycardias is not difficult if a

DOI 10.1007/978-3-319-24328-3_6

detailed analysis is used, taking into account several diagnostic signs: [4–12] the idea that a single quick item can offer an immediate and reliable solution is something of an illusion.

If, despite a complete diagnostic approach, the dilemma cannot be resolved, it is necessary to assume a ventricular origin of the arrhythmia since (1) a wide QRS tachycardia is more likely VT than SVT and (2) it is less dangerous to treat an SVT like it were ventricular in origin than applying to a patient with VT the treatment commonly used for SVTs. In particular, intravenous verapamil should be avoided whenever SVT diagnosis is not certain, since this drug is harmful in some VT patients [1–3].

6.2 General Criteria

6.2.1 Atrioventricular Dissociation

Whenever the electrical activity of the atria is recognizable, two different situations may occur:

1. Atrioventricular (A-V) dissociation
2. Relationship between P waves and QRS complexes.

A-V dissociation demonstrates the ventricular origin of the wide QRS complexes and occurs in a percentage variable from 19 to 70 % of VT cases [5, 6, 10, 11]. Dissociation, however, is often difficult to be diagnosed since in several cases, sinus P waves are not easily recognizable, being simultaneous to QRS complexes or T waves. Moreover, in the presence of atrial fibrillation, A-V dissociation cannot be appreciated. Before excluding, in a wide QRS complexes tachycardia, the presence of P waves independent of QRS complexes, however, one should observe with great attention the configuration of several consecutive complexes in all 12 leads, paying the greatest attention to leads II and V1 (the ones where sinus P waves are usually evident). Aim of this analysis is comparing consecutive complexes searching for slight differences in QRS or T morphology: with this approach it is not rare to discover, in the presence of VT, that in some leads, slight variations in QRS complex or T wave configuration occur. To be sure that such differences express the presence of P waves dissociated from QRS complexes, and superimposed on these, it is necessary to measure the intervals separating the "disturbing" events: in case of A-V dissociation, they are separated from relatively constant intervals, being "long" intervals in multiples of the "short" ones (Fig. 6.1a). When, in contrast, the intervals separating the changes in morphology of T waves and/or QRS complexes are irregular, it is more likely that artifacts, rather than dissociated sinus P waves, are involved (Fig. 6.1b).

The best ECG leads to be analyzed, searching for "dissociated" P waves, are leads II and V1, the ones where sinus P wave voltage is usually relatively high; it is also advisable to observe the leads where the QRS complex and/or the T wave is of

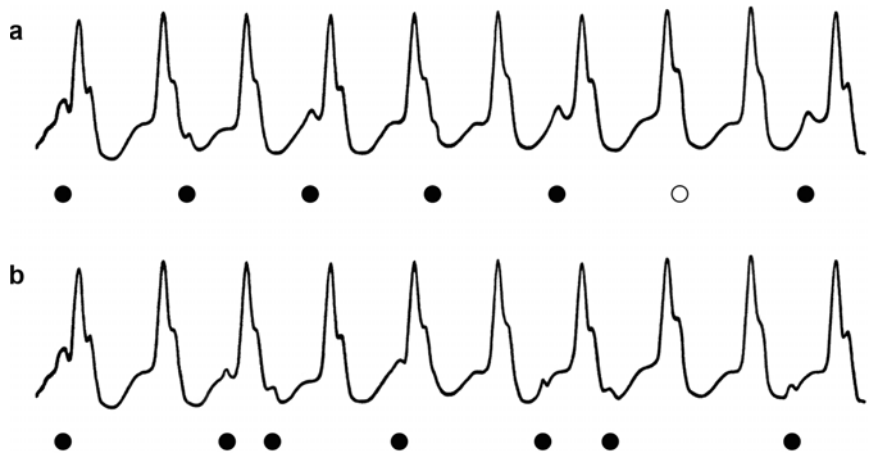

Fig. 6.1 Diagrams (**a**, **b**) show two wide QRS complex tachycardias. In both diagrams, small positive deflections, independent of QRS complexes, are present. In diagram (**a**) these deflections are rhythmic and separated by constant intervals; whenever a deflection is invisible, being coincident with a QRS complex (*circle*), the interval between two manifest waves is twice the basic interval. These small waves are, therefore, sinus P waves: accordingly, A-V dissociation can be diagnosed, revealing a ventricular origin of tachycardia. In diagram (**b**), in contrast, the small positive deflections are arrhythmic: they are not P waves but artifacts

low voltage, since it is relatively easy to detect the small atrial waves whenever these are not "buried" within large QRS or T deflections. This is expressed by the "haystack principle": if you are searching for a needle in a haystack, select a small haystack" (Fig. 6.2).

The bedside diagnosis of A-V dissociation can be improved by heart sound auscultation and arterial pulse palpation: whenever the atrial contraction is dissociated from ventricular activity, it is possible to appreciate a variable loudness of the 1st heart sound and variability in peripheral pulse amplitude. This is because (1) whenever atrial contraction occurs immediately before ventricular systole, the blood flow "opens" the atrioventricular valves, resulting in a relatively loud 1st heart sound, a phenomenon that does not occur if mitral and tricuspid valves are closed at the time of atrial systole, and (2) if atrial contraction occurs when the A-V valves are open, the diastolic ventricular filling is improved, resulting in a relatively increased stroke volume: accordingly, the pulse amplitude will be higher with respect to that of heart beats in which atrial systole occurs while the A-V valves are closed.

6.2.2 Second-Degree V-A Block

In ventricular tachycardia, atrial electrical activity may be not dissociated from ventricular one if retrograde ventricular-atrial (V-A) conduction occurs, as it happens in about one half of cases. The V-A ratio may be 1 (every QRS complex is followed by a

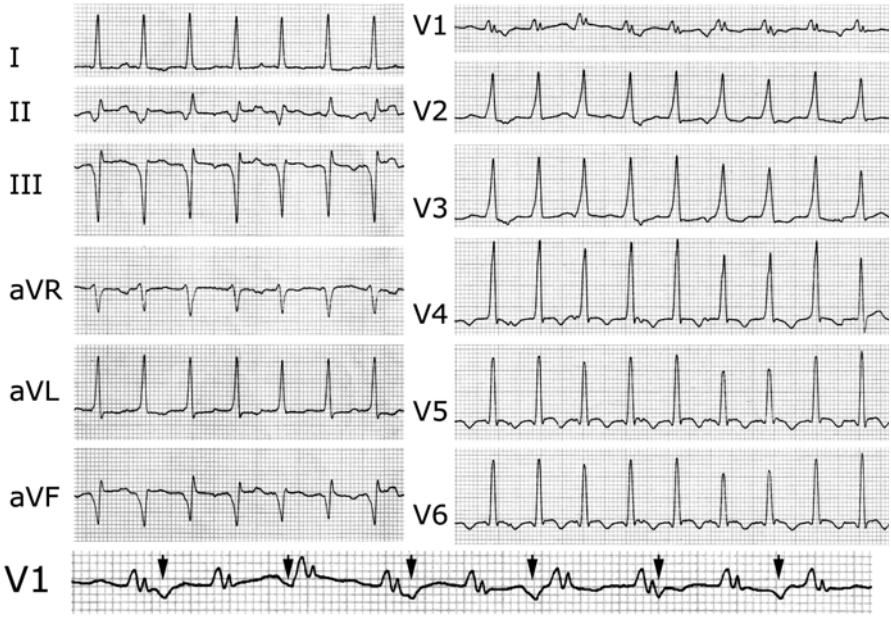

Fig. 6.2 Wide QRS complex tachycardia. QRS duration is 0.12 s, but since in some leads ventricular complexes are relatively narrow, a supraventricular tachycardia could be diagnosed at first glance. The ventricular origin of tachycardia is demonstrated by A-V dissociation; the P waves independent of ventricular complexes (*arrows*), and separated from constant intervals, are easily recognized in lead V1, since in this lead both QRS complexes ant T wave voltages are very low (the haystack principle)

retrograde P wave) or less than 1 when some ventricular impulses are not conducted to the atria. In a wide QRS complex tachycardia, a QRS/P ratio >1 (more QRS complexes than P waves) demonstrates the ventricular origin of the arrhythmia [6–8, 12], (Fig. 6.3), whereas a 1:1 ratio does not permit any definite conclusion since P waves may (a) express a supraventricular tachycardia with 1:1 A-V conduction or (b) represent the retrograde atrial activation during ventricular tachycardia. If analysis of P wave configuration is possible, a main P vector directed inferiorly demonstrates supraventricular origin of the arrhythmia, whereas a P vector directed superiorly (negative P waves in the inferior leads) does not permit any conclusion since not only VT but also several supraventricular tachycardias share a retrograde activation of the atria. In some cases of VT, however, retrograde P waves appear as positive in the inferior leads, a phenomenon that has been called "the illusion of retrograde positive P waves" (Fig. 6.4) [8, 13, 14].

6.2.3 Capture and Fusion Beats

The presence of narrow, or relatively narrow, beats during wide QRS tachycardia suggests a diagnosis of VT, *provided that narrow complexes are preceded by a P wave with an interval consistent with anterograde A-V conduction of the impulse*. The narrow, or less wide, complexes are *capture* or *fusion* beats that occur

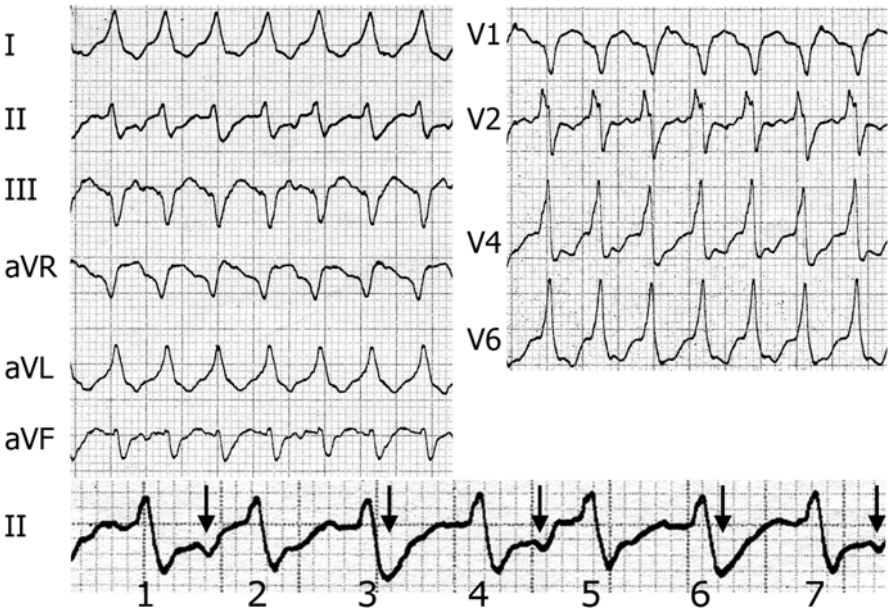

Fig. 6.3 Ventricular tachycardia with 3:2 retrograde block of the Wenckebach type. Lead II (enlarged in the *bottom row*) analysis reveals that ventricular complexes *1*, *4,* and *7* are followed by negative P waves occurring midway between two consecutive QRS complexes. Beats *3* and *6*, in turn, show very wide "S waves" that never occur in the other beats, whereas complexes *2* and *5* do not show any of the 2 above characteristics (negative P wave, wide "s wave"). It is, therefore, evident that in a group of 3 beats, the 1st one (complexes *3* and *6*) is followed by a retrograde P wave with a short R-P interval, whereas the P wave following the 2nd beat of the group (complexes *1*, *4*, *7*) occurs with a relatively long interval, and after the 3rd complex of the series (beats *2* and *5*), no P wave occurs. In other words, there is a retrograde 2nd-degree 3:2 Wenckebach type block, and this establishes the diagnosis of ventricular tachycardia. In this tracing, the r wave peak time in lead II is 30 ms

whenever, during VT, a sinus or supraventricular impulse succeeds in reaching the ventricles, whose depolarization is due totally (capture) or partially (fusion) to that impulse (Fig. 6.5). Capture and fusion beats are reliable signs of VT, but they are rare (4 % in a study based on 96 cases of proved VT [10]) and can be observed only in the presence of A-V dissociation. Since the latter phenomenon is, in itself, a clear sign of VT, the further help provided by capture and fusion beats is trivial, provided that these never occur whenever the heart rate is very high, being the A-V node made always refractory by ectopic ventricular impulses [6, 8].

6.2.4 Precordial QRS Concordance

A "concordant" QRS morphology in all the precordial leads, namely, ventricular complexes totally negative (QS pattern) or positive (R or qR pattern), demonstrates a ventricular origin of tachycardia, since no intraventricular conduction

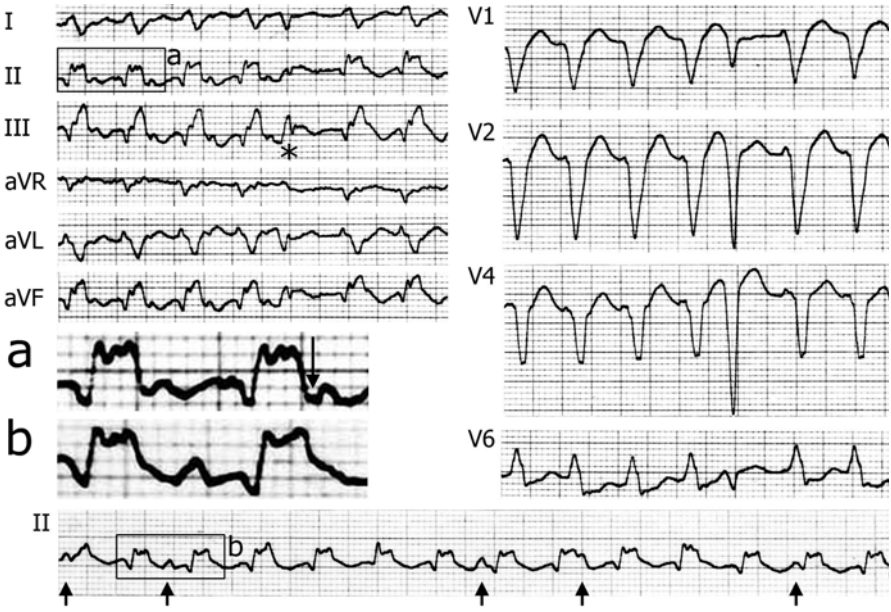

Fig. 6.4 Ventricular tachycardia with retrograde P waves apparently positive in the inferior leads. In all leads, that are simultaneous, apart from the tracing in the bottom strip, the 5th beat (*asterisk*) is a ventricular extrasystole. Beats 1–4 are followed by P waves that seem, at first glance, positive in the inferior leads and negative in aVR and aVL. The premature beat alters the relationship between QRS complexes and P waves, being the last two ventricular beats not followed by P waves. The bottom strip (lead II) has been recorded later with respect to the others and clearly shows A-V dissociation: P waves of sinus origin are positive (*arrows*) and independent of QRS complexes; some sinus P waves, occurring simultaneously with ventricular complexes, are invisible, being "buried" within the ventricular complexes. Panels (**a**, **b**) show enlarged beats: during retrograde V-A conduction, P waves are negative (*arrow* in section **a**), not positive as they seem at first glance. In section (**b**), a positive P wave is evident in between two QRS complexes, demonstrating A-V dissociation

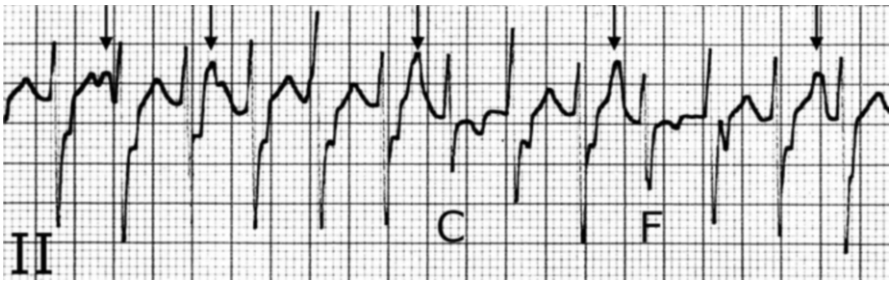

Fig. 6.5 Capture and fusion beats during ventricular tachycardia. In this ECG strip, A-V dissociation is evident (*arrows* point out sinus P waves that modify T wave morphology). In two occasions, the sinus impulse is conducted to the ventricles, giving rise to a narrow QRS complex (capture beat, labeled *C*) or to a fusion beat (labeled *F*). These are intermediate in configuration between ectopic wide complexes and capture beat

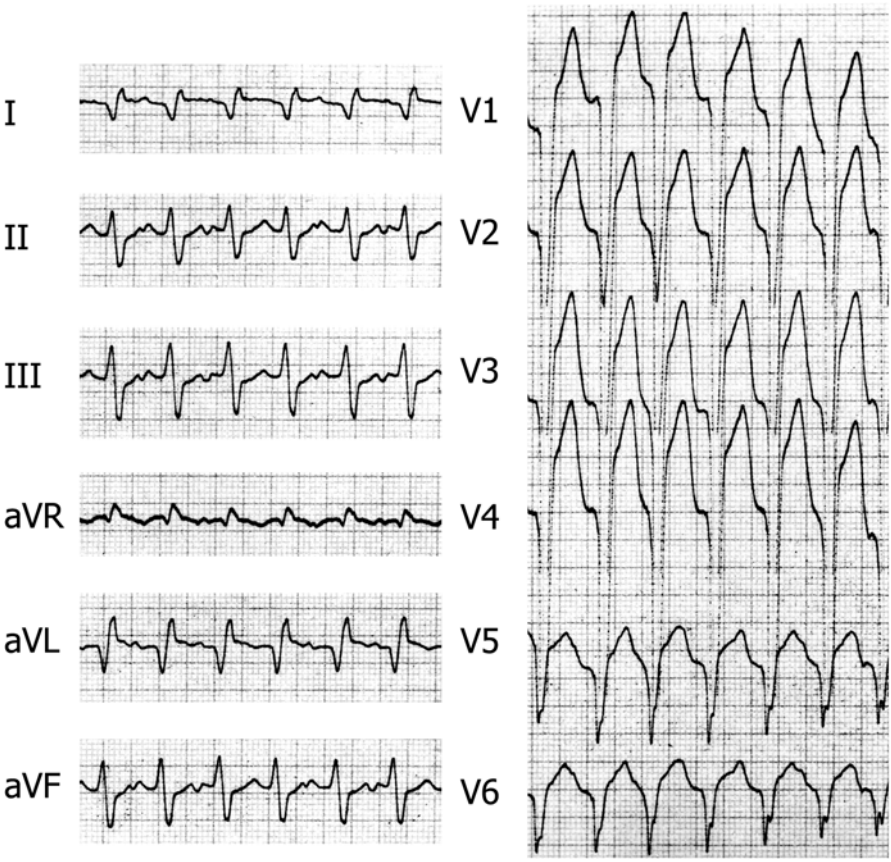

Fig. 6.6 Precordial concordance. In this tachycardia, wide QRS complexes with QS morphology are present in all precordial leads. This pattern demonstrates without any exception the ventricular origin of tachycardia. Analysis of the inferior leads also reveals a 2nd-degree V-A block with 3:2 ratio; the retrograde negative P waves modify the T wave configuration in two consecutive beats, whereas in the 3rd QRS complex, the T wave is not affected

disturbance can result in such a configuration [15]. Concordance, however, cannot be diagnosed if rS, Rs, or rs complexes occur even in one single precordial lead. In a study based on 232 electrocardiograms with bundle branch block analyzed during sinus rhythm, none showed precordial concordance, suggesting a 100 % specificity of this sign indicating the ventricular origin of the arrhythmia [16]. Negative concordance (QS morphology in all precordial leads, Fig. 6.6), however, is specific of VT, whereas positive concordance could be observed, although rarely, in a preexcited tachycardia due to a left-sided Kent bundle [7, 8]. Negative concordance in the bipolar limb leads (I, II, III) has also been proposed as a specific pattern suggesting VT; [17] such a configuration demonstrates an extreme right axis deviation, a phenomenon that never occurs in adults, apart from some cases of congenital heart disease or dextrocardia.

6.2.5 Absence of RS Complexes in the Precordial Leads

In several cases of VT, none of the precordial leads shows ventricular complexes with a configuration characterized by an R wave followed by an S wave (rs, RS, rS, or Rs). This sign, expressing in a slightly different manner the concept of "precordial concordance," suggests a ventricular origin of the arrhythmia. The sign specificity was 100 % both in the original study [5] and in another research based on 133 patients with wide QRS tachycardia; [10] in a different series, however, specificity was 81 and 98 % in the presence of positive and negative precordial QRS complexes, respectively [16].

6.2.6 Interval >100 ms from QRS Complex Beginning to S Wave Nadir in a Precordial Lead

It has been observed that whenever, in a wide QRS complex tachycardia, the interval from QRS complex beginning to S wave nadir exceeds 100 ms in a precordial lead, tachycardia is ventricular in origin [5]. The above criterion was fulfilled in 41 % of patients with previous myocardial infarction and VT [18]. In subjects with slowed down intraventricular conduction, however, leads V4–V6 show at times the above-mentioned sign even during sinus rhythm, particularly in the presence of left axis deviation. In a study based on electrocardiograms with left bundle branch block and sinus rhythm, 34 % of cases had an interval from QRS complex beginning to S wave nadir >100 ms [16], demonstrating a low specificity of this sign in revealing VT.

6.2.7 Vagal Stimulation Maneuvers

In the presence of QRS wide complex tachycardia, vagal stimulation can result in the following responses:

1. No change in tachycardia morphology or rate: the question remains open.
2. Sinus rhythm restoration: supraventricular reentrant tachycardia with a circuit incorporating the A-V node.
3. Variation in A-V conduction ratio, with appearance of P or F waves: atrial tachycardia or atrial flutter.
4. Variation in V-A conduction ratio, demonstrated by QRS complexes not followed by a retrograde P wave: ventricular origin of tachycardia.

6.3 The Electrocardiogram in the Absence of Tachycardia

An ECG recorded in the absence of tachycardia can be at times helpful, since a conduction disturbance or preexcitation observed during sinus rhythm can be the key to recognize the mechanism underlying the wide QRS complexes. In the great

majority of cases, however, no ECG recorded during sinus rhythm is available at the moment of the arrhythmic emergence. Whenever the ECG during tachycardia is identical to that obtained in sinus rhythm, the arrhythmia is supraventricular in origin, apart from a single exception: the bundle branch reentry tachycardia [19]. In the latter condition, a tracing in sinus rhythm can be misleading, since it suggests a supraventricular, rather than ventricular, origin of the arrhythmia [19].

6.4 QRS Complex Morphology in Leads V1 and V6

Analysis of QRS complex configuration represents an important tool in wide QRS complex tachycardia. Whenever other diagnostic signs (A-V dissociation, capture and fusion beats, precordial concordance, etc.) are either absent or controversial, the distinction between supraventricular and ventricular tachycardia lies on morphologic analysis of ventricular complexes, taking particularly into account leads V1 and V6. The 1st step is tachycardia classification based on QRS morphology in lead V1: whenever ventricular complex is mainly positive in this lead, tachycardia will be defined as "RBBB type," whereas if in that lead ventricular complexes are negative, tachycardia will be classified as "LBBB type." In any situation, the leads to be analyzed are V1 and V6.

6.4.1 Wide QRS Complex Tachycardia with Right Bundle Branch Block-Type Configuration (Positive QRS Complex in Lead V1)

V1. Ventricular complexes with morphology *R* or *Rr′* (the 1st R wave higher than the 2nd one), as well as *qR* or *RS* complexes, suggest VT, whereas both a triphasic (*rsR*Đ or *rSR*Đ) or biphasic configurations *rR*Đ with the 2nd R wave higher than the 1st one suggest SVT with aberrant conduction (Fig. 6.7).
V6. In this lead, *rS*, *QS,* or *qR* complexes are specific of VT (Fig. 6.8), whereas *qRs* complexes suggest aberrant conduction (specificity 95 %). Whenever the R/S ratio, however, is <1 (larger S wave than R wave voltage in lead V6), the ventricular, rather than supraventricular, origin of tachycardia is more likely [10, 16, 20].

6.4.2 Wide QRS Complex Tachycardia with Left Bundle Branch Block-Type Morphology (Negative QRS Complex in Lead V1)

V1. In the presence *of SVT with aberrant conduction and LBBB morphology, this lead shows either a QS configuration or a small and relatively narrow (≤30 ms) r wave* followed by a deep S wave with an early (<60 ms) nadir. R wave duration >30 ms or S wave nadir later than 60 ms from the QRS complex beginning suggest ventricular origin of the arrhythmia. Moreover, a notch in the proximal (descending) limb of S wave indicates VT (Fig. 6.8).

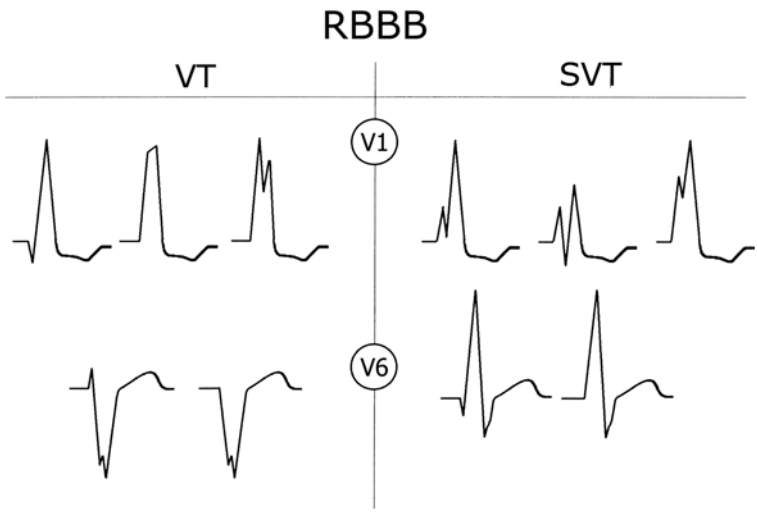

Fig. 6.7 Ventricular complex morphology suggesting either VT or SVT with aberrant conduction in wide QRS complex tachycardia with RBBB-like configuration (QRS complex mainly positive in lead V1)

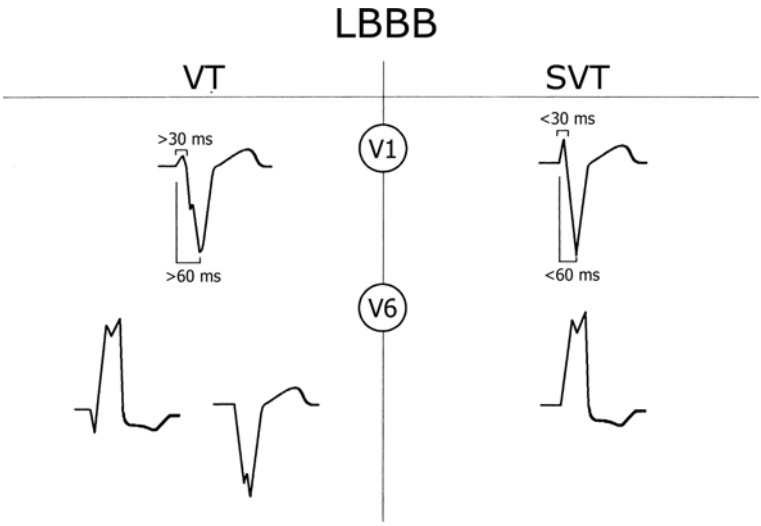

Fig. 6.8 Ventricular complex morphology suggesting either VT or SVT with aberrant conduction in wide QRS complex tachycardia with LBBB-like configuration (QRS complex mainly negative in lead V1)

V6. In a wide QRS complex tachycardia, negative or predominantly *negative QRS complexes in lead V6 suggest at first glance a ventricular origin* of the arrhythmia independent of the associated intraventricular disturbance pattern [20]. Impulses

of ventricular origin show often (69 % of cases) a negative net QRS amplitude (algebraic sum of positive and negative deflections) in V6, whereas this pattern is relatively rare (27 % of cases) in supraventricular tachycardia.

These signs based on QRS morphology in leads V1 and V6, introduced by Kindwall [21], express the slow initial progression of the ventricular wave front when the depolarization is not due to an impulse conducted over the His-Purkinje system. In true LBBB, thus, the 1st ventricular vector, expressing the right-to-left septal depolarization, is directed to the left and anteriorly: lead V1, thus, cannot show a *wide* r wave since the initial ventricular depolarization is fast, being the supraventricular impulse conducted over the Purkinje system. Accordingly, *in a broad QRS tachycardia with LBBB configuration, a relatively wide (≥30 ms) r wave in lead V1 strongly suggests a ventricular origin of the arrhythmia*. The same holds true for a relatively late (>60 ms) S wave nadir in lead V1 and for the presence of a notch in the descending S wave limb. The specificity of the above "ectopic" QRS morphologies in lead V1, however, is not 100 %: a study based on electrocardiograms with LBBB during sinus rhythm has reported a specificity of 78, 66 and 66 % for r wave duration in lead V1 >30 ms, S wave nadir >60 ms, and notch in the descending S wave limb, respectively [16].

6.4.3 Limitations of Criteria Based on QRS Morphology in Wide QRS Complex Tachycardia

Despite being useful, morphologic criteria are not absolute; the equations *typical bundle branch block = aberrant conduction, atypical bundle branch block = ventricular tachycardia* suffer some *limitations and may lead to wrong conclusions in patients treated with antiarrhythmic drugs, particularly those belonging to class 1C*. This is because these drugs slow down the intraventricular conduction, resulting in very abnormal ventricular complexes. Patients treated with 1C drugs may show extremely wide QRS complexes during SVT, to the extent that morphological analysis leads to a wrong diagnosis. This occurs not rarely in patients with atrial flutter treated with 1C antiarrhythmic drugs, that result in tachycardia rate reduction, favoring 1:1 A-V conduction of atrial impulses, and QRS complex widening.

6.5 Other Signs

6.5.1 QRS Duration >140 ms

It has been observed that a wide complex tachycardia with QRS duration >0.14 s is very likely ventricular in origin [11], but this criterion has a low specificity, ranging from 43 % [16] to 69 % [10]. Moreover, QRS complexes can be, although rarely, relatively narrow (<0.12 s) in ventricular tachycardia.

6.5.2 QRS Axis Deviation

In several cases of VT, left or right axis deviation occurs [9–11], and rarely the QRS axis is normal (between 0° and +90°) in VT. Superior QRS axis deviation, however, has been considered not suggestive of VT in the presence of ventricular complexes with LBBB configuration, whereas an RBBB morphology is often associated with VT (87 % specificity) [16].

6.5.3 Regularity

Apart from atrial fibrillation and atrial flutter or tachycardia with variable A-V conduction ratio, supraventricular tachycardias are usually regular. This is also true for sustained ventricular tachycardias, although irregularity in itself does not exclude VT, the variability of R-R intervals being not uncommon in focal tachycardias, particularly at the beginning or at the end of tachycardia. Sustained VT cycle variability has also been attributed to exit block [22] or longitudinal dissociation in the reentry pathway of tachycardia [23, 24].

6.6 Lead aVR Analysis

A new algorithm based on lead aVR analysis has recently been proposed to distinguish ectopy from aberrant conduction in wide QRS complex tachycardia [25, 26]. The procedure is based on four steps (Fig. 6.9): the first three ones are simple and quick, whereas the 4th step requires complicated voltage measurements. Whenever the sign looked for in steps 1, 2, or 3 is present, the diagnosis is VT, whereas only in step 4 becomes possible the recognition of SVT with aberrant conduction (Fig. 6.9).

6.6.1 Step 1: Dominant Initial R Wave

146 out of 482 cases of wide QRS tachycardia showed in lead aVR *a dominant initial R wave*, which was the largest ventricular complex deflection (Figs. 6.9 and 6.10). This pattern *demonstrated a ventricular origin* of the arrhythmia, confirmed by intracardiac recordings, in 144/146 cases (sensitivity 38.9 %, specificity 98.2 %).

6.6.2 Step 2: q or r initial Wave with Duration >40 ms in qR or rS complexes

A ventricular complex starting, in aVR, *not with a dominant R wave but with a low voltage q or r wave whose duration was ≥40 ms* was present in 74 out of 336 cases without a dominant initial R wave. In 65 of these, the diagnosis was VT (sensitivity 28.8 %, specificity 91.8 %).

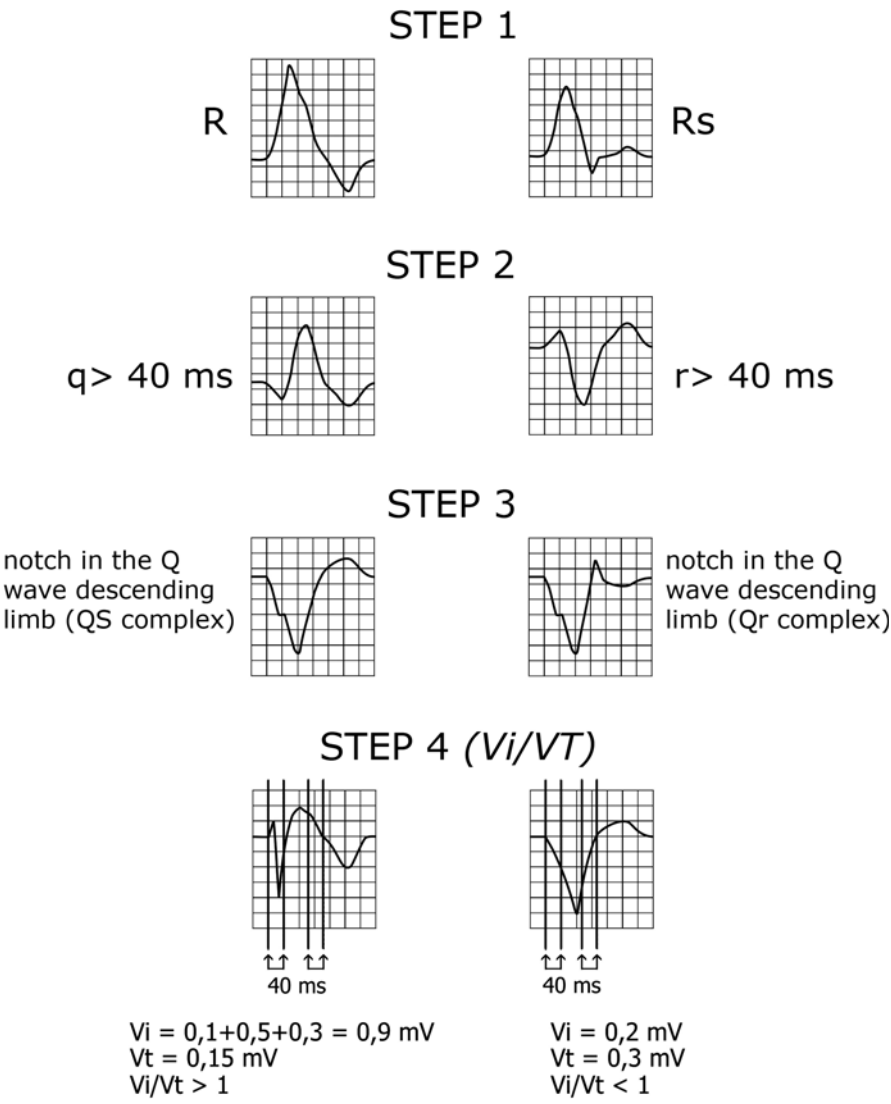

Fig. 6.9 Algorithm based on aVR analysis. *Vi* voltage of the first 40 ms, *Vt* voltage of the final 40 ms (see text)

6.6.3 Step 3: Notch in the Descending Q Wave Limb of a Negative (QS or Qr) Ventricular Complex

This pattern was present in 32 over 37 VT cases where the first 2 criteria were absent (sensitivity 19.9 %, specificity 95 %).

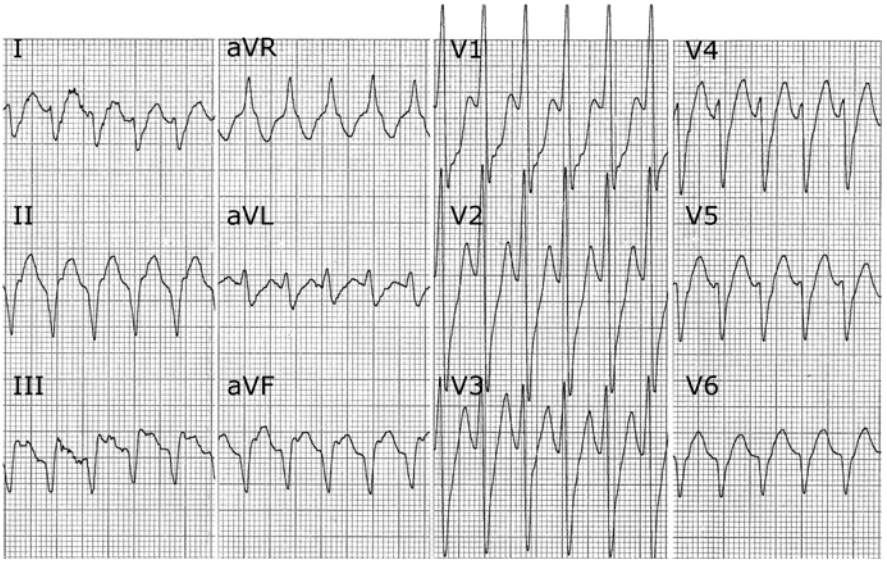

Fig. 6.10 Ventricular tachycardia. In this wide QRS complex tachycardia, negative P waves follow ventricular complexes in the inferior leads. The arrhythmia cannot be classified as "RBBB morphology" or "LBBB morphology" since lead V1 shows complexes with RS configuration. Both QS complexes in lead V6 and aVR analysis (entirely positive complexes) suggest VT

6.6.4 Step 4: *Vi*/*Vt* Ratio

The presence of any sign in steps 1–3 demonstrates the ventricular origin of the arrhythmia, but *the absence of these criteria does not permit to exclude VT and does not demonstrate SVT.* In this situation it is necessary to evaluate the *Vi/Vt ratio, namely, the ratio between the voltages recorded during the first 40 ms of the QRS complex (Vi) and those measured during the last 40 ms of the complex (Vt*). To calculate *Vi* (initial voltage) and *Vt* (terminal voltage), it is necessary to sum the amplitude of *all the deflections present in the first and the last 40 ms*, respectively (Fig. 6.10). This is not a very easy task, since the authors suggest to measure not the simple voltage of the deflection, but to take into account separately any limb of the waves. For example, if an R wave of 3 mm is present at the beginning of the ventricular complex, the corresponding calculated voltage is 6 mm (3 of the ascending limb + 3 of the descending limb). Unfortunately, it is not easy to distinguish exactly the moment of QRS complex beginning and/or termination, to the extent that the authors suggest to use a simultaneous recording of several leads (at least aVR, aVL, aVF) in order to make easier the identification of QRS complex beginning and/or termination.

A Vi/Vt ratio ≥1 suggests a diagnosis of SVT with aberrant conduction, while *a ratio ≤1 speaks in favor of VT.* This criterion has a logical basis: in VT, intraventricular conduction is totally independent of the conduction system, and the ectopic impulse is slowly conducted; accordingly, a small amount of ventricular muscle is

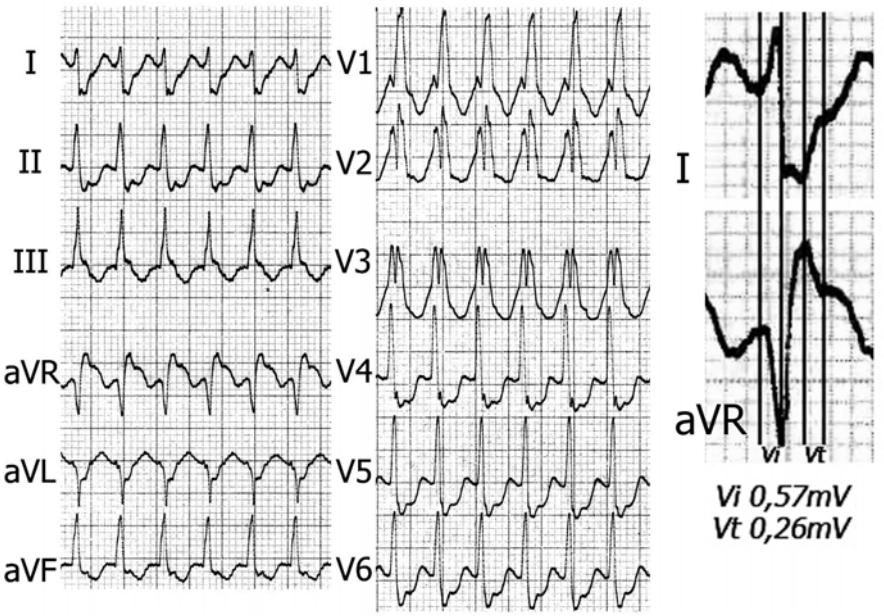

Fig. 6.11 Supraventricular tachycardia with aberrant conduction. Neither P waves nor signs of A-V dissociation are recognizable in this ECG. The morphology of ventricular complexes (rsR′ in V1, Rs with wide s wave in V6) suggests aberrant conduction. The same diagnosis results from lead aVR analysis, since neither dominant initial R wave nor wide q or r wave with duration >40 ms occurs, and is also absent a notch in the proximal q wave limb. Moreover, the ratio between the initial (first 40 ms, *Vi*) and the terminal (final 40 ms, *Vt*) voltage is >1, pinpointing the diagnosis of aberrant conduction

depolarized during the first 40 ms, resulting in a relatively low voltage of the corresponding ECG deflections. When, in contrast, the initial ventricular depolarization occurs using the Purkinje system, as it happens in bundle branch block, a relatively large myocardial mass is depolarized during the first 40 ms, resulting in relatively high voltage-related deflections. Examples of correct diagnosis arrived by means of aVR analysis are reported in Figs. 6.11, 6.12, and 6.13.

In conclusion, aVR analysis can be very helpful whenever one of the signs described in steps 1–3 is present, but becomes less useful in their absence.

6.7 R Wave Peak Time at Lead II

It has recently been reported that the *R wave peak time (RWPT) duration in lead II (the interval from the QRS complex beginning to the 1st change in polarity*) permits a quick and reliable distinction between VT and SVT [27]. The authors have observed that an *RWPT ≤50 ms demonstrates a supraventricular origin* of the arrhythmia, whereas an *RWPT ≥50 ms in lead II suggests VT*. The underlying reason why a long RWPT speaks in favor of ventricular origin of tachycardia is

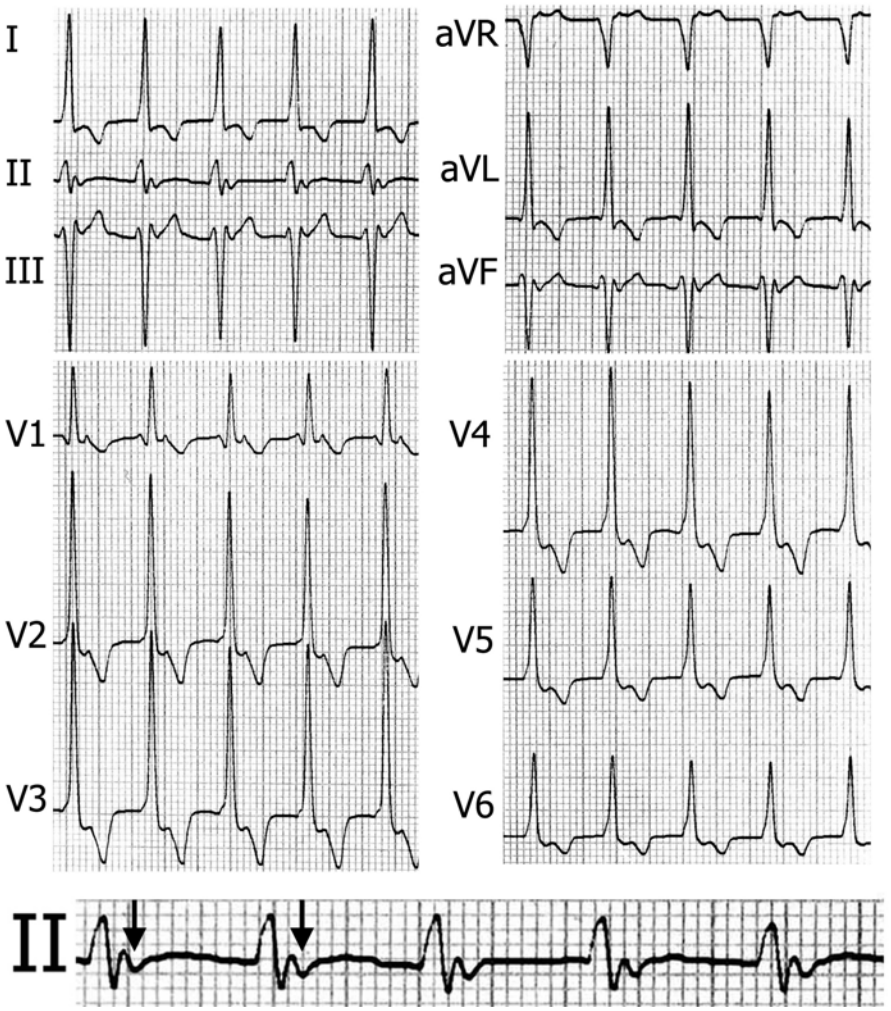

Fig. 6.12 Wide QRS tachycardia with 1:1 V-A conduction. Negative P waves follow ventricular complexes with constant R-P interval in the inferior leads (*arrows* in the *bottom strip*, representing lead II enlarged). This pattern suggests a diagnosis of ventricular (fascicular) tachycardia, despite the relatively narrow QRS complexes

likely the slow initial diffusion of the depolarization wave front in VT. In SVT, in contrast, at the beginning of ventricular depolarization, the supraventricular impulse is normally conducted over a bundle branch (or a fascicle) and the Purkinje system, in such a way that a relatively large myocardial mass is quickly depolarized, resulting in a short RWPT. In the case of VT, in contrast, the cardiac impulse slowly travels over the common myocardial tissue, resulting in a long RWPT. The efficacy of this sign in discriminating VT from SVT is very high in the study that has described such a criterion; the experience of our group,

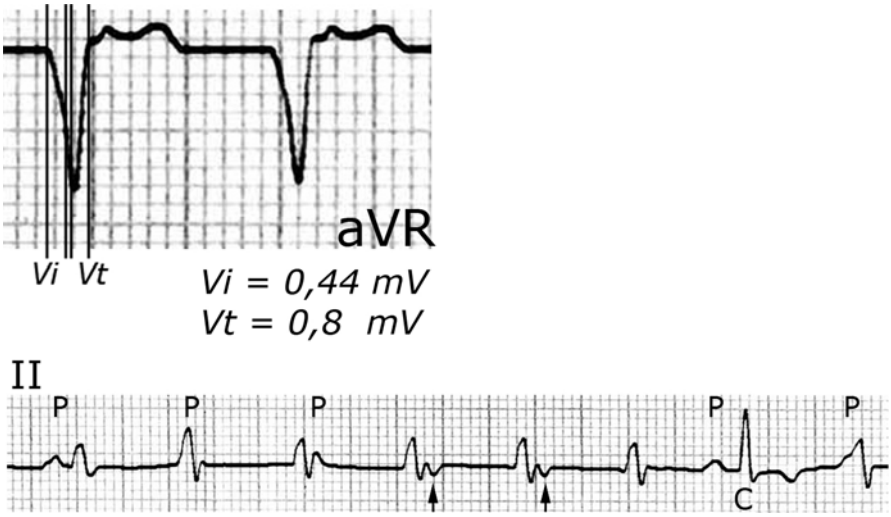

Fig. 6.13 Same case of the preceding figure. Analysis of lead aVR (*top*) and effect of verapamil administration (*bottom*). Despite the absence of (a) dominant initial R wave, (b) q wave with duration >40 ms, (c) notch in the q wave descending limb, the ratio between the voltages of the first and the final 40 ms (*Vi/Vt*) is less than 1, supporting the diagnosis of VT. The ECG recorded during intravenous verapamil administration (strip of lead II) shows A-V dissociation (the 1st three and the last QRS complex) and a capture beat (*C*); *arrows* indicate retrograde conduction restarting

however, is less satisfactory. Further research is necessary to evaluate the real efficacy of RWPT in lead II. Figure 6.3 shows a case of VT in which the RWPT does not exceed 30 ms.

In conclusion, the classic diagnostic criteria to distinguish VT from SVT with aberrant conduction include the following:

1. A-V dissociation, characterized by absence of any relationship between QRS complexes and P waves; this phenomenon is at times immediately recognizable but more often can be discovered only by means of a detailed analysis of the tracing.
2. Second-degree ventriculoatrial block, namely, a relationship between P waves and QRS complexes, but with more ventricular complexes than P waves.
3. Fusion and/or capture beats.
4. Concordant precordial pattern, a sign that can be also expressed as absence of RS (or even rs, Rs, rS) complexes in the precordial leads.
5. Analysis of QRS complexes aimed at discriminating a typical pattern of intraventricular conduction disturbance from a QRS configuration that is impossible or unlikely whenever the ventricular depolarization is dependent on a supraventricular impulse.

Several further criteria have been introduced to identify the origin of wide QRS complex tachycardia, but none of these is able to provide a simple and quick solution of the problem.

Vagal maneuvers and analysis of previous electrocardiograms recorded during sinus rhythm, if available, can provide further keys to the diagnosis. Some criteria proposed in the past, such as QRS axis or ventricular complex duration, are nowadays no longer considered; in addition, it has been demonstrated that items such as age, hemodynamic status, heart rate, and regularity of R-R intervals can be misleading and should not be taken into account.

Analysis of QRS configuration in leads V1 and V6 is a keystone in distinguishing the origin of wide QRS tachycardias: diagnostic criteria rely upon the assumption that aberration is due to a functional bundle branch block, whereas ectopy derives from a totally abnormal activation of the ventricles. Aberration, thus, results in a "typical" bundle branch block morphology, whereas ectopy is expressed by an "atypical" bundle branch block. Specific criteria, based on analysis of leads V1 and V6, have been developed to distinguish from each other the two conditions. Criteria based on QRS configuration, however, suffer from limitations since unexpected complicating factors, such as a previous myocardial infarction, can result in an "atypical" form of bundle branch block even in the presence of supraventricular tachycardia.

Recently proposed items (lead aVR analysis, peak R wave time in lead II) can be at times useful, but they need further investigation to confirm the results obtained by the authors that introduced such criteria.

6.8 Ventricular Versus Preexcited Tachycardia

In preexcited tachycardia, supraventricular impulses are conducted to the ventricles over an accessory pathway, resulting in wide QRS complexes; this is because ventricular depolarization is entirely (or, less commonly, partially) due to the impulse conducted over the abnormal conduction pathway. Such a situation may occur in the presence of (1) atrial tachycardia, (2) atrial flutter, (3) A-V nodal reentrant tachycardia, and (4) antidromic A-V reentrant tachycardia.

In all of these conditions, ventricular depolarization is due to the accessory pathway, and the QRS complexes are very wide ("pure" delta waves), mimicking a VT. It is, thus, necessary to distinguish VT from preexcited tachycardia, since at first glance QRS complex morphology suggests in the latter ventricular, rather than supraventricular, origin of the arrhythmia. In antidromic A-V reentrant tachycardia due to Mahaim fibers, however, the morphology of QRS complexes suggests supraventricular, rather than ventricular, origin of the arrhythmia, since the accessory pathway is usually connected with the right bundle branch, resulting in a typical left bundle branch block pattern [28].

Distinction between VT and preexcited tachycardia is based on the following concept: VT can originate from any part of the ventricular myocardium, whereas in preexcited tachycardia, ventricular depolarization starts (apart the rare exception represented by Mahaim fibers) from the atrioventricular rings, in correspondence of ventricular insertion of the Kent bundle. Accordingly, there is a relatively limited possible patterns, and each of them is characteristic of a defined Kent bundle

location. Since the ECG in sinus rhythm permits in most cases a reliable localization of the accessory pathways [29, 30], the question to be raised in the presence of a wide QRS complex tachycardia should be the following: "Is the morphology of this arrhythmia consistent with the typical pattern of ventricular depolarization due to an accessory pathway?" If the answer is "yes," a preexcited tachycardia is possible, whereas in the case of negative answer, such a diagnosis can be excluded.

It has been reported that in a wide QRS complex tachycardia, the following morphologies suggest VT rather than preexcitation: [4]

1. Negative QRS complexes in V4–V6
2. Negative precordial QRS concordance (negative QRS complexes in all precordial leads)
3. Deep Q waves or Qr complexes in a precordial lead except V1

Although Q waves in precordial leads other than V1 are virtually impossible in preexcitation, negative complexes in V4–V6 are not rarely observed in preexcitation due to a posteroseptal accessory pathway, since the superiorly directed vector can result in large S waves.

Acute Management of Arrhythmias in Patients with Known Congenital Heart Disease

7

Francesca Bianchi and Stefano Grossi

7.1 Focusing on the Issue

Surgical advances for congenital heart disease (CHD) allow long-term survival for a unique group of patients who would otherwise have died during early childhood. Improved longevity had eventually exposed to late complications, atrial and ventricular arrhythmias contributing to sudden cardiac death (SCD) [1]. Arrhythmias are the consequences of both native abnormalities and surgical procedures. It seems that the arrhythmic burden is the price paid to survival and mostly occurs in adults with CHD. It is now estimated that there are over 1.8 million of adult patients with CHD in Europe [2] and one million in North America [1].

Some defects are best known since studies have focused on specific lesions with predilection for common malformations with effective surgical solution and large number of patients surviving into middle age: this is the case of tetralogy of Fallot that has been studied more extensively than other conditions and so arrhythmic mechanisms and risks are best known [1]; other conditions, less common or with a more recent improvement of survival, are less known.

The entire spectrum of arrhythmias may be encountered in adults with CHD, with several subtypes often coexisting. For some conditions, arrhythmias are intrinsic to the structural malformation itself, as is the case with Wolff-Parkinson-White syndrome in the setting of Ebstein's anomaly, twin atrioventricular (AV) node tachycardia in heterotaxy, or AV block in the setting of "congenitally corrected" transposition of the great arteries (L-TGA). For most other CHD patients, arrhythmias represent an acquired condition related to the unique myocardial substrate

created by surgical scars in conjunction with cyanosis and abnormal pressure/volume loads of long duration [3, 4].

Arrhythmia substrate and consequent management is peculiar for any CHD, but some general principles can be identified, and recently international scientific boards have provided evidence-based recommendations on best practice procedures for the evaluation, diagnosis, and management of arrhythmias [5, 6].

Arrhythmia management is strictly connected to anatomical native and surgical substrate and to hemodynamic status. Classification of CHD complexity (simple, moderate, and great/severe) proposed by the ACC/AHA task force [7] reported in Table 7.1 is used to orientate management.

7.2 What Physicians Working in ED Should Know

Facing acute arrhythmias in CHD patients needs an early interplay between emergency physician and cardiologists.

Hemodynamically poorly tolerated tachycardia or ventricular fibrillation resulting in pulseless arrest requires management according to AHA/ACC/ESC guidelines for Adult Cardiac Life Support (ACLS) [8]. When direct current cardioversion is required, paddles or patches have to be positioned taking into account cardiac location in the chest [6].

In tolerated arrhythmias, 12-lead electrocardiogram (ECG) of the event should be registered. Knowledge of anatomical defect and collection of surgical reports are also fundamental for best acute and long-term management and should be obtained as soon as possible.

Hemodynamically tolerated tachycardia should be managed according to well-established adult guidelines, while taking into consideration CHD-specific issues [6] on drug therapy: antiarrhythmic drugs (AAD) are frequently poorly tolerated due to negative inotropic and other side effects, and few data exist on their safety and efficacy [6].

For atrial arrhythmias the *thromboembolic risk* must be assessed before cardioversion, reminding that in moderate and severe complexity CHD, it is high even when onset is <48 h [6].

Unexplained syncope in adults with CHD is an alarming event that may have several potential etiologies, including conduction abnormalities and bradyarrhythmias, atrial and/or ventricular arrhythmias, and nonarrhythmic causes [6].

In patients with CHD, the majority of *sudden cardiac deaths* (SCD) have an arrhythmic etiology, but up to 20 % may be nonarrhythmic, as in cerebral or pulmonary embolism, myocardial infarction, heart failure, and aortic or aneurysmal rupture [5]. SCD is responsible for approximately one-fifth of the mortality in adult's CHD, with a greater risk observed in certain malformations (tetralogy of Fallot, Ebstein's disease, left-sided obstructive disease). However, the annual mortality rates are low compared with adult population (0.1–0.3 % per patient-year) [1].

Table 7.1 Complexity of diagnosis in adult patients with congenital heart disease

Simple	Moderate complexity	Great/severe complexity

Native disease:
Isolated congenital aortic valve disease
Isolated congenital mitral valve disease (except parachute valve, cleft leaflet)
Small atrial septal defect
Isolated small ventricular septal defect (no associated lesions)
Mild pulmonary stenosis
Small patent ductus arteriosus
Repaired conditions:
Previously ligated or occluded ductus arteriosus
Repaired secundum or sinus venosus atrial septal defect without residua
Repaired ventricular septal defect without residua
	Aorto-left ventricular fistulas
	Anomalous pulmonary venous drainage, partial or total
	Atrioventricular septal defects, partial or complete
	Coarctation of the aorta
	Ebstein's anomaly
	Infundibular right ventricular outflow obstruction of significance
	Ostium primum atrial septal defect
	Patent ductus arteriosus (not closed)
	Pulmonary valve regurgitation, moderate to severe
	Pulmonary valve stenosis, moderate to severe
	Sinus of Valsalva fistula/ aneurysm
	Sinus venosus atrial septal defect Subvalvular or supravalvular aortic stenosis
	Tetralogy of Fallot
	Ventricular septal defect with:
	  Absent valve or valves
	  Aortic regurgitation
	Coarctation of the aorta
	  Mitral disease
	  Right ventricular outflow tract obstruction
	  Straddling tricuspid or mitral valve
	  Subaortic stenosis
		Conduits, valved or nonvalved
		Cyanotic congenital heart disease (all forms)
		Double-outlet ventricle
		Eisenmenger syndrome
		Fontan procedure
		Mitral atresia
		Single ventricle (also called double inlet or outlet, common, or primitive)
		Pulmonary atresia (all forms)
		Pulmonary vascular obstructive disease
		Transposition of the great arteries
		Tricuspid atresia
		Truncus arteriosus/hemitruncus
		Other abnormalities of atrioventricular or ventriculoarterial connection not included above (e.g., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

7.3 What Cardiologist Should Know

Atrial tachyarrhythmias (ATs), the most frequent in CHD, have been identified as a risk factor for SCD. The mechanism has been attributed to rapid AV conduction, most notably at times of exertion, with hemodynamic instability caused by the atrial

tachyarrhythmia itself or by its degeneration into a secondary ventricular tachyarrhythmia [7].

Prevalence of ATs is 3 times higher than what is observed in general population, and it is reported that 20-year-old patients with CHD have an equivalent risk of a 55-year-old women without CHD: patients with CHD are young with aged hearts [9]; atrial fibrillation (AF) is less common than atrial flutter accounting for 20–30 % of all ATs [10, 11].

The most common mechanism of tachycardia seen in the adult CHD patient population is macro-reentry within the atrial muscle. It is defined as *intra-atrial reentrant tachycardia (IART*) [7].

This arrhythmia usually is a late postoperative disorder, and it may arise after nearly all procedures involving a right atriotomy (even simple closure of an atrial septal defect); the incidence is clearly highest after the Mustard–Senning and Fontan operations, in which 30–50 % can be expected to develop a symptomatic episode during follow-up. Generally, IART tends to be slower than typical flutter, with atrial rates in the range of 170–250 beats per minute. In the setting of a healthy AV node, these rates will frequently allow a pattern of 1:1 AV conduction that may result in hemodynamic instability, syncope, or possibly death [3, 7]. Rate control should be achieved as soon as possible. Beta-blocking drugs and nondihydropyridine calcium channel antagonists can be used to achieve ventricular rate control with insufficient evidence to recommend one agent over another; since beta-blockers are associated with a decreased incidence of ventricular tachyarrhythmias in many conditions, it may be reasonable to liberalize their use in this patient population if well tolerated [6].

Sustained IART or AF lasting ≥48 h is an established *risk for thromboembolism* [12, 13], but moderate and complex forms of CHD have a predisposition to thromboembolic complications estimated to be10- to100-fold higher than in age-matched controls: in these patients it may be prudent to rule out intracardiac thrombus prior to cardioversion regardless of the duration of IART or AF [6].

Once atrial arrhythmia is recognized and thromboembolic risk ruled out, acute interruption can be performed with electrical cardioversion, overdrive pacing (in patients with implanted atrial or dual chamber pacemaker/defibrillators), or antiarrhythmic drugs.

Reciprocating tachycardia and some non-automatic focal atrial tachycardias may be terminated by vagal maneuvers, intravenous adenosine, or non-dihydropyridine calcium channel antagonists, with the exception of patients with an anterograde conducting accessory pathway (WPW).

There is a paucity of literature regarding pharmacologic conversion of IART or AF in adults with CHD; ibutilide has been tested in a small pediatric series [14], but there are no efficacy and safety data regarding acute conversion of IART or atrial fibrillation with class IA and IC and other class III drugs in patients with CHD [6]: *electrical cardioversion should therefore be preferred*. Anterior–posterior pad positioning may be needed in the setting of marked atrial dilation [5].

Experience with chronic pharmacologic therapy for IART in adults with CHD has been discouraging [6, 10, 11, 15], resulting in a growing preference for nonpharmacologic options in most centers.

Nevertheless, in those with moderate or complex forms of CHD, a rhythm control treatment strategy (i.e., maintenance of sinus rhythm) is generally preferred to rate control as the initial management approach [6].

Ventricular arrhythmias. There are several scenarios in which high-grade ventricular arrhythmias may develop in CHD. The most familiar involves macroreentrant VT as a late complication in postoperative patients who have undergone ventriculotomy and/or patching such as tetralogy of Fallot repair which is the best studied. Reentry circuit is caused by conduction corridors around regions of scar in the RV outflow tract (RVOT). The incidence of late VT or SCD for repaired tetralogy has been estimated between 0.5 and 6.0 % in various series [3, 7]. Some patients with slow organized VT may be hemodynamically stable at presentation, but VT tends to be rapid for the majority, producing syncope or cardiac arrest as the presenting symptom. Serious ventricular arrhythmias may also develop in a number of other malformations, even in the absence of direct surgical scarring to ventricular muscle when the right ventricle supports the systemic circulation or in the presence of a failing systemic ventricle. The appearance of ventricular arrhythmias in these cases commonly coincides with deterioration in hemodynamic status [7].

Cardioversion should be expeditiously performed for any sustained ventricular arrhythmia; electrical cardioversion in tolerated arrhythmias has the disadvantage of requiring sedation, while drugs carry the disadvantage of delayed effect.

The most efficacious pharmacologic agent is intravenous amiodarone; this agent may be associated with hypotension if administered rapidly: patients should be continuously observed and intravenous sedation and cardioversion readily available. Beta-blockers can be combined to amiodarone to improve rhythm stability, while lidocaine is a third-choice drug for short-term treatment [8].

When triggered activity is the suspected underlying mechanism, intravenous beta-blockers or calcium channel antagonists may be used, but the latter can be more harmful in the presence of scar-related macroreentry or ischemic ventricular tachycardia [6, 8].

7.4 Indications for Hospitalization, Follow-Up, and Referral

Guidelines recommend that health care for adults with CHD and arrhythmias should be coordinated by regional adult CHD centers of excellence with multidisciplinary staff that serve the surrounding medical community for consultation and referral [5–7, 16].

Syncope, ventricular arrhythmias, and in general arrhythmias in the setting of moderate to severe complexity CHD should be hospitalized.

The onset of arrhythmias may be a signal of hemodynamic decompensation, and the risk associates may be amplified in the presence of the abnormal underlying circulation [16]; a new evaluation with echocardiography and eventually further imaging (transesophageal echocardiogram, MRI/CT scan) or catheterization should be planned after a new-onset arrhythmic event.

Unexplained syncope and "high-risk" CHD substrates should be evaluated with an *electrophysiologic study,* which is also useful in life-threatening arrhythmias or resuscitated sudden cardiac death when the proximate cause for the event is unknown or there is potential for ablation [5, 6].

Before planning any invasive procedure, patients should undergo an individualized and multidisciplinary evaluation and the best knowledge of cardiac and vascular anatomy achieved [5, 6].

Patients with *AF/flutter/IART* and simple forms of CHD could be reasonably managed according to AF guidelines for AF or flutter and no or minimally heart disease [6, 12, 13] for rate/rhythm control strategies as well for anticoagulation: in *nonvalvular simple CHD,* CHADSVASC and HASBLD score should be used and either vitamin K antagonists (VKA) or a novel anticoagulant (NOAC) can be used [5].

In all patients initial therapy for atrial arrhythmias should include adequate rate control, best performed with beta-blockers, if tolerated.

Late postoperative atrial tachyarrhythmias in adults with CHD are most often due to *cavotricuspid isthmus-dependent,* and catheter ablation has proven to be safe and considerably effective, generally preferred over long-term pharmacologic management [6].

In CHD of moderate to severe complexity, an initial strategy of rhythm control is reasonable [5], and patients should be treated with VKA; NOAC is not recommended in this context due to lack of safety data [5, 6]. Non-pharmacologic strategy for rhythm control should be preferred to long-term pharmacologic therapy even if acute success rates of catheter ablation (CA) in CHD seem to be lower compared with the general adult population [5, 11]. If catheter ablation is not feasible or unsuccessful, long-term pharmacologic therapy can be necessary [6, 7]. Class I drugs and dronedarone are not recommended in this setting. *Sotalol* can be considered in patients with preserved ventricular function and without renal insufficiency, hypokalemia, severe sinus node dysfunction, or QT prolongation; *amiodarone* can be considered as first-line antiarrhythmic agent for the long-term maintenance of sinus rhythm in the presence of pathologic hypertrophy of the systemic ventricle, systemic or subpulmonary ventricular dysfunction, or coronary artery disease; in all other conditions, it is a second-line therapy due to high time and dose-dependent side effects; induced thyrotoxicosis is especially common in women with CHD and cyanotic heart disease or univentricular hearts with Fontan palliation and in those with a body mass index $\leq$21 kg/m2 [5, 14]. *Dofetilide* appears to be a reasonable alternative to amiodarone in normal QT patients if available [5].

Rate control may be the definitive therapeutic strategy after failed attempts at rhythm control and in whom rate control is well tolerated [6].

Catheter ablation is also recommended in recurrent symptomatic and/or drug-refractory supraventricular tachycardia related to accessory AV connections or twin AV nodes and in high-risk or multiple accessory pathways and can be beneficial for recurrent symptomatic and/or drug-refractory AV nodal reentrant tachycardia [5, 6].

Ventricular arrhythmias: *ICD* is the first-line therapy for the secondary prevention of sudden death in adults with CHD [17] and should be considered in high-risk patients [5, 6, 8, 15, 19].

Abnormal systemic venous pathways, impaired or lack of venous access to the ventricle, or right-sided AV valve disease may need *epicardial and/or subcutaneous coils* [5].

The subcutaneous ICD may be a reasonable option in adults with CHD in whom transvenous access is not possible or desirable and in whom anti-bradycardia and ATP functions are not essential [5].

Beta-blockers are associated with a decreased incidence of ventricular tachyarrhythmias in patients with transposition of the great arteries and atrial switch surgery, and they should be used in long-term VA prevention if tolerated [5, 6].

Catheter ablation is indicated as adjunctive therapy to an ICD in adults with CHD and recurrent monomorphic ventricular tachycardia, a ventricular tachycardia storm, or multiple appropriate shocks that are not manageable by device reprogramming or drug therapy [6]. The most common CHD associated with sustained ventricular tachycardia is tetralogy of Fallot: a macroreentry mechanism is at the base of monomorphic ventricular tachycardias, which can be cured with catheter ablation as an alternative to drug therapy; in limited Fallot series after VT ablation, ICD was considered necessary only if CA was unsuccessful [16, 18].

Frequent ventricular ectopy associated with deteriorating ventricular function can reasonably be treated by catheter ablation.

Acute Management of Arrhythmias in Patients with Channelopathies

8

Francesca Bianchi and Stefano Grossi

The term "channelopathies" defines a group of inherited arrhythmic syndromes caused by mutations of genes encoding for proteins that regulate ion currents [1] in patients without structural heart disease. Mutations disrupt the balance in the cardiac action potential favoring peculiar ECG abnormalities and the risk of life-threatening arrhythmias.

A gain or a loss of function of ionic channels or trafficking proteins underlies the development of arrhythmogenic triggers and substrate and the amplification of transmural heterogeneities [2]. It is estimated that inherited arrhythmia disorders (long and short QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, early repolarization syndrome, idiopathic ventricular fibrillation) cause 10 % of the1.1 million sudden deaths in Europe and the USA [3].

Due to the peculiarity of these rare disorders, some of the commonly used emergency protocols should be applied with caution, since some of antiarrhythmic and resuscitation drugs could be contraindicated and potentially worsen arrhythmias in this specific group of patients.

The congenital *long QT syndromes (LQTS)* are the most common channelopathies, with an estimated prevalence of 1:2000–2500 [4], and are characterized by prolonged repolarization, resulting in a prolonged QT interval on the ECG, and by a susceptibility to polymorphic ventricular arrhythmias known as torsades de pointes [2]. Causes for this primary electrical myocardial disease are mutations in genes coding for cardiac potassium and sodium channels and proteins associating with potassium channels, or mutations in the ankyrin-B gene, that reduce net repolarization currents in the ventricular myocardium prolonging repolarization phase and predispose to early afterdepolarization (EAD)-induced triggered activity. DOI 10.1007/978-3-319-24328-3_8

triggered by EADs, torsades de pointes can be maintained by a reentrant mechanism [1, 4–6].

Short QT syndrome (SQTS), characterized by a short QT interval on ECG with a high sharp T wave and a reduced repolarization phase, has a high familial incidence of palpitations, atrial fibrillation, syncope, and SCD [7, 8], typically during childhood. It is considered the most lethal channelopathy; incidence and prevalence are difficult to determine due to limited data [4, 6–8].

The *Brugada syndrome (BrS)* is an autosomal dominant inherited arrhythmic disorder characterized by an ECG pattern consisting in coved-type ST segment elevation in atypical right bundle branch block in right precordial leads (V1–V3) and risk of SCD resulting from episodes or polymorphic ventricular arrhythmias [9–11]; men are affected with a ratio 8:1 in respect to women; reported prevalence in Europe is 1:2000, while in Asian population, it is 2,4:2000; life-threatening events typically involve young male adults (30–40 years old) during sleep [6, 11].

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is a rare but highly malignant genetic disease leading to an increase in intracellular Ca^{++} concentration, resulting in polymorphic arrhythmias due to a cascade of delayed afterdepolarization and triggered activity occurring during emotional or physical stress that cause syncope and high mortality (30 % by the age of 30 years); the estimated prevalence is 1:10,000 [4, 12].

Recently, several studies have reported that J-point and ST segment elevation in the inferior or lateral leads, which is also called early repolarization (ER) pattern, can be associated with ventricular fibrillation (VF) and SCD in patients without apparent structural heart diseases. However, J-wave elevation is fairly commonly seen in young healthy individuals (estimated prevalence, 1–9 %) and frequently considered to be benign [6]: the vast majority of patients with the ECG pattern are asymptomatic and have a low arrhythmic risk, while strategies for risk stratification remain suboptimal. It is reported that unexplained syncope in patients with an ER pattern, particularly with a "malignant variant" of the pattern, may be an important predictor of future arrhythmic events [4, 13]; the presence of an ER pattern with otherwise unexplained ventricular arrhythmia is commonly referred to as *ER syndrome* [4, 6, 13, 14].

8.1 Focusing on the Issue

The ED physician could deal with a patient with an already established diagnosis of inherited arrhythmia, eventually already treated with drugs and or implanted cardiac defibrillator (ICD).

On the other hand, the referral event could be the first clinical manifestation of an unrecognized inherited arrhythmogenic disorder that, especially in young and otherwise healthy subject, must be suspected, investigated, and finally confirmed or ruled out.

All patients with a known or suspected channelopathy who refer for arrhythmic suggestive symptoms should be ECG monitored and a cardiologic evaluation sought.

Patients resuscitated from cardiac arrest must be rapidly evaluated for the presence of structural heart disease, an inherited arrhythmia syndrome, a triggering ventricular arrhythmia focus, or a noncardiac cause [15].

Most of inherited arrhythmic disorders could be diagnosed on the basis of a standard 12-lead ECG that should therefore be obtained as soon as possible as the chance to make a correct diagnosis is highest in proximity of the arrhythmic event [15]. This is a simple and useful instrument to confirm the presence or suspect a channelopathy, aside from excluding other acquired acute cardiac conditions (such as acute coronary syndrome); however, a single normal resting ECG may not exclude all forms of channelopathies. ECG recording of arrhythmic event, when possible, could be useful for the subsequent management [15].

In all cases it is indicated to avoid pro-arrhythmic triggering conditions and discontinue potentially harmful drugs that are specific for any different channelopathy: currently used antiarrhythmic and resuscitation drugs may hasten the electrical instability in these particular patients and should be therefore avoided when a specific channelopathy is known or suspected (see below).

8.2 Different Ways of Presentation

Cardiac arrest and hemodynamic nontolerated arrhythmias should be managed with early defibrillation [15] with special considerations required for drug administration.

Polymorphic ventricular tachycardia is defined as ventricular rhythm faster than 100 bpm with clearly defined QRS complexes that change continuously from beat to beat; it is the typical life-threatening arrhythmia observed in patients with channelopathies; its occurrence, in the absence of structural heart disease, suggests the presence of an inherited arrhythmia syndrome [15]; it could be self-terminating or degenerate into VF.

Bidirectional ventricular tachycardia, characterized by two alternating QRS complex morphologies with different polarity, is recognized as a hallmark of CPVT; it can degenerate into polymorphic ventricular tachycardia and VF. It may be encountered also in the rarest Andersen-Tawil syndrome and in several other conditions which predispose to delayed afterdepolarizations (DADs) and triggered activity (i.e., digitalis intoxication) [4, 16] See Fig. 8.2.

The term *torsades de pointes* (TdP) was coined by Dessertenne [17] in 1966 as a polymorphic ventricular tachycardia characterized by a pattern where the QRS complexes appear to be twisting around the isoelectric baseline [15]. The trigger for TdP is thought to be a PVC that results from an EAD generated during the abnormally prolonged repolarization phase; this arrhythmia has a typical long-short ventricular cycle length as initiating sequence and is typical for congenital or acquired long QT syndrome. TdP usually self-terminates and it is often responsible for syncopal episodes but when it deteriorates into VF may cause sudden death [4] see fig. 8.2. Since TdP is strongly associated with drugs or electrolyte imbalances that further delay repolarization, precipitating factors should promptly be searched and corrected [15, 18, 19].

Ventricular tachycardia/ventricular fibrillation storm represents a true medical emergency that requires a multidisciplinary approach to care [15] (see Chap. 11).

In patients with known diagnosis of channelopathy (including known gene carriers), the occurrence of *syncope* is an independent predictor of life-threatening arrhythmic events [4].

In most patients, syncope is the first clinical manifestation of inherited arrhythmic disorders that should therefore be evaluated.

Atrial fibrillation (AF) affects 1–2 % of the population and increases in prevalence with aging [20]. Ion channel disorders can predispose to atrial fibrillation, and prevalence in this population is increased, since the same imbalance of the action potential that causes ventricular arrhythmias could affect the atria. On the contrary, AF could be the first manifestation of an inherited cardiac arrhythmia (sometimes unmasked by drug administration [21]) which should be always considered in young otherwise healthy subjects.

Since commonly used drugs for rhythm or heart rate control may be contraindicated due to the potentially life-threatening pro-arrhythmic effect, a non-pharmacological strategy should be considered, with immediate electrical cardioversion always indicated in poorly tolerated AF, but also drugs for anesthesia/sedation should carefully be considered as potentially harmful: for example, propofol should be avoided in Brugada patients, who have a reported prevalence of atrial fibrillation between 9 to 25 and 39 % [21]. Short QT syndrome is characterized by atrial fibrillation [7, 8] with young age onset, being the first clinical manifestation in several reported SQTS cases, since a short repolarization time is a known mechanism in AF [22]: it was observed in 15 % of SQTS population, also younger than 35 years [23]. Adrenergically mediated atrial arrhythmias are also common manifestation of CPVT [4]. In LQTS frequent short-lasting atrial arrhythmias have been reported [23, 24].

Patients presenting with *ICD discharge* should be ECG monitored and device interrogation, even by remote monitoring when available, performed as soon as possible: appropriate shocks due to ventricular arrhythmia should be promptly managed, according to the peculiar diagnosis of the patient. Inappropriate shocks (which may have a high incidence in this population due to young age, high incidence of AF, and sometimes peculiar ECG [25] leading to incorrect recognition of the rhythm) and discharges on non-sustained VT should be avoided as part of the emergency treatment: painful shocks can increase the sympathetic tone and trigger further arrhythmias leading to a malignant cycle of ICD shocks and even death [15]; inhibition through magnet application could be the first intervention before device specialist intervention in case of incessant and clearly inappropriate shocks.

Therapy: The first step of management of acute events in these patients is to avoid and correct potentially triggering conditions:

Fever: In *Brugada* syndrome avoidance of fever is generally accepted to be an important part of prophylactic treatment since it is a well-known trigger of cardiac events [26, 45, 27]. Fever can also be a risk factor for the development of life-threatening ventricular arrhythmias in the *LQT2* form of congenital long QT syndrome [28, 29].

Autonomic influences play an important role in unmasking the electrocardiographic phenotype and precipitating lethal arrhythmias. Sympathetic stimulation precipitates tachyarrhythmias and sudden cardiac death in CPVT and LQTS, while in BrS and ER, it can prevent them [30]. Most episodes of VF in patients with Brugada syndrome and some in LQT3 are observed during periods of high vagal tone, such as at rest, during sleep, or after alcohol intake [30]. In LQTS 1 and 2 and CPVT patients, sympathetic stimulation and sympathomimetic drugs should be avoided, and the use of sedation to reduce emotional stress may be considered as a support to drug therapy.

Drugs to avoid: Several AAD as well as noncardiac drugs may have a pro-arrhythmic effect in this group of disease. Arrhythmias are due to the effects of drugs on ion channels (with worse harm for potassium channel blockers in LQTS and sodium channel blockers in Brugada), that is, a target effect in AAD and a collateral effect of several other compounds. These drugs should be avoided or discontinued as a principal part of acute arrhythmia management in channelopathies; two panels of experts have created a web-based platform reporting and periodically updating all drugs that should be avoided in LQTS and Brugada syndrome: www.crediblemeds.org and www.brugadadrugs.org, respectively [18, 19, 26, 45].

These websites should be promptly consulted while managing these patients, mostly in emergency setting. In SQTS, at present, only one drug is known to have pro-arrhythmic effect and should be avoided (rufinamide, an antiepileptic drug), but other molecules may shorten QT in experimental isolated hearts and the list could grow in the future. *Electrolyte* abnormalities should be corrected (see Chap. 8) and sometimes overcorrected: *Potassium* repletion to 4.5–5 mmol/L may be considered for patients who present with torsades de pointes [31]; in CPVT patients calcium should not be administered.

Management with intravenous *magnesium sulfate* is reasonable for patients who present with *LQTS* and episodes of *torsades de pointes. Beta-blockers* can be combined with pacing for patients who present with TdP and sinus bradycardia [31]. In LQT3 intravenous *lidocaine or oral mexiletine* may be considered.

Acute drug therapy of *polymorphic ventricular arrhythmia in Brugada* syndrome is based on isoproterenol infusion which increases the L-type calcium currents (1–2 μg bolus i.v. followed by continuous infusion of 0.15–2.0 μg/min) and/or quinidine (300–1500 mg/day) [18, 21, 26]; quinidine is also useful for atrial fibrillation in Brugada patients and should be considered in chronic prevention of recurrences of both atrial and ventricular arrhythmias [4, 18, 21, 45]. Electrical storm in patients with early repolarization syndrome has to be managed by *isoproterenol infusion* (initiated at 1 μg/min targeting a 20 % increase in heart rate or an absolute heart rate >90 bpm, titrated to hemodynamic response, and suppression of recurrent ventricular arrhythmia); *quinidine* can be helpful for acute and long-term treatment [4, 32].

In CPVT patients therapy of acute ventricular arrhythmias is mainly based in adrenergic suppression; *verapamil* i.v. could be of use for short-term therapy [4, 16, 33].

8.3 What Cardiologists Should Know

Cardiologist should be promptly involved in the management of "channelopathy patients" in the setting of acute arrhythmias in order to:

1. Rule out structural heart disease and secondary causes that mimic channelopathies.
2. Define diagnosis.
3. Provide risk stratification in order to plan long-term management.

Diagnosis in channelopathies is essentially 12-lead ECG based, and more than 1 recording is usually indicated; triggering conditions could give a clue. *LQTS* diagnosis is based on QT measurement [34] corrected with Bazett formula: a QTc value ≥480 ms in repeated 12-lead ECG is diagnostic [45]; LQTS is diagnosed also in the presence of a risk score ≥3 [4, 35, 36, 45] or in the presence of an unequivocally pathogenic mutation in one of the LQTS genes. LQTS can be diagnosed in patients with QTc > or = 460 ms and unexplained syncope in the absence of secondary causes [4, 45].

Most arrhythmic events occur during physical or emotional stress in LQT1, at rest or in association with sudden noise in LQT2, and at rest or during sleep in LQT3 [37].

The use of provocative tests have been proposed to unmask LQTS in patients with normal QTc at resting ECG, like measurement during change from supine to standing position, in the recovery phase of exercise testing; clinical use of epinephrine for unmasking LQTS, however, is not unequivocally accepted [4].

SQTS is diagnosed in the presence of QTc ≤340 ms and diagnosis should be considered if QTc ≤360 ms in the presence of a pathogenic mutation or family history of SQTS/SCD at age <40 years or a VT or VF episode in the absence of heart disease [4, 45]. In one of the largest published SQTS series, it is reported that more than 60 % of the subjects had symptoms at presentation: cardiac arrest, the first clinical manifestation in one third of the patients, can occur in children during first year of life and in males between the second and fourth decade; syncope is the second most frequent clinical manifestation (15 % of cases). Events may occur both at rest and during effort, so it is not possible to identify a uniform trigger.

Brugada syndrome is diagnosed when a type 1 ST segment elevation is observed in at least one right precordial lead placed in a standard or superior position (up to the 2nd intercostal space) spontaneously or after intravenous administration of a sodium channel-blocking agent, as aymaline or flecainide [4, 9–11, 45]. Arrhythmic events typically occur during sleep or vagal stimulation. Risk stratification is based on the presence of spontaneous type 1 pattern and symptoms; there is no consensus on the value of electrophysiologic study in predicting long-term arrhythmic events [4].

CPVT is diagnosed in the presence of unexplained exercise or catecholamine-induced bidirectional or polymorphic ventricular tachycardia in individual without structural heart disease and with normal resting ECG [45]. In individuals >40 years of age, it can be diagnosed, but in this population, coronary artery disease should be excluded. CPVT is also diagnosed in patients with a pathogenic mutation [4, 45]. Arrhythmic events are typically induced by exercise and emotional stress and since basal ECG is usually normal and exercise stress test and loop recorders are pivotal investigations for diagnosis [4].

8.4 A Possible Algorithm/Pathway for Diagnosis and Treatment (Fig. 8.1; Table 8.1)

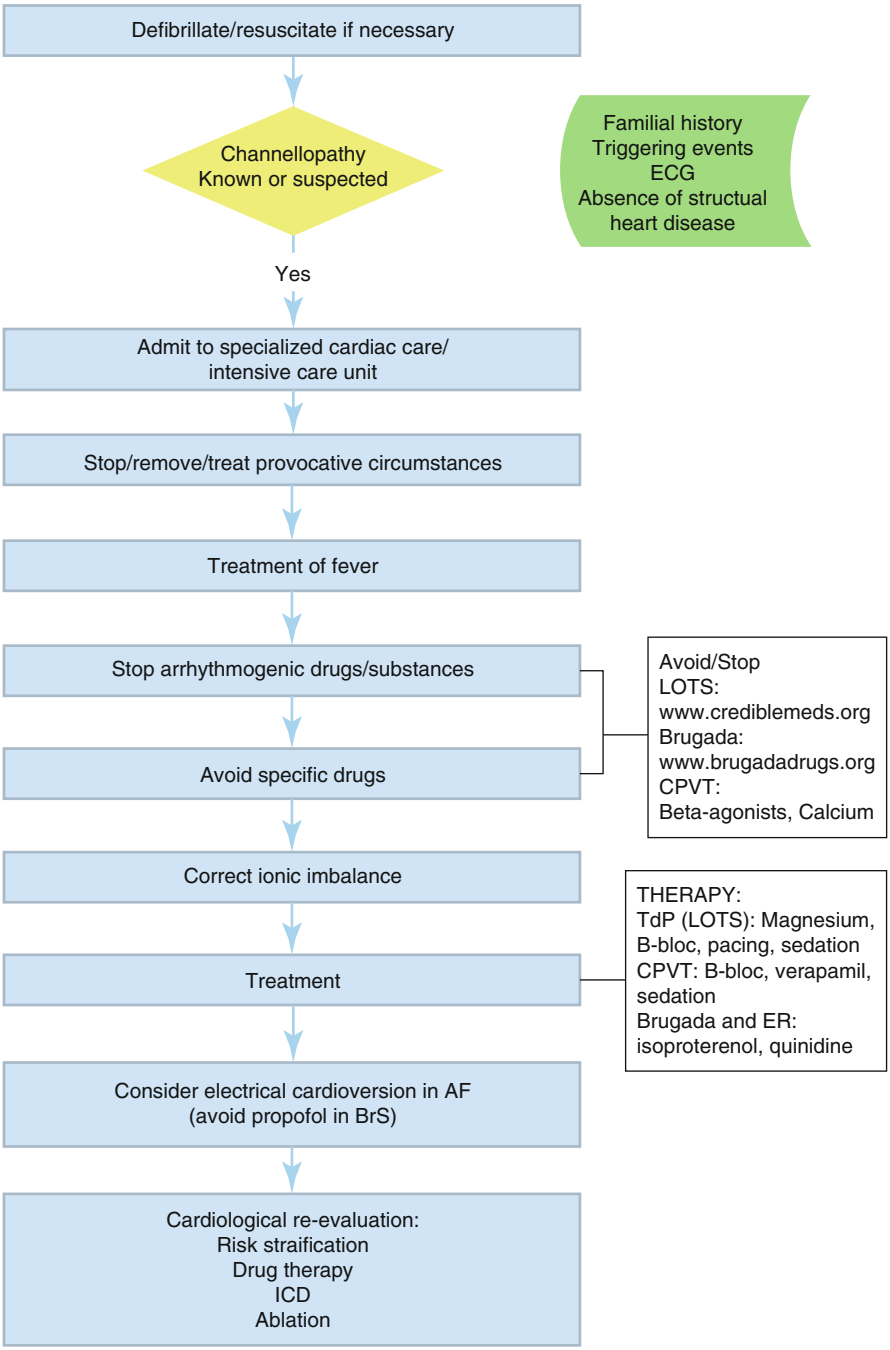

Fig. 8.1 A possible algorithm/pathway for diagnosis and treatment of arrhythmias in patients with channelopathies

Table 8.1 Conditions that can cause PVT/VF and potential therapies

Clues	Test to consider	Diagnoses	Therapies
Long QT/T wave alternans TdP History of seizures Specific triggers (loud noise)	ECG/monitor Epinephrine challenge Exercise stress test Genetic testing	Congenital LQTS	Beta-blockers Avoid QT-prolonging drugs In LQT3: mexiletine/flecainide PM/ICD Stellatectomy
Incomplete RBBB with STE in leads V1–V2 Fever	ECG Drug challenge Genetic testing	BrS	Isoproterenol/quinidine Antipyretic Ablation ICD
J-point elevation	ECG	Early repolarization	ICD
Short QT interval	ECG	SQTS	ICD Quinidine or sotalol
Bidirectional VT exercise induced	Exercise stress test Genetic testing	CPVT Andersen-Tawil syndrome	Beta-blockers/flecainide/verapamil ICD

8.5 Indications for Hospitalization, Follow-Up, and Referral

Following the arrhythmic index event, channelopathy patient should be reevaluated for risk stratification and prevention of recurrences. Expert centers with a focus on inherited arrhythmias should be involved in complex cases [4].

Atrial arrhythmias in low-risk patients could be managed in out-of-hospital setting with referral to arrhythmia experts to set up indication for pharmacological or non-pharmacological strategy. Thromboembolism should be managed according to AF guidelines using CHA_2DS_2VASC score [20]. First line therapy consists in avoiding potentially pro-arrhythmic drugs and conditions: a complete list should be supplied to the patient and to the general practitioner.

CPVT and LQT patients should be advised to limit/avoid competitive sport, strenuous exercise, and exposure to stressful environments (which in LQT2 should include exposure to loud/abrupt noises, i.e., alarm bell); Brugada patients should avoid excessive alcohol intake and large meals and should be advised to a prompt treatment of fever [45].

Syncope and life-threatening arrhythmias require hospitalization.

Aborted sudden death and sustained ventricular arrhythmias require an ICD for secondary prevention [4, 15, 31, 45] with or without adjunctive therapy.

CPVT and LQTS patients should be treated with *beta-blockers: nadolol and propranolol* are the drugs of choice [1, 4, 33]; in patients with recurrent symptoms/arrhythmias already on beta-blockers, it should be considered *flecainide for CPVT*

Fig. 8.2 Panel (**a**):12-lead ECG from a 9-year-old boy with ryanodine-positive CPVT shows a transition from triggered bidirectional ventricular tachycardia followed by brief polymorphic ventricular tachycardia to reentrant ventricular fibrillation. patients [33] and *flecainide or ranolazine or mexiletine in LQT3* patients [4]; ICD and left cardiac denervation should be considered in patients refractory to pharmacological therapy [4, 33]. Repeated exercise stress test is used in CPVT patients to evaluate drug efficacy.

Brugada and SQTS patients symptomatic for syncope should be treated with *ICD*; quinidine therapy could be used as adjunctive therapy or in cases in which ICD is refused or contraindicated or in recurrent appropriate ICD intervention [22, 26].

Hydroquinidine has proven to play a role in AF recurrence prevention in Brugada patients [4, 21].

Refractory electrical storm could be evaluated for catheter ablation of triggers [15, 39–41, 45].

All clinically diagnosed patients with LQTS and CPVT should undergo *genetic evaluation* if not previously performed, and it can be useful in Brugada (type1) patients and SQTS [42]. Routine genetic testing is not indicated for the survivor of an unexplained out-of-hospital cardiac arrest in the absence of a clinical index of suspicion for a specific cardiomyopathy or channelopathy [42] (Figs. 8.2 and 8.3)

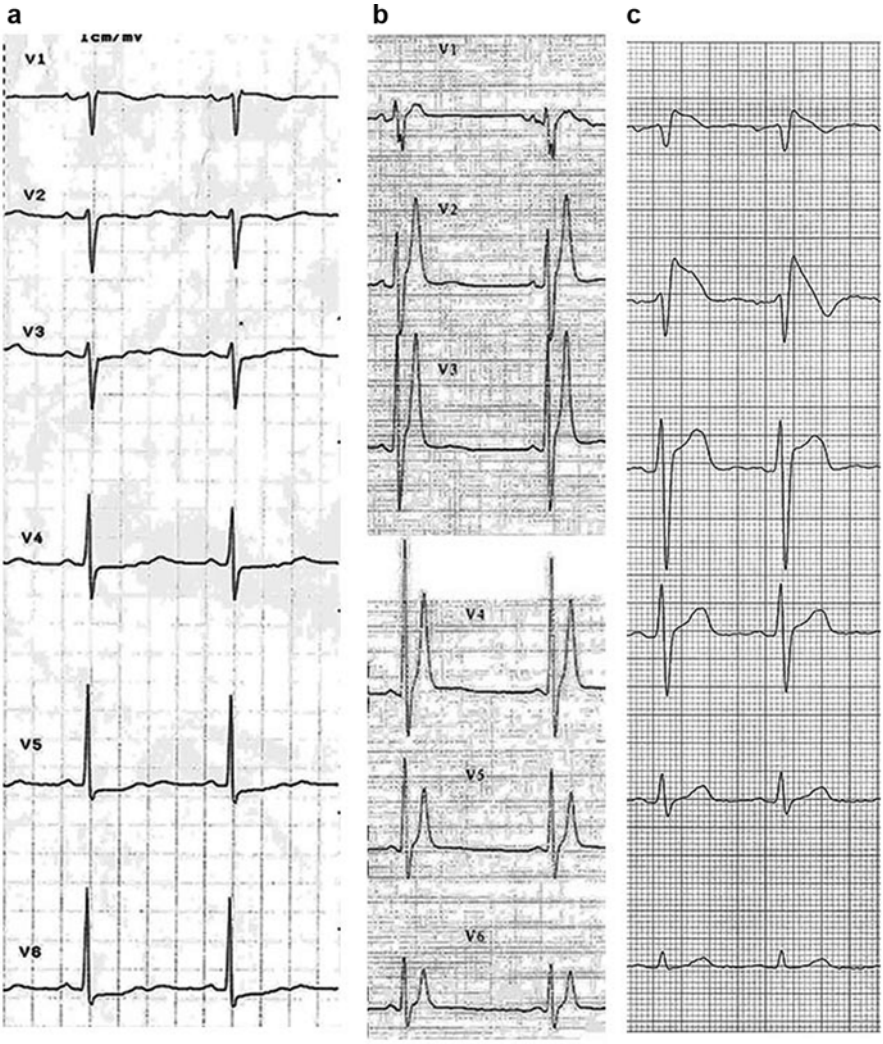

Fig. 8.3 Precordial leads ECG in patients with panel (**a**), long QT syndrome, heart rate 58 beats per minute, QTc 600 ms; panel (**b**), short QT syndrome, heart rate 52 beats per minute (bpm), QT 280 ms*; panel (**c**), Brugada syndrome, coved ST elevation in V1–V2. *With permission from Gaita F. et al. 9 Acute Management of Patients with Arrhythmias and Non-cardiac Diseases: Metabolite Disorders and Ion Disturbances

Stefano Bardari, Biancamaria D'Agata, and Gianfranco Sinagra

9.1 Focusing on the Issue

Acute metabolic disorders are relatively common amongst medical and surgical patients, especially if critically ill. Whilst increasing the complexity of management plans, these circumstances also increase the risk of cardiac complications, such as arrhythmias, and furthermore are associated with increased mortality. Arrhythmic risk is promoted by electrolyte, acid-base and fluid balance disturbance, increased sympathetic drive and cardiac ischaemia. Particularly, electrolyte abnormalities may generate or facilitate clinical arrhythmias, even in the setting of normal cardiac tissue, by modulating ion conduction across (specific) cardiac cell membrane channels [1], and management of the underlying pathology may be all that is required to allow rapid normalisation of the metabolic profile. Moreover, complex pharmacological regimes may exacerbate the situation [2].

9.1.1 Metabolite Disorders

Endocrine disorders can induce ventricular tachycardia (VT) and sudden cardiac death (SCD) by excess or insufficient hormonal activity on myocardial receptors (e.g. pheochromocytoma, hypothyroidism). The endocrinopathy can also cause myocardial changes (e.g. acromegaly) or electrolyte disturbances produced by

hormone excess (e.g. hyperkalaemia in Addison disease and hypokalaemia in Conn syndrome), and certain endocrine disorders can accelerate the progression of conditions such as underlying structural heart disease secondary to dyslipidaemia or hypertension, increasing the risk of serious arrhythmias [3].

In addition to electrolyte shifts and ischemia, other systemic influences found in the critically ill patient, such as acid-base abnormalities, hypoxia and enhanced catecholamine levels, can also predispose to ventricular arrhythmias [4]. The mechanism of these arrhythmias is due to automaticity or triggered activity through stimulation of the β-adrenergic receptor, sympathetic activation or exogenous catecholamines. Re-entry may also be facilitated, particularly in the presence of ischemia [5]. The management of ventricular arrhythmias secondary to endocrine disorders should address the electrolyte (potassium, magnesium and calcium) imbalance and the treatment of the underlying endocrinopathy.

9.1.1.1 Thyroid Disorders

Thyrotoxicosis commonly causes atrial arrhythmias; cases of VT/SCD are extremely uncommon but may occur with concomitant electrolyte disturbances. VT/SCD is more common in hypothyroidism, the basic underlying mechanism being possibly related to prolongation of the QT interval [6, 7]. Thyroxin replacement therapy usually corrects this abnormality and prevents any further arrhythmias, but antiarrhythmic drugs, such as procainamide, have been used successfully in an emergency.

9.1.1.2 Phaeochromocytoma

Phaeochromocytoma may present with VT/SCD, but there are no data to quantify its incidence, best mode of management or response to treatment. Conventional antagonism of catecholamine excess with α-receptor blockers followed by β-blockade helps control hypertension and reverses or prevents any further structural deterioration [8], but there is only anecdotal evidence that it prevents recurrence of ventricular arrhythmia [9]. Early definite surgical treatment of the phaeochromocytoma should be a priority, especially in cases with documented life-threatening arrhythmias. In some patients with VT associated with phaeochromocytoma, a long QT interval has been identified [10, 11].

9.1.1.3 Acromegaly

SCD is an established manifestation of acromegaly, and life-threatening arrhythmias are likely to be an important cause [12]. Up to one half of all acromegalic patients have complex ventricular arrhythmias on 24-h Holter recordings, and of these, approximately two thirds are repetitive [13]. Appropriate surgical management of the pituitary tumour is paramount for improved long-term outcome, as cardiac changes are reversible, especially in the young [14, 15]. Somatostatin analogues such as octreotide and lanreotide have both been shown to improve the ventricular arrhythmia profile [16–18].

9.1.1.4 Primary Aldosteronism, Addison Disease, Hyperparathyroidism and Hypoparathyroidism

Severe electrolyte disturbances form the basis of arrhythmogenesis and VT/SCD associated with the previously mentioned endocrinopathies. Electrocardiographic (ECG) changes including prolongation of QRS and QTc intervals can accompany

the electrolyte disturbance. Electrolyte imbalance requires immediate attention before definitive treatment of the underlying cause [19–21].

9.1.1.5 Diabetic Ketoacidosis (DKA)

As its name suggests, DKA is defined by the presence of metabolic acidosis, along with hyperglycaemia, as a result of insulin deficiency. These factors are generally accompanied by severe dehydration, catecholamine release and disordered potassium homeostasis; deviation of magnesium, sodium and other electrolytes can also occur. The syndrome is most often precipitated by sepsis or poor medication compliance with direct cardiac consequences, such as arrhythmias [22]. With appropriate insulin and fluid therapy, the acidosis is reversed and concomitantly potassium is forced into cells, often resulting in rebound hypokalaemia. Without frequent biochemical monitoring, such dynamic metabolic changes may deviate from normality without being acted upon, so increasing the likelihood of cardiac compromise.

During the acute phase of treatment, the rapid transition of potassium gradients changes the type of arrhythmia susceptibility. Initially, hyperkalaemia slows conduction and normal automaticity favouring bradycardias, re-entrant VT and ventricular fibrillation (VF). Later, hypokalaemia favours re-entrant arrhythmias, polymorphic VT and atrial fibrillation (AF) due to triggered activity. However, the broader spectrum of dynamic metabolic changes present in DKA will also impact upon the risk of arrhythmia, potentially through complex interactions between all of the mechanisms outlined earlier. This has led to recommendations of continuous electrocardiographic monitoring during the acute phase of treatment, although the evidence of benefit for this as a routine approach is lacking [23].

9.1.2 Ion Disturbances

Electrolyte abnormalities are commonly associated with cardiovascular emergencies. These abnormalities are amongst the most common causes of cardiac arrhythmias, and they can (cause or) complicate resuscitation attempts and post-resuscitation care. If extreme, even isolated electrolyte deficiency or excess can cause life-threatening cardiac involvement in patients with structurally normal hearts. Clinical syndromes that create hypo- and hyper-concentrations of potassium, calcium and magnesium are associated with the most common and clinically important disturbances of cardiac rhythm related to electrolyte abnormality. Despite the frequency of sodium abnormalities, particularly hyponatraemia, its electrophysiological effects are rarely clinically significant. It is important to identify clinical situations in which electrolyte problems may be expected. In some cases therapy for life-threatening electrolyte disorders should be initiated even before laboratory results become available. Of all the electrolyte abnormalities, hyperkalaemia is the most rapidly fatal. A high degree of clinical suspicion and aggressive treatment of underlying electrolyte abnormalities can prevent these abnormalities from progressing to cardiac arrest [24]. Electrocardiographic findings associated with these disturbances can provide clues to the diagnosis as well as guide therapeutic interventions. Although discussed individually, it is important to remember that there is a dynamic physiologic interrelationship to electrolyte homeostasis and that aberration in one ‘compartment’ may have impact on another [25].

9.1.2.1 Potassium

Potassium (K^+) is the most abundant intracellular cation with only 2 % of the total body potassium in the extracellular space, and hypokalaemia is the most common electrolyte abnormality in clinical practice. Potassium plays an important role in maintaining the electrical potential across the cellular membrane as well as in depolarisation and repolarisation of the myocytes. The electrophysiological effects of potassium depend not only on its extracellular concentration but also on the direction (hypokalaemia *vs* hyperkalaemia) and rate of change. Although the mechanism of potassium regulation between compartments is complex, there are two main transport processes. An active transport process involves the Na^+/K^+ ATPase pump, insulin, beta-adrenergic agents and mineral corticosteroids and a passive transport that results from alterations in the pH and extracellular cellular fluid osmolality. Homeostatic serum potassium concentration is maintained by terminal nephron segments of the kidney. Factors that lead to alterations in serum potassium regulation include renal failure and medications such as non-steroidal anti-inflammatory agents, angiotensin-converting enzyme inhibitors, diuretics and digitalis [26, 27]. Alterations in serum potassium levels can have dramatic effects on cardiac cell conduction and may lead to EKG changes, and the electrocardiogram is a useful screening tool for gauging the severity of the serum potassium abnormality and the urgency of therapeutic intervention [28, 29].

Hyperkalaemia

Hyperkalaemia is a common disorder, although less common than hypokalaemia, occurring both in the outpatient setting and in up to 8 % of patients who have been admitted to hospital, mainly in the setting of compromised renal function [30–33]. Hyperkalaemia is defined as an excess concentration of potassium ions in the extracellular fluid compartment above the normal range of 3.5–5.0 mEq/L. Moderate (6–7 mEq/L) and severe (>7 mEq/L) hyperkalaemia is life-threatening and requires immediate therapy. Although mild hyperkalaemia is often asymptomatic and easily treated, acute and severe hyperkalaemia, if left untreated, can result in fatal cardiac arrhythmias [34–36].

The most common clinical presentation of severe hyperkalaemia involves patients with end-stage renal failure. Identification of potential causes of hyperkalaemia will contribute to rapid identification and treatment of patients who may be experiencing hyperkalaemic cardiac arrhythmias [37–39]. Potassium-sparing diuretics such as spironolactone, triamterene and amiloride are well-recognised causes of hyperkalaemia. Use of angiotensin-converting enzyme (ACE) inhibitors can also lead to elevation of serum potassium, particularly when combined with oral potassium supplements. Moreover, non-steroidal anti-inflammatory medicines can cause hyperkalaemia through direct effects on the kidney.

Physical symptoms of hyperkalaemia include weakness, ascending paralysis and respiratory failure.

Electrocardiographic manifestations of hyperkalaemia. The EKG manifestation of hyperkalaemia depends on serum K^+ level. Studies validate a good correlation with hyperkalaemia and EKG changes, but 50 % of patients with potassium levels greater than 6.5 mEq/L will not manifest any ECG changes.

The increased extracellular concentration of K^+ causes an influx of K^+ into the cells. There is an alteration of the transmembrane potential gradient, a decrease in

magnitude of the resting potential and a decrease in velocity of phase 0 of the action potential. The K^+ influx causes a shortening of the action potential and results in delayed conduction between the myocytes and ECG change, such as the *T wave tenting*, classically described as symmetrically narrow or peaked, though the deflection is often wide and of large amplitude [40]. In addition, inverted T waves associated with left ventricular hypertrophy can *pseudonormalise* (i.e., flip upright) [41]. These T wave changes occur as a result of the acceleration of the terminal phase of repolarisation, are most prominently seen in the precordial leads and are often seen when potassium levels exceed *5.5 mEq/L*. With higher levels of serum potassium, cardiac conduction between myocytes is suppressed. Reduction in atrial and ventricular transmembrane potential causes an inactivation of the sodium channel, decreasing the cellular action potential. Atrial tissue is more sensitive to these changes earlier, and, as a result, P wave flattening and PR interval prolongation may be seen before QRS interval prolongation. These changes generally occur when potassium levels exceed *6.5 mEq/L* [42]. As the serum level continues to rise to levels above *twice the normal value*, there is suppression of sinoatrial and atrioventricular conduction, resulting in sinoatrial and atrioventricular blocks, often with escape beats. Other blocks including intraventricular conduction delay, bundle branch block and fascicular blocks have been reported. The bundle branch blocks associated with hyperkalaemia are atypical in the sense that they involve the initial and terminal forces of the QRS complex. Shifts in the QRS axis indicate disproportionate conduction delays in the left bundle fascicles [43]. As hyperkalaemia progresses, depolarisation merges with repolarisation, expressed in the ECG with *QT shortening* and *apparent ST segment elevation* simulating acute injury [44]. Atypical bundle branch blocks (LBBB and RBBB), intraventricular conduction delays, VT, ventricular fibrillation and idioventricular rhythm are more commonly seen in cases of severe hyperkalaemia.

Hypokalaemia

Hypokalaemia, defined as a serum potassium level *<3.5 mEq/L*, is the most common electrolyte abnormality encountered in clinical practice. It is observed in over 20 % of hospitalised patients [45], because of the high prevalence of patients on medications that can result in hypokalaemia, as 10–40 % of patients on thiazide diuretics have low potassium levels [46]; moreover, almost 50 % of patients resuscitated from out-of-hospital VF [47].

The most common causes of low serum potassium are gastrointestinal loss (diarrhoea, laxatives), renal loss (hyperaldosteronism), severe hyperglycaemia, potassium depleting, diuretics, carbenicillin, sodium penicillin, amphotericin B, intracellular shift (alkalosis or a rise in pH) and malnutrition.

The major consequences of severe hypokalaemia result from its effects on nerves and muscles (including the heart). The myocardium is extremely sensitive to the effects of hypokalaemia, particularly if the patient is taking a digitalis derivative. Symptoms of mild hypokalaemia are weakness, fatigue, paralysis, respiratory difficulty, constipation, paralytic ileus and leg cramps; more severe hypokalaemia will alter cardiac tissue excitability and conduction.

Electrocardiographic manifestations of hypokalaemia. In cases of severe hypokalaemia, EKG changes can be a very useful, quick, inexpensive and widely

available diagnostic tool. The ECG manifestations of hypokalaemia [48] are due to its effects on repolarisation and conduction. As serum potassium levels decline, transmembrane potassium gradient decreases. The effect on cell membrane is elevation in resting membrane potential and prolongation of the action potential, particularly phase 3 repolarisation and refractory periods.

The *earliest ECG change* associated with hypokalaemia is a *decrease in the T wave amplitude*.

As potassium *levels further decline*, *ST segment depression and T wave inversions* can be seen and the *U wave becomes more prominent*. The *PR interval can be prolonged,* and there can be an *increase in the amplitude of the P wave*.

With *even lower serum potassium levels*, the classic ECG change associated with hypokalaemia is the development of *U waves*. The U wave is described as a positive deflection after the T wave that is often best seen in the mid-precordial leads, such as V2 and V3. These changes have been reported in almost 80 % of patients with potassium levels <2.7 mEq/L [49].

With *extreme hypokalaemia*, *giant U waves* may often mask the smaller preceding T waves or following P waves [50]. The characteristic reversal in the relative amplitude of the T and U waves is the most distinctive change in waveform morphology in hypokalaemia. The U wave in hypokalaemia is caused by prolongation of the recovery phase of the cardiac potential, the relative refractory period predisposing to re-entrant tachyarrhythmias.

Magnesium

Although magnesium is the fourth most common mineral and the second most abundant intracellular cation (after potassium) in the human body, the significance of magnesium disorders is controversial partly because of the frequent association of other electrolyte abnormalities. Magnesium is an important cofactor in several enzymatic reactions contributing to normal cardiovascular physiology.

The average adult contains about 24 g of magnesium, with only 1 % found in the extracellular space [51]. One third of extracellular magnesium is bound to serum albumin. Therefore, serum magnesium levels are not reliable predictors of total body magnesium stores. It plays an important role in stabilising excitable membranes and may influence the incidence of cardiac arrhythmias through a direct effect, by modulating the effects of potassium, or through its action as a calcium channel blocker. Magnesium deficiency is thought to interfere with the normal functioning of membrane ATPase and thus the pumping of sodium out of the cell and potassium into the cell [52].

Hypermagnesaemia. Hypermagnesaemia is defined as a serum magnesium concentration *>2.2 mEq/L* (normal: 1.3–2.2 mEq/L). Magnesium balance is influenced by many of the same regulatory systems that control calcium balance and by diseases and factors that control serum potassium. As a result, magnesium balance is closely tied to both calcium and potassium balance. The most common cause of hypermagnesaemia is renal failure. Hypermagnesaemia may also be iatrogenic (caused by overuse of magnesium) or caused by continued use of laxatives or antacids containing magnesium (an important cause in the elderly). Severe symptoms include neurological symptoms, areflexia, muscular weakness, paralysis, ataxia,

drowsiness, confusion, respiratory failure and, rarely, cardiac arrest. Gastrointestinal symptoms include nausea and vomiting. Moderate hypermagnesaemia can produce vasodilation, and severe hypermagnesaemia can produce hypotension. Extremely high serum magnesium levels may produce a depressed level of consciousness, bradycardia, hypoventilation and cardiorespiratory arrest [53].

Electrocardiographic manifestations of hypermagnesaemia. ECG changes of hypermagnesaemia include the following:

- Increased QRS duration
- Increased PR and QT intervals
- Variable decrease in P wave voltage
- Variable degree of T wave peaking
- Complete AV block and asystole

Hypomagnesaemia. Hypomagnesaemia, defined as a serum magnesium concentration <1.3 mEq/L, is far more common than hypermagnesaemia. It is caused by decreased intake, increased losses or altered intracellular-extracellular distribution. Hypomagnesaemia usually results from decreased absorption or increased loss, either from the kidneys or intestines (diarrhoea). Alterations in parathyroid hormone and certain medications (e.g. pentamidine, diuretics, alcohol) can also induce hypomagnesaemia. Lactating women are at higher risk of developing hypomagnesaemia.

Measurement of serum levels do not correlate well with clinical manifestations. Hypomagnesaemia is associated with far-reaching adversity across the physiologic spectrum, including central nervous system effects (seizures, mental status changes), cardiovascular effects (dysrhythmias, vasospasm), endocrine effects (hypokalaemia, hypocalcaemia) and muscle effect (bronchospasm, muscle weakness) [54].

Electrocardiographic manifestations of hypomagnesaemia. A number of ECG abnormalities occur with low magnesium levels, including the following:

- ST segment depression
- Prolonged QT and PR intervals
- T wave inversion
- Flattening or inversion of precordial P waves
- Widening of QRS
- Torsades de pointes, treatment-resistant VF (and other arrhythmias) and worsening of digitalis toxicity [55]

Calcium

Calcium (Ca^{++}) is the most abundant mineral in the body. It is essential for bone strength and neuromuscular function and plays a major role in myocardial contraction. The human body has a nearly inexhaustible reservoir of Ca^{++} stored as hydroxyapatite in skeletal bone. Of the total 1–2 kg of adult total body Ca^{++}, only 1 g of calcium is present in plasma. Ca^{++} is important in a myriad of regulatory mechanisms, skeletal muscle contraction and control of enzymatic reactions and is a key ion in myocyte electrical activity and myocardial contraction [56]. Although total

serum calcium $Ca^{++,}$ is directly related to serum albumin, the ionised Ca^{++} is inversely related to serum albumin. The lower the serum albumin, the higher the ionised calcium. Isolated abnormalities of extracellular Ca^{++} produce clinically significant electrophysiological effects only when they are extreme in either direction.

Hypercalcaemia. Hypercalcaemia is defined as a serum Ca^{++} concentration above the normal range of 8.5–10.5 mEq/L (or an elevation in ionised calcium above 4.2–4.8 mg/dL).

Hypercalcaemia is the cardinal feature of *hyperparathyroidism*. Primary hyperparathyroidism and malignancy account for >90 % of reported cases [57]. It is typically chronic, mild and well tolerated. Severe hypercalcaemia with serum levels *above 14 mg/dL* can be precipitated in these patients by dehydration from gastrointestinal losses, diuretic therapy or ingestion of large amounts of calcium salts.

Symptoms of hypercalcaemia usually develop when the total serum Ca^{++} concentration reaches or exceeds 12–15 mg/dL and can be relatively vague, including fatigue, lethargy, motor weakness, anorexia, nausea, constipation and abdominal pain. Effects on the kidney include diminished ability to concentrate urine; diuresis, leading to loss of sodium, potassium, magnesium and phosphate; and a vicious circle of calcium reabsorption that further worsens hypercalcaemia. At higher levels patients may exhibit hallucinations, disorientation, hypotonicity and coma. Cardiovascular symptoms of elevated Ca^{++} levels are variable. Myocardial contractility may initially increase until the Ca^{++} level reaches *15–20 mg/dL. Above* this level myocardial depression occurs. Automaticity is decreased, but arrhythmias occur because the refractory period is shortened, many patients develop hypokalaemia and digitalis toxicity is worsened [58].

Electrocardiographic manifestations of hypercalcaemia. The effect of hypercalcaemia on the electrocardiogram is the opposite of hypocalcaemia with the hallmark of abnormal shortening of the QTc interval. Cardiac conduction abnormalities may occur, with bradydysrhythmias being the most common [59]. ECG changes of hypercalcaemia include the following:

- Prolonged PR and QRS intervals
- Shortened QT interval (usually when Ca^{++} is >13 mg/dL)
- Increased QRS voltage with notching of QRS complex
- T wave flattening and widening
- AV block, progressing to complete heart block and to cardiac arrest when serum calcium is >15–20 mg/dL

Hypocalcaemia. Hypocalcaemia is defined as a serum calcium concentration below the normal range of 8.5–10.5 mg/dL (or an ionised calcium below the range of 4.2–4.8 mg/dL). Hypocalcaemia is classically seen with *functional parathyroid hormone deficiency*, either as absolute hormone deficiency (primary hypoparathyroidism), post-parathyroidectomy or related to a pseudo-hypoparathyroid syndrome. Other causes of hypocalcaemia include *vitamin D deficiency, congenital disorders of calcium metabolism, chronic renal failure, acute pancreatitis, rhabdomyolysis and sepsis*. Hypocalcaemia is commonly seen in critically ill patients, with a reported incidence of as high as 50 % [60]. Furthermore, hypocalcaemia is often

associated with hypomagnesaemia. Symptoms usually occur when ionised levels fall *below 2.5 mg/dL.* Neuromuscular irritability is the cardinal feature, with carpal-pedal spasm being the classical physical sign that may progress to tetany, laryngospasm or hyperreflexia and positive Chvostek and Trousseau signs.

Hypocalcaemia prolongs phase 2 of the action potential. *Prolongation of the QTc interval* is associated with early after-repolarisations and triggered dysrhythmias. Torsades de pointes potentially can be triggered by hypocalcaemia but is much less common than with hypokalaemia or hypomagnesaemia.

Severe symptoms and life-threatening dysrhythmias mandate immediate treatment; in addition, associated electrolyte abnormalities, including hypomagnesaemia, phosphate abnormalities and acidemia, may need to be corrected.

Electrocardiographic manifestations of hypocalcaemia. Hypocalcaemia results in *prolonged ST segment and QT interval,* a potential cause of torsades de pointes, although much less commonly than with hypokalaemia or hypomagnesaemia [61]. Whereas electrocardiographic conduction abnormalities are common, serious hypocalcaemia-induced dysrhythmias such as heart block and ventricular dysrhythmias are infrequent.

9.1.2.2 Management of Arrhythmic Complications

Encountering a seriously ill patient with complex metabolic derangement and cardiac, or multi-organ, compromise can be daunting. Firstly, the basic principles of resuscitation provide a means of optimising basic cardiorespiratory physiology whilst giving time to consider the more complex metabolic needs of the patient. Depending on the underlying presentation or disorder, an appropriate initial assessment of electrolytes, acid-base and fluid balance status should be made. The results of this, in addition to the likelihood of rapid changes due to treatment or the natural history of the disorder, should be used to guide timing of repeat assessments. Furthermore, a strategy to normalise the patient's biochemical profile should be planned and regularly updated; addressing the underlying disorder may be all that is required in some cases. Where profound derangement is present, or when treatment of the underlying disease is failing to achieve the goal of physiological normalisation, it may be necessary to provide additional treatment targeted at specific metabolic parameters. This may involve electrolyte correction, rehydration and reduction of other factors, such as hypoxia, which worsens ischaemia. *Manipulation of acid-base status is generally not recommended* [62, 63]; in DKA, or other forms of acidosis, expert consensus suggests sodium bicarbonate therapy results in net harm, perhaps by worsening intracellular acidosis. Bicarbonate is still administered on occasions, but in the most profoundly acidotic patients and often as an act of desperation.

Unfortunately, the evidence base to guide such decisions is limited and so relies upon expert consensus. A 12-lead ECG with continuous recording of the rhythm strip provides invaluable information, but should not be allowed to interfere with emergent treatment where required. If the patient is 'compensating' haemodynamically for their rhythm disturbance, then time is available to classify the rhythm disturbance and manage according to accepted guidance [64]. It is crucial to remember that any 'antiarrhythmic' pharmacotherapy commenced may have unintended pro-arrhythmic consequences, particularly in the setting of metabolic abnormalities

[65]. The principle of never prescribing antiarrhythmic 'cocktails' is even more pertinent in this scenario.

Treatment of Hyperkalaemia

A variety of treatment options are considered for the acute management of hyperkalaemia, including insulin, β2-adrenergic agonists (inhaled, nebulised and intravenous), bicarbonate, resins, fludrocortisone, aminophylline and dialysis.

The treatment of hyperkalaemia is determined by its severity and the patient's clinical condition. First you need to stop the sources of exogenous potassium administration (e.g. consider supplements and maintenance IV fluids) and evaluate drugs that can increase serum potassium (e.g. potassium-sparing diuretics, ACE inhibitors, non-steroidal anti-inflammatory agents). The level of potassium at which treatment should be initiated has not been established by evidence. Several treatment options have been proposed, particularly for shifting potassium into the cells, with differing onset and duration of action [66].

For *mild* elevation *(5.5–6 mEq/L)*, remove potassium from the body with the following:

1. Diuretics—furosemide 1 mg/kg IV slowly
2. Resins—Kayexalate 15–30 g in 50–100 mL of 20 % sorbitol either orally or by retention enema (50 g of Kayexalate)

For *moderate* elevation (*6–7 mEq/L),* shift potassium intracellularly with the following:

1. Sodium bicarbonate—50 mEq IV over 5 min (sodium bicarbonate alone is less effective than glucose plus insulin or nebulised albuterol, particularly for the treatment of patients with renal failure; it is best used in conjunction with these medications) [67, 68]
2. Glucose plus insulin—mix 50 g glucose and 10 U regular insulin and give IV over 15–30 min
3. Nebulised albuterol 10–20 mg nebulised over 15 min

For *severe* elevation *(>7 mEq/L* with toxic ECG changes), you need to shift potassium into the cells and eliminate potassium from the body. Therapies that shift potassium will act rapidly, but they are temporary; if the serum potassium rebounds, you may need to repeat those therapies. In order of priority, treatment includes the following:

- *Shift potassium into cells:*
  1. Calcium chloride (10 %): 500–1000 mg (5–10 mL) IV over 2–5 min to reduce the effects of potassium at the myocardial cell membrane (lowers risk of VF)
  2. Sodium bicarbonate: 50 mEq IV over 5 min (may be less effective for patients with end-stage renal disease)
  3. Glucose plus insulin: mix 25 g (50 mL of D50) glucose and 10 U regular insulin and give IV over 15–30 min

4. Nebulised albuterol: 10–20 mg nebulised over 15 min

- *Promote potassium excretion:*
  5. Diuresis (furosemide 40–80 mg IV)
  6. Kayexalate enema: 15–50 g plus sorbitol PO or per rectum
  7. Dialysis

Treatment of Hypokalaemia

Treatment of hypokalaemia focuses on parenteral and oral potassium supplementation as well as identification and treatment of the source of the electrolyte abnormality. IV administration of potassium is indicated when arrhythmias are present or hypokalaemia is *severe* (*<2.5 mEq/L).* Gradual correction of hypokalaemia is preferable to rapid correction unless the patient is clinically unstable. Acute potassium administration may be empirical in emergent conditions. When indicated, maximum IV K^+ replacement should be 10–20 mEq/h with continuous ECG monitoring during infusion. Central or peripheral IV sites may be used. A more concentrated solution of potassium may be infused if a central line is used, but the catheter tip should not extend into the right atrium.

If cardiac arrest from hypokalaemia is imminent (i.e. malignant ventricular arrhythmias), rapid replacement of potassium is required. Give an initial infusion of 10 mEq IV over 5 min; repeat once if needed. In the patient's chart, document that rapid infusion is intentional in response to life-threatening hypokalaemia. Once the patient is stabilised, reduce the infusion to continue potassium replacement more gradually. Estimates of total body deficit of potassium range from 150 to 400 mEq for every 1 mEq decrease in serum potassium. The lower range of the estimate would be appropriate for an elderly woman with low muscle mass and the higher range for a young, muscular man.

Treatment of Hypermagnesaemia

Hypermagnesaemia is treated with administration of *calcium*, which removes magnesium from serum. Cardiorespiratory support may be needed until magnesium levels are reduced. It is important to eliminate sources of ongoing magnesium intake. Administration of 10 % solution of calcium chloride (5–10 mL [500–1000 mg] IV) will often correct lethal arrhythmias. This dose may be repeated if needed. Dialysis is the treatment of choice for hypermagnesaemia. Until that can be done, if renal function is normal and cardiovascular function adequate, IV saline dieresis (IV normal saline and furosemide) can be used to increase renal excretion of magnesium until dialysis can be performed. However, this diuresis can also increase calcium excretion; the development of hypocalcaemia will deteriorate signs and symptoms of hypermagnesaemia.

Treatment of Hypomagnesaemia

Treatment of hypomagnesaemia depends on its severity and the patient's clinical status. For severe or symptomatic hypomagnesaemia, administer 1–2 g IV MgSO4 over 5–60 min. For torsades de pointes with cardiac arrest, give 1–2 g of MgSO4 IV pushed over 5–20 min. If torsades de pointes is intermittent and not associated with

arrest, administer the magnesium over 5–60 min IV. If seizures are present, administer 2 g IV MgSO4 over 10 min. Calcium gluconate administration (1 g) is usually appropriate because most patients with hypomagnesaemia are also hypocalcaemic [69]. Replace magnesium cautiously in patients with renal insufficiency because there is a real danger of causing life-threatening hypermagnesaemia.

Treatment of Hypercalcaemia

If hypercalcaemia is due to malignancy, careful consideration of the patient's prognosis and wishes is needed. Therapy for hypercalcaemia is generally instituted based on clinical signs more than absolute serum levels, although empiric therapy is often started at levels of 12 mg/dL even in the asymptomatic patient. In patients with hypoalbuminaemia, measured serum calcium levels may mask significant elevations in free ionised extracellular calcium. Treatment is instituted at a level *>15 mg/dL* regardless of symptoms. Immediate therapy is directed at promoting calcium excretion in the urine. The mainstays of treatment are intravenous volume repletion and bisphosphonate agents that inhibit osteoclastic bone resorption. This is accomplished in patients with adequate cardiovascular and renal function with infusion of 0.9 % saline at 300–500 mL/h until any fluid deficit is replaced and diuresis occurs (urine output 200–300 mL/h). Once adequate rehydration has occurred, the saline infusion rate is reduced to 100–200 mL/h. This diuresis will further reduce serum potassium and magnesium concentrations, which may increase the arrhythmogenic potential of the hypercalcaemia. Thus, potassium and magnesium concentrations should be closely monitored and maintained. Hemodialysis is the treatment of choice to rapidly decrease serum calcium in patients with heart failure or renal insufficiency [70]. The use of loop diuretics (furosemide 1 mg/kg IV) to promote calciuresis is often recommended but is problematic in the hypovolemic patient.

Treatment of Hypocalcaemia

Calcium exchange is dependent on concentrations of potassium and magnesium, so treatment depends on replacing all 3 electrolytes.

Treatment of hypocalcaemia requires administration of calcium. Treat acute, symptomatic hypocalcaemia with 10 % calcium gluconate, 90–180 mg of elemental calcium IV over 10 min. Follow this with an IV drip of 540–720 mg of elemental calcium in 500–1000 mL D5W at 0.5–2.0 mg/kg per hour (10–15 mg/kg). Measure serum calcium every 4–6 h. Aim to maintain the total serum calcium concentration between 7 and 9 mg/dL.

Vitamin D and oral calcium supplementation can be administered for chronic hypocalcaemia.

9.1.2.3 When Should Electrolyte Level Be Rechecked?

The studies did not address the frequency and duration of monitoring of patients with ion disturbances; therefore, recommendations regarding ongoing assessment are based on opinion. In the acute management of electrolyte deficiency/excess, the frequency of monitoring depends on the electrolyte level as well as underlying comorbidities. After initial interventions, electrolyte level should be rechecked

within *1–2 h*, to ensure effectiveness of the intervention, following which the frequency of monitoring could be reduced. Subsequent monitoring depends on the electrolyte abnormalities and the potential reversibility of the underlying cause.

We believe the management and treatment of metabolic disorders and ion disturbances that can lead to severe complications, such as life-threatening arrhythmias, should be common knowledge for both the physician working in ED and for the cardiologist. Here, however, we emphasise some peculiarities related to the disorders described that can be particularly useful.

9.2 What Physicians Working in ED Should Know

Profound diarrhoea has the potential to 'waste' large quantities of essential electrolytes, in addition to water and bicarbonate. Without appropriate and timely management, it is possible to develop a highly proarrhythmic situation with metabolic acidosis, increased adrenergic activity, hypokalaemia, hypocalcaemia, hypomagnesaemia and so on. Vomiting can equally result in many of these abnormalities and so in combination with diarrhoea, or when added to other disease states such as DKA, can cause a significant combined cardiac insult. Appropriate identification of these metabolic and fluid balance abnormalities is imperative in order to prevent complications. Thus, regular assessment of hydration, acid-base and electrolyte status is crucial.

Potassium

- Evaluation of serum potassium must consider the effects of changes in serum pH. When serum pH falls, serum potassium rises because potassium shifts from the cellular to the vascular space. When serum pH rises, serum potassium falls because potassium shifts intracellularly. In general, serum K decreases by approximately 0.3 mEq/L for every 0.1 U increase in pH above normal. Effects of pH changes on serum potassium should be anticipated during therapy for hyperkalaemia or hypokalaemia and during any therapy that may cause changes in serum pH (e.g. treatment of diabetic ketoacidosis). Correction of an alkalotic pH will produce an increase in serum potassium even without administration of additional potassium. If serum potassium is 'normal' in the face of acidosis, a fall in serum potassium should be anticipated when the acidosis is corrected, and potassium administration should be planned.
- Hypokalaemia exacerbates digitalis toxicity. Thus, hypokalaemia should be avoided or treated promptly in patients receiving digitalis derivatives.
- The ECG correlates of hypokalaemia can be confused with myocardial ischemia. In addition, it can be difficult to differentiate a U wave from a peaked T wave that is present in hyperkalaemia.
- The use of a beta-agonist appeared to be effective in rapid reduction of hyperkalaemia: salbutamol is effective when given intravenously, in a nebulised form and

as a multi-dose inhaler. IV insulin and glucose is effective and has a rapid onset of action. The evidence for the use of bicarbonate in hyperkalaemia is equivocal, and it is not recommended as monotherapy. If used in conjunction with other treatments, the possible effects on pH and extracellular volume must be carefully considered in the assessment of the risk-benefit ratio for an individual patient.

Combining insulin-glucose with salbutamol (albuterol) probably leads to greater reductions in serum potassium than either alone. In animal and human studies, IV calcium stabilises membranes and reduces the arrhythmic threshold. Though no randomised evidence exists to support its use, it is recommended that calcium chloride be given in the presence of ECG changes or arrhythmia and repeated as needed.

Magnesium

- Abnormalities in magnesium, potassium and pH must be corrected simultaneously.
- Untreated hypomagnesaemia will make hypocalcaemia refractory to therapy.

Calcium

- The concentration of ionised calcium is pH dependent. Alkalosis increases the binding of calcium to albumin and thus reduces ionised calcium. Conversely, the development of acidosis will produce an increase in the ionised calcium level.
- In the presence of hypoalbuminaemia, although total calcium level may be low, the ionised calcium level may be normal.
- Calcium antagonises the effects of both potassium and magnesium at the cell membrane. Therefore, it is extremely useful for treating the effects of hyperkalaemia and hypermagnesaemia.
- Calcium may also be lowered by drugs that reduce bone resorption (e.g. calcitonin, glucocorticoids).

9.3 What Cardiologists Should Know

A diverse array of metabolic disorders is known to precipitate arrhythmia, though their individual proarrhythmic effects can be simplified by considering broad unifying pathophysiological mechanisms.

Metabolic disturbance mediates re-entry because regions of physiologically and pathological conduction (accelerated myocyte repolarisation or reduced myocardial conduction velocity) are both present, although anatomical substrates can interact and so produce complex disturbances of myocardial excitation and conduction.

Acidosis is proarrhythmic through promoting re-entry and triggered activity [71]. It is notable that re-entry on a much larger scale is the cause of certain supraventricular tachycardia, for example, atrioventricular re-entry tachycardia in the Wolff-Parkinson-White syndrome. Metabolic derangement can alter the conduction

properties of the abnormal anatomic pathways in these disorders, promoting re-entry and/or augmenting the maximum heart rate supported by the circuit. More complex re-entry is also a contributory factor to other arrhythmias witnessed in critically ill patients, such as atrial fibrillation and VT. After-depolarisation, or triggered activity, is the other major mechanism through which electrolyte disturbance encourages arrhythmias.

This process may be repeated resulting in tachycardia, and it is through this mechanism in which polymorphic VT, or torsades de pointes, develops. Delayed after-depolarisations are less relevant to proarrhythmia in the context of pure metabolic disarray, though in certain circumstances remain relevant. The classical example is arrhythmia due to digoxin toxicity which is aggravated by hypokalaemia and hypercalcaemia. Catecholamine excess and myocardial ischaemia are also important, and relatively common, precipitants in patients with metabolic disarray.

Potassium

- Interestingly, bypass tracts are more sensitive to delayed conduction from potassium elevation, which can result in the normalisation of the ECG and loss of the delta wave in patients with Wolff-Parkinson-White syndrome.
- With extremely high serum potassium levels, a markedly prolonged and wide QRS complex can fuse with the T wave, producing a slurred, 'sine-wave' appearance on the ECG. This finding is a pre-terminal event unless treatment is initiated immediately. The fatal event is either asystole, as there is complete block in ventricular conduction, or ventricular fibrillation.
- Hyperkalaemia can induce a Brugada-like pattern in the ECG [72]. This usually occurs in critically ill patient with significant hyperkalaemia (serum potassium >7.0 mmol/L) and is associated with pseudo-right bundle branch block and persistent coved ST segment elevation in at least two precordial leads. Prompt recognition of this ECG entity will enable clinicians to identify severe hyperkalaemia, which may result in high mortality.
- The effect of hyperkalaemia on QRS morphology of ventricular paced beats has also been studied [73]: hyperkalaemia is the most common electrolyte abnormality to cause loss of capture. In patients with pacemakers, hyperkalaemia causes two important clinical abnormalities: [1] widening of the paced QRS complex (and paced P wave) on the basis of delayed myocardial conduction; when the K level exceeds 7 mEq/L, the intraventricular conduction velocity is usually decreased and the paced QRS complex widens, [2] and increased atrial and ventricular pacing thresholds with or without increased latency.
- In patients with cardiac resynchronisation therapy, the hyperkalaemia can result in a loss of capture and/or sensing failure of even only one of the two ventricular electrodes, leading to a biventricular activation failure.
- Several cardiac and non-cardiac drugs are known to suppress the HERG K+ channel and hence the IK and, especially in the presence of hypokalaemia, can result in prolonged action potential duration and QT interval, early after-depolarisations and torsades de pointes.

- Hyperkalaemia is a common disorder that can be fatal if unrecognised or untreated. Insulin administered intravenously has the fastest onset of action and is very effective in reducing serum potassium. β2-Adrenergic agonists are as effective as insulin for lowering serum potassium and have a longer duration of action. The combination of β2-agonists and insulin is more effective than either treatment alone. The use of intravenously administered sodium bicarbonate for the management of acute hyperkalaemia is supported only by studies with weak and equivocal results [74] .
- Changes in pH inversely affect serum potassium. Acidosis (low pH) leads to an extracellular shift of potassium, thus raising serum potassium. Conversely, high pH (alkalosis) shifts potassium back into the cell, lowering serum potassium. Metabolic alterations such as alkalosis, hypernatraemia or hypercalcaemia can antagonise the transmembrane effects of hyperkalaemia and result in the blunting of the ECG changes associated with elevated potassium levels.
- Hyperkalaemia inhibits glycoside binding to (Na+, K+) ATPase, decreases the inotropic effect of digitalis and suppresses digitalis-induced ectopic rhythms. Alternatively, hypokalaemia increases glycoside binding to (Na+, K+) ATPase, decreases the rate of digoxin elimination and potentiates the toxic effects of digitalis.

Magnesium

- Low potassium in combination with low magnesium is a risk factor for severe arrhythmias.
- It is well known that both supraventricular and ventricular dysrhythmias can be potentiated if not directly caused by hypomagnesaemia.
- Magnesium has been shown to be efficacious in the management of atrial tachydysrhythmias although there is no correlation between rhythm conversion and plasma concentration.
- Magnesium sulphate is considered first-line therapy by the American Heart Association ACLS Guidelines for torsades de pointes.

Calcium

- The combination of hyperkalaemia and hypocalcaemia has a cumulative effect on the atrioventricular and intraventricular conduction delay and facilitates the development of VF. Hypercalcaemia, through its membrane-stabilising effect, counteracts the effects of hyperkalaemia on AV and intraventricular conduction and averts the development of VF.
- Half of all calcium in the extracellular fluid is bound to albumin; the other half is in the biologically active, ionised form. The ionised form is most active. The serum ionised calcium level must be evaluated in light of serum pH and serum albumin.
- Hypocalcaemia can exacerbate digitalis toxicity Table 9.1.

Table 9.1 Ion disturbances: etiology, diagnosis and treatment

Ione	Disorders	Aetiology	Signs	EKG changes	Treatment
K+	Hyperkalaemia mild (5–6 mEq/L)	Drugs End-stage renal disease Rhabdomyolysis Metabolic acidosis Pseudohyperkalaemia Hemolysis Tumour lysis syndrome Diet Hypoaldosteronism (Addison disease, hyporeninemia) Type 4 renal tubular acidosis Hyperkalaemic periodic paralysis	Weakness Ascending paralysis Respiratory failure	Flattened P waves Prolonged PR interval Widened QRS complex Deepened S waves Merging of S and T waves Sine-wave pattern Idioventricular rhythm Asystolic cardiac arrest	1. Furosemide 1 mg/kg IV slowly 2. Kayexalate 15–30 g in 50–100 mL of 20 % sorbitol
	Hyperkalaemia moderate (6–7 mEq/L)				1. Sodium bicarbonate—50 mEq IV over 5 min 2. Glucose plus insulin—mix 50 g glucose and 10 U regular insulin and give IV over 15–30 min 3. Nebulised albuterol 10–20 mg nebulised over 15 min
	Hyperkalaemia severe (>7 mEq/L)				1. Calcium chloride (10 %): 500–1000 mg (5–10 mL) IV over 2–5 min 2. Sodium bicarbonate: 50 mEq IV over 5 min 3. Glucose plus insulin: mix 25 g (50 mL of D50) glucose and 10 U regular insulin and give IV over 15–30 min 4. Nebulised albuterol: 10–20 mg nebulised over 15 min 5. Furosemide 40–80 mg IV) 6. Kayexalate enema: 15–50 g plus sorbitol PO or per rectum 7. Dialysis
	Hypokalaemia mild (3.5–2.5 mEq/L)	Diarrhoea, Laxatives Hyperaldosteronism Hyperglycaemia Potassium depleting Diuretics Carbenicillin, sodium penicillin, amphotericin B Intracellular shift (alkalosis or a rise in pH) Malnutrition	Weakness Fatigue Paralysis Respiratory difficulty Constipation Paralytic ileus Leg cramps	U waves T wave flattening Ventricular arrhythmias –Pulseless electrical activity (PEA) Asystole	Gradual correction of hypokalaemia is preferable to rapid correction
	Hypokalaemia severe (<2.5 mEq/L)				1. Maximum IV K replacement should be 10 to 20 mEq/h 2. Infusion of 10 mEq IV over 5 min (if cardiac arrest)

Cardiac Arrhythmias in Drug Abuse and Intoxication

10

Laura Vitali-Serdoz, Francesco Furlanello, and Ilaria Puggia

10.1 Focusing on the Issue

Cardiac arrhythmias are common in acute intoxication, although epidemiological data are often restricted to specific substances. A 10 % incidence of cardiac arrhythmias during acute intoxication has been reported by a referral poison center in Germany that analyzed the data of 91,285 patients referred between 1995 and 2003 using the inquiries of physicians and paramedics [1].

A large amount of substances and their association can lead to worsening of preclinical or active cardiovascular diseases and, on occasion, to ex-novo cardiovascular diseases or arrhythmic manifestations. Negative cardiovascular effects are mainly caused by the pharmacokinetics of substances, in particular if drugs are administered or abused in combination, or in cases of concomitant metabolic, renal, or liver diseases; moreover, negative effects can be the result of pharmacodynamics, as in the presence of an interaction between a not otherwise toxic substance and an altered morphofunctional cardiac substrate (e.g., long QT or Brugada syndrome).

10.2 What Physicians Working in Emergency Departments Should Know

The management of patients with a certain diagnosis or at high risk for "poisoning" or "drug abuse" should be oriented toward the acute handling of symptoms of intoxication and support of hemodynamics (e.g., intubation and respiratory support, electrolyte substitution and hydration, and temporary pacing in the case of bradycardia).

Physicians working in the emergency department (ED) should be aware that people using or abusing illicit drugs are often prone to mix different substances, alcohol being the most abused and coabused substance. Cannabis is the most frequently used illicit drug, followed by cocaine, ecstasy, and amphetamines [2]. Physicians in the ED should be familiar with the telephone number of the local poison control center as well as internal protocols and resources.

When deciding the therapeutic strategy, the medical history of the patient plays a pivotal role, and it is important to follow a systematic approach, starting with the following:

- Habitual medications
- Coexisting diseases
- Which substance or mix was taken, and when
- If a mix of substances was taken, which was the sequela
- Way of substance abuse: pills, sublingual, intravenous, inhalation

It is then important to initiate a treatment as soon as possible in order to achieve a stabilization:

- Cardiopulmonary support including fluids, direct current shock if hemodynamically unstable arrhythmia, or temporary pacing if bradycardia
- Gastrointestinal decontamination of an ingested drug
- Administration of an antidote if available
- Correction of acid–base and electrolyte alterations

10.3 What Physicians Working in the ED and Cardiologists Should Know

In order to offer a pragmatic approach to the management of patients presenting with arrhythmias associated with drug abuse and intoxication, this section focuses firstly on recreational drugs and secondly on the most common prescription drugs.

10.3.1 Recreational Drugs

The use and abuse of recreational drugs is increasing, and every year new "designer drugs" appear on the recreational drug market, such as the novel class of cathinone

derivatives, often proposed as "legal highs" by categorizing them as odorizers, stain removers, potpourri, or most recently the notorious "bath salts" [3].

An updated list of many recreational drugs can be easily found by consulting the web site of the World Anti-Doping Agency [4] (WADA list 2015, updated yearly; www.wada-ama.org). This list comprises all those substances abused by the general population and in particular by athletes with ergogenic scope during their lifetime. Many of these drugs can induce cardiovascular effects, particularly arrhythmias, during short-, mid-, and long-term use [5–8].

10.3.1.1 Stimulants

The heterogeneous group of stimulants includes many classes of drugs, widely used to obtain a performance enhancement, a raise in aggressiveness and competitiveness levels, and a reduction of fatigue perception, or simply for "recreational" purposes.

Among stimulants, amphetamines also are widely used for weight-loss regimens [9–11]. Ephedrine and other similar alkaloids are also contained in the herbal product ephedra, marketed as dietary supplement [12, 13].

The amphetamines are the chemical basis of many designer drugs usually sold as "club drugs": methylenedioxymethamphetamine (MDA) is well known as the "love pill," and 3,4-methylenedioxymethamphetamine (MDMA or Ecstasy) is commonly available under confounding names such as "clarity" or "lover's speed," but many chemical variants are commonly abused. The tablets can contain between 50 and 200 mg, and the toxic effects can be manifest starting from a dose of 50 mg [14, 15].

This class of stimulants (amphetamine or ephedrine derivatives) acts through the release of noradrenaline, dopamine, and serotonin. The symptoms of patients presenting in the ED can include sympathomimetic effects such as arterial hypertension, hyperthermia, mydriasis, dry mouth, and tachycardia. Commonly the patients also present with hyperactivity reactions such as logorrhea, restless syndrome, anxiety, tremors, myoclonus and coma.

Regarding the arrhythmias, patients present commonly with sinus or atrial tachycardia, although atrial flutter, atrial fibrillation, supraventricular reentrant tachycardia, and ventricular tachycardia have also been reported. Re-entry arrhythmias may be due to adrenergic activity during myocardial refractory periods [16, 17]. These patients should be treated with intravenous saline volumes, electrolyte substitution, and a β-blocker can be used through a slow intravenous injection for the management of tachycardia and hypertension.

Several cases of cardiac arrest and sudden death in users were reported to be associated with coronary artery disease, cardiomyopathy and myocarditis, and others with direct myocyte toxicity [14, 16]. In patients with Wolff-Parkinson-White (WPW) syndrome, stimulants can induce rapid atrial fibrillation and ventricular fibrillation [18], increasing atrial and ventricular excitability and shortening accessory pathway refractoriness.

Particular attention should be paid to young patients intoxicated with Ecstasy after physically extreme activity (e.g., "rave parties" or athletes after competitions) presenting with a "serotonin syndrome": the combination of central effects (i.e., hyperthermia) and severe dehydration and electrolyte disorders can lead to

malignant arrhythmias whose management must combine arrhythmia therapy (cardioversion or β-blocker) with cooling, rehydration, and electrolyte replacement.

Physicians in the ED should also keep in mind that patients with amphetamine intoxication commonly present with associated rhabdomyolysis.

In recent years patients taking a new class of recreational designer drugs based on cathinones mixed with amphetamine, so-called bath salts, have been admitted to the ED. 3,4-Methylenedioxypyrovalerone (MDPV), 4-methylmethcathinone (4-MMC or mephedrone), and 4-methylephedrone are some examples. In the USA, MDPV seems to be the primary active ingredient in the majority of bath salts; on the other hand, in the European Union mephedrone is more common [19].

Cathinone is a β-ketone amphetamine analogue naturally present in the leaves of the plant *Catha edulis* (also known as *Khat*) [3]. Cathinone acts as a mild stimulant by inhibiting monoamine transporters for dopamine, serotonin, and norepinephrine within the central nervous system, and is internationally regulated.

Patients who have taken MDPV may present in the ED with sinus tachycardia and other arrhythmias including ventricular tachycardia [3]. Many different symptoms have been reported, particularly related to a dopaminergic mechanism that leads to serotonin syndrome. It is important to be aware of the prolonged psychogenic effects, which may last for up to 1 week [20]. Deaths after the use of bath salts have been reported [3].

Among cathinone derivatives, only bupropion is legally approved for medical purposes as an antidepressant medication.

10.3.1.2 Cocaine

Cocaine is an alkaloid derived from a plant, *Erythroxylum coca*. It can be inhaled or smoked, only rarely being injected [21, 22]. On the illicit drugs market it can be found as a salt (hydrochloride or sulfate) or a free Base ("crack"). Indeed, this alkaloid may cause different kinds of focal or re-entry supraventricular and ventricular arrhythmias, such as ectopic beats, atrial fibrillation, atrioventricular node re-entry tachycardia, WPW arrhythmias, and nonsustained and sustained ventricular tachycardia and ventricular fibrillation. Arrhythmias are frequently associated with physical effort, which can induce a sympathomimetic effect synergic with cocaine addiction [23].

Regarding electrocardiographic (ECG) alterations and arrhythmias, experimental animal studies on the effects of cocaine showed prolongation of PR, QT, and QTc intervals, a wider QRS, supraventricular and ventricular ectopic activity, ventricular tachycardia, and ventricular fibrillation [21, 24–26].

Cocaine can lead to cardiac side effects through multiple arrhythmogenic mechanisms:

- Local anesthetic effect with block of both sodium and potassium channels
- Sympathomimetic effect with α- and β-receptor stimulation, and consequent increase in heart rate and atrial and ventricular excitability
- Intracellular calcium overload (afterdepolarization arrhythmias)
- Arrhythmias due to ischemia/reperfusion mechanisms
- Increase in heart rate through vagolytic effect
- Inhibitor of generations and conduction of the action potential, with prolongation of QRS caused by sodium channel-blocking effects [27].

Arrhythmias may be also "secondary" to systemic effects of the drug such as hyperthermia, acidosis, stroke or subarachnoid haemorrhage or in Crack-smokers also to pneumotorax.The ability of cocaine to cause myocardial infarction, frequently with severe complications, is well known [22, 23, 28, 29], with the risk in the first hour after use increasing by up to 24-fold [30].

Myocardial infarction as well as various arrhythmias can occur even after the first administration of cocaine, regardless of dose.

In the ED the patients who have used/abused cocaine may present with many different types of arrhythmias whether in the setting of ischemic/reperfusion events or not. "Chaotic atrial arrhythmia," similar to that observed in severe respiratory insufficiency or acute myocarditis, is considered a typical toxic cocaine-related arrhythmia (Fig. 10.1). Moreover, supraventricular tachycardia, atrial fibrillation, ventricular tachycardia/fibrillation, torsade des pointes due to secondary long QT syndrome frequently related to hERG potassium channel blockade [25, 31], asystole (sporadic reports of asystole treated with emergent cardiac pacing), and cardiac arrest [18] have also been reported. Cocaine-induced wide complex ventricular tachycardia may be considered a typical toxic arrhythmia, frequently caused by high doses of the drug [22], and the treatment is based on administration of sodium bicarbonate [32].

Cocaine can also induce ECG modifications such as a V1–V3 ST elevation (coved type) typical for Brugada syndrome, due to a selective block of myocardial sodium channels in subjects with latent arrhythmic disease [33].

Moreover, patients abusing cocaine also commonly mix it with different substances such as hallucinogens, strychnine ("dead hit"), heroin ("speedball"), and alcohol ("liquid lady"): in case of associated intake of alcohol and cocaine the risk of sudden death has been found to be higher probably because of the additive effects of a metabolite, coca-ethylene, which can block the dopamine reuptake, enhancing the toxic effect of the cocaine used alone [34].

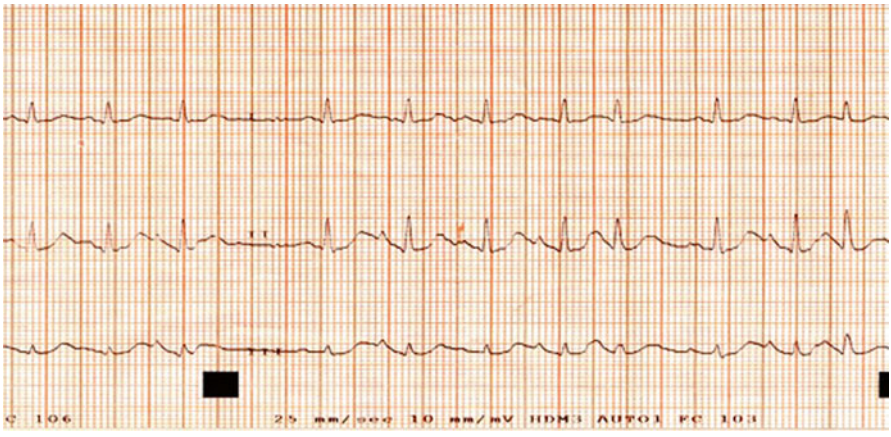

Fig. 10.1 Amateur football player, 17 years old, suspected cocaine intoxication and "chaotic atrial arrhythmia," i.e., sinus rhythm and polymorphic supraventricular ectopic beats

10.3.1.3 Cannabinoids

Many patients can present to the ED after consumption of cannabinoids, including marijuana and hashish, with different arrhythmic disorders: exercise-related sinus tachycardia, atrial fibrillation, paroxysmal supraventricular tachycardia, supraventricular and/or ventricular ectopic beats, and severe ventricular arrhythmias [35, 36], which can be mediated by catecholamines (Fig. 10.2).

The onset of arrhythmias is usually 30 or 60 min after smoking, and the arrhythmic disorders are related to the dose. At low and moderate doses there is an increase in sympathetic activity and a decrease in parasympathetic activity, and patients commonly present with sinus tachycardia, ectopic beats, or paroxysmal supraventricular tachycardia. At higher doses, there is a decrease in sympathetic activity and an increase in parasympathetic activity that can favour atrial fibrillation [37].

10.3.2 Prescription Drugs

Different common prescription drugs can induce arrhythmic complications in cases of involuntary abuse, suicidality, or in case of multiple interactions. Rather than providing an exhaustive list of all possible arrhythmias related to the use or abuse of prescription drugs, this section aims to help physicians working in the ED to get

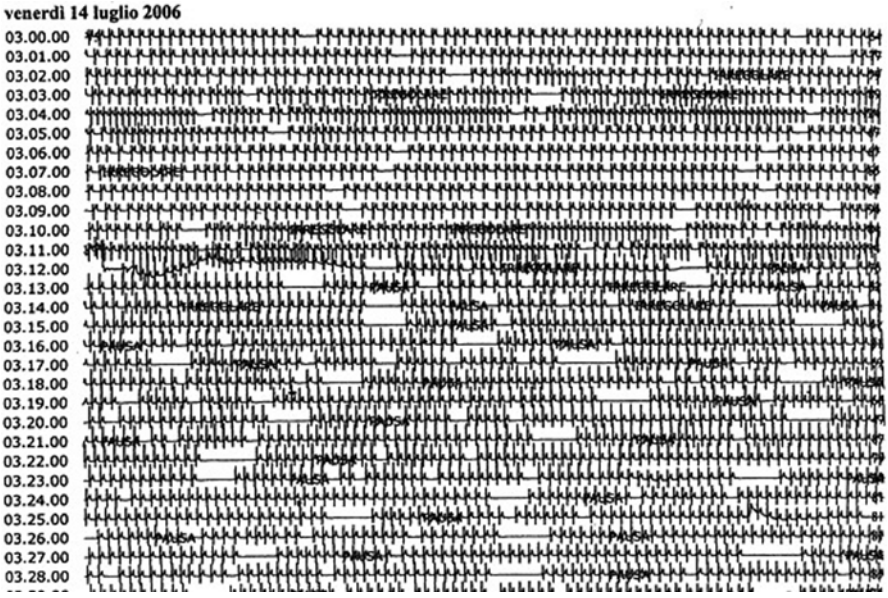

Fig. 10.2 ECG-Holter monitoring of a young male athlete (soccer player), 22 years old. Chronic use of cannabinoids and sporadic use of cocaine. This ECG-Holter tracing taken overnight shows a sick sinus syndrome with sinus arrest, sinus tachycardia, and nonsustained atrial tachycardia

used to a comprehensive attitude on managing not only the arrhythmias but also the whole pathologic affections.

Here, the most common prescription drugs whose abuse or misuse can present with arrhythmias are reviewed.

10.3.2.1 β-Blockers

Abuse of β-blockers can induce bradyarrhythmias with atrio-ventricular blocks of various degrees, sinus bradycardia, junctional and ventricular escape rhythms, bradycardia-dependent ventricular ectopic beats, and asystole, especially in patients with underlying structural and electrical disorders. Among the β-blockers, sotalol is associated with a high rate of cardiac dysrhythmias [1] and related QT prolongation. Other symptoms can be associated as hypotension, syncope, muscular contractions, mydriasis, bronchial obstruction and often hypoglycaemia especially in children.

The doctors in the ER should perform a gastrointestinal decontamination with activated charcoal and a correction of the hypoglicemia and other electrolyte disorders if present. Intravenous dopamine or adrenaline may be necessary, and the cardiologist should prepare a central venous access for a promt temporary pacing if required.

10.3.2.2 Digitalis

Patients presenting in the ED with symptoms of digitalis intoxication, mainly gastrointestinal in nature, such as anorexia, nausea, and vomiting, may suffer from many different dysrhythmias involving almost any rhythm or conduction disturbance [38–40]. The most common disorders are first-degree AV block or more advanced AV block degree and premature ventricular contractions.

Digoxin has two main actions in the cardiac myocyte: inhibition of the Na^+-K^+ Adenosinetryphosphate pump, interfering with AV conduction and increase in calcium concentrations, enhancing automaticity [41].

It is therefore important to recognize associated electrolyte disturbances, acid-base alterations, and renal or hepatic failure. In digoxin intoxication, hyperkalemia can be also sustained via a toxic mechanism of the Na^+-K^+ pump, which can be difficult to treat and can result after the treatment in hypokalemia.

In the presence of bradyarrhythmias, both atropine and cardiac pacing are usually effective. The most effective treatment for digitalis overdose is the administration of antidigitalis immunoglobulin IgG. The administration of magnesium and lidocaine often successfully treats premature ventricular contractions.

10.3.2.3 Antiarrhythmic Drugs

A patient with a history of atrial fibrillation treated with an antiarrhythmic drug such as flecainide or propafenone can present at the ED with an atrial flutter with a 2:1 or 1:1 atrioventricular conduction, or, in cases of drug abuse, also with a wide complex tachycardia related to class I effects on Na channels and QRS prolongation (Fig. 10.3).

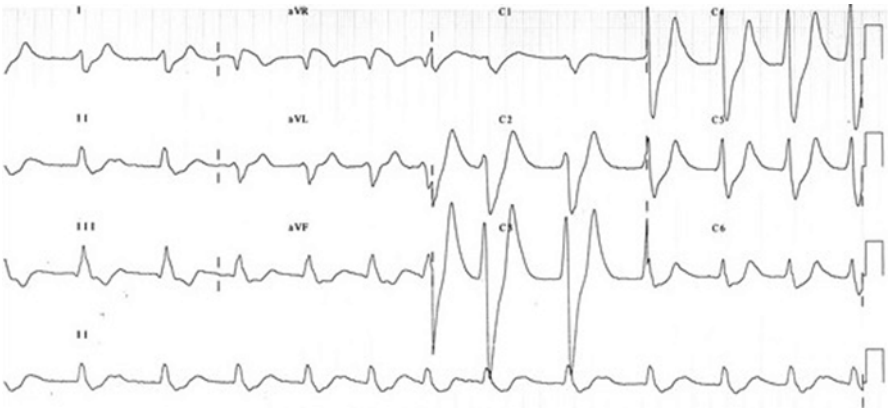

Fig. 10.3 A 60-year-old woman, 60 kg, with a history of paroxysmal atrial fibrillation; intake of 300 mg flecainide per os

10.3.2.4 Benzodiazepine

When a patient with a history of anxiety presents at the ED with palpitations, the medical history plays, as usual, an important role; in fact, discontinuation of benzodiazepine (BDZ) can cause a withdrawal syndrome with reactions that vary in severity and duration. Withdrawal syndrome is more common with triazolam and BDZs with a short to intermediate half-life, in particular if taken in repeated doses during the day, whereas the syndrome is rare with long-half-life BDZs and virtually absent with BDZ analogues such as zolpidem and zopiclone.

Arrhythmias during withdrawal syndrome are induced by autonomic arousal caused by sympathetic hyperactivity, and include mainly sinus tachycardia and ectopic beats, often associated with blood pressure imbalance (orthostatic hypotension and mild systolic hypertension). The administration of β-blockers or clonidine can help in managing reactions resulting from sympathetic hyperactivity [42].

10.3.2.5 Antidepressant Agents

Depressed patients seem to be predisposed to cardiac arrhythmias, one of the proposed mechanisms involves a reduced parasympathetic nervous system activity, that can be often present as a decreased heart rate variability [43].

In patients with depression presenting with dysrhythmias in the ED, it is important to recognize the different classes of drugs.

- *Tricyclic antidepressant agents* (TCA), such as imipramine, amitriptyline, and clomipramine, act as nonselective monoamine reuptake inhibitors. TCAs induce quinidine-like effects that are frequently encountered in older patients and children. On surface ECG it's often recognizable an intraventricular block and atrio-ventricular conduction block of different degrees with an increase in QRS width and PR interval; moreover, there are repolarization abnormalities with QT interval prolongation and negative T waves: therefore these patients present with

a higher risk of ventricular arrhythmias, in particular torsade de pointes. TCA can also induce sinus tachycardia (5–20 % of patients treated), with a mean increase of 15–20 bpm, probably caused by peripheral anticholinergic activity. Patients with cardiac diseases treated with class IC antiarrhythmic drugs (flecainide, propafenone) or quinidine should be closely monitored because the interaction between these drugs can lead to an increase in TCA blood concentration.

- *Selective serotonin reuptake inhibitors* (SSRI) include fluoxetine, sertraline, paroxetine, and citalopram, among others. A sinus tachycardia can be frequently recorded and, rarely, palpitations. In older patients SSRI can lead to sinus bradycardia and, rarely, syncope. In the case of drug overdose rhythm disorders, both bradyarrhythmia and tachyarrhythmia, as well as hypotension, are frequently present [44]. SSRI inhibits hepatic CYP3A4 and it is important to avoid or administer with reduced doses antiarrhythmic drugs as amiodarone, flecainide, propafenone, and lidocaine (i.v.) or sildenafil. [44, 45].
- *Monoamine oxidase inhibitors* (MAOI), such as phenelzine, tranylcypromine, and isocarboxazid, comprise the third main group of drugs used in clinical practice. A patient taking MAOI and presenting at the ED with palpitations and either tachycardia or bradycardia should be evaluated for a hypertensive surge, which has sometimes been reported as fatal. The anamnesis plays a pivotal role; in fact if the patient has ingested cheese or other foods with a high tyramine content, the arrhythmias could be due to norepinephrine release and an exaggerated adrenergic reaction induced by high tyramine blood levels [46–48].

10.3.2.6 Antibiotics

Patients treated with antibiotics can often present at the ED with sinus tachycardia or palpitations related to ectopic beats or to high rate atrial fibrillation; both dysrhythmias are probably related to the underlying condition (usually an infection) and subsequent fever and electrolyte disturbances.

In any event, a 12-lead ECG is mandatory to exclude a QTc prolongation and the risk of ventricular arrhythmias, in particular torsade de pointes.

These arrhythmias can be due to the following classes of antibiotics:

- *Macrolides* such as erythromycin, clarithromycin, and azithromycin. The risk of QT prolongation is higher if an H1 antagonist (e.g., terfenadine, astemizole) is administered at the same time. QT prolongation has been described with erythromycin, spiramycin and, less frequently, clarithromycin and azithromycin. Moreover, palpitations have been reported in patients taking azithromycin. An increase in digoxin levels has been reported in patients receiving erythromycin attributable to killing of digoxin-metabolizing bacteria [49].
- *Fluoroquinolones* such as levofloxacin and ciprofloxacin. Rarely, ventricular arrhythmias resulting from QT prolongation have been described during fluoroquinolone therapy.

10.4 A Suggested Algorithm/Pathway for Diagnosis and Treatment

All patients with bradyarrhythmia or tachyarrhythmia and suspected drug abuse or intoxication	What to do	How to do it
	Medical history and identification of suspected drug/s	Habitual medications Coexisting diseases Which substance or mix was taken (! alcohol) When the substance/mix was taken If a mix of substances was taken, which was the sequela Route of substance abuse: tablets, intravenous, inhalation, transdermal, sublingual
	Search for antidote	Contact local poison control center (the telephone number should be available in every ED)
	Medical management	Cardiopulmonary support including fluids DC shock if hemodynamically unstable arrhythmias or temporary pacing if bradycardia Gastrointestinal decontamination of an ingested drug Administration of an antidote if available Correction of acid–base and electrolyte alterations

Pacemaker Malfunction: Myth or Reality?

11

Roberto Verlato, Maria Stella Baccillieri, and Pietro Turrini

11.1 Focusing on the Issue

Pacemaker (PM) and implantable cardiac defibrillator (ICD) malfunction is a serious and frequent finding in clinical setting. Depending on baseline rhythm and the type of malfunction, symptoms with different severity can occur, from no symptoms to syncope and sudden death due to asystole or ventricular fibrillation. Unfortunately, symptoms, such as asthenia, dizziness, dyspnea, and palpitations, are often vague, and this can lead to a dangerous delay in cardiac implantable electronic device (CIED) malfunction detection. An ECG recording and careful device and lead evaluation by means of telemetry are necessary for the diagnosis. A great help to early detection of CIED malfunctions is coming from remote control, allowing therapeutic interventions within 24 h since the malfunction occurs in most cases.

CIED malfunctions include two main categories: problems with sensing and problems with pacing. Problems with sensing are made of failure to sense, or *undersensing*, and excessive sensing of noncardiac or cardiac signals, called *oversensing*. Undersensing causes asynchronous inappropriate and not necessary pacing, which in turn can precipitate ventricular arrhythmias due to pacing during the ventricular refractory period (R-on-T phenomenon). Oversensing of spurious signals will lead to lack of stimulation and asystole in PM-dependent patients. In ICDs, inappropriate shocks are frequently caused by oversensing. Undersensing and oversensing are mostly due to lead-related problems, either insulation failure or conductor fractures. A connection defect must be considered as differential diagnosis. The problems with pacing have a common final result: PM spikes ineffective to capture the myocardium. If such malfunction is of minor importance in the atrium, it is a life-threatening emergency in PM-dependent patients, which can exit in sudden death.

DOI 10.1007/978-3-319-24328-3_11

In patients with an implanted biventricular PM or ICD for cardiac resynchronization therapy (CRT), the loss of left ventricular capture is associated with recurrence of heart failure symptoms.

Battery depletion can lead to asynchronous pacing and other functional abnormalities mimicking either under- and oversensing.

11.2 What Physicians Working in Emergency Department Should Know

11.2.1 About Basic Function of Pacemakers and ECG Interpretation

The basics of PM are illustrated in Fig. 11.1, showing the normal function of a dual chamber (DDD) PM. These systems are preferred by cardiologists as they reproduce the normal atrioventricular (AV) conduction and physiology. They can sense and pace both the atrium and the ventricle. When they sense an atrial signal, a ventricular impulse is delivered at the end of the programmed AV delay. If no atrial signal is detected at the end of the programmed escape interval, the atrium is paced. If a ventricular spontaneous signal is sensed within the AV delay, no ventricular impulse is delivered to the ventricle [1].

The basics of single chamber (SSI), more often ventricular (VVI) PM, are more simple: the ventricle is paced at the end of the programmed escape interval, or basic rate, when nonsensed signal occurs within this time. In rate-responsive PM, either VVI or DDD, the stimulation rate is increased during effort according with sensors [1].

11.2.2 Most Important, Basic Programmable Functions in a Pacemaker

(a) *Lower rate*: it is the rate below which the pacemaker will stimulate the heart. If spontaneous activity is higher than the programmed lower rate, pacemaker output is inhibited. If programmed rate is higher than spontaneous rate and PM spikes are not visible, a malfunction is present, usually oversensing. The only exception is the presence of a "hysteresis" algorithm programmed on.

(b) *Hysteresis*: if this function is activated, the lower heart rate below which the PM will start the stimulation is different from the programmed pacing lower rate. For example, if hysteresis is programmed at 40/min and lower rate at 70/min, the PM will start the stimulation only if spontaneous heart rate drops below 40/min, but stimulation rate will be 70/min. The PM will check periodically the presence of spontaneous rate between 40 and 70/min.

(c) *Rate-responsive pacing*: the stimulation rate is increased when activity sensors detect patient movements (accelerometers). Respiratory activity sensors or other algorithms are also able to increase the basic pacing rate.

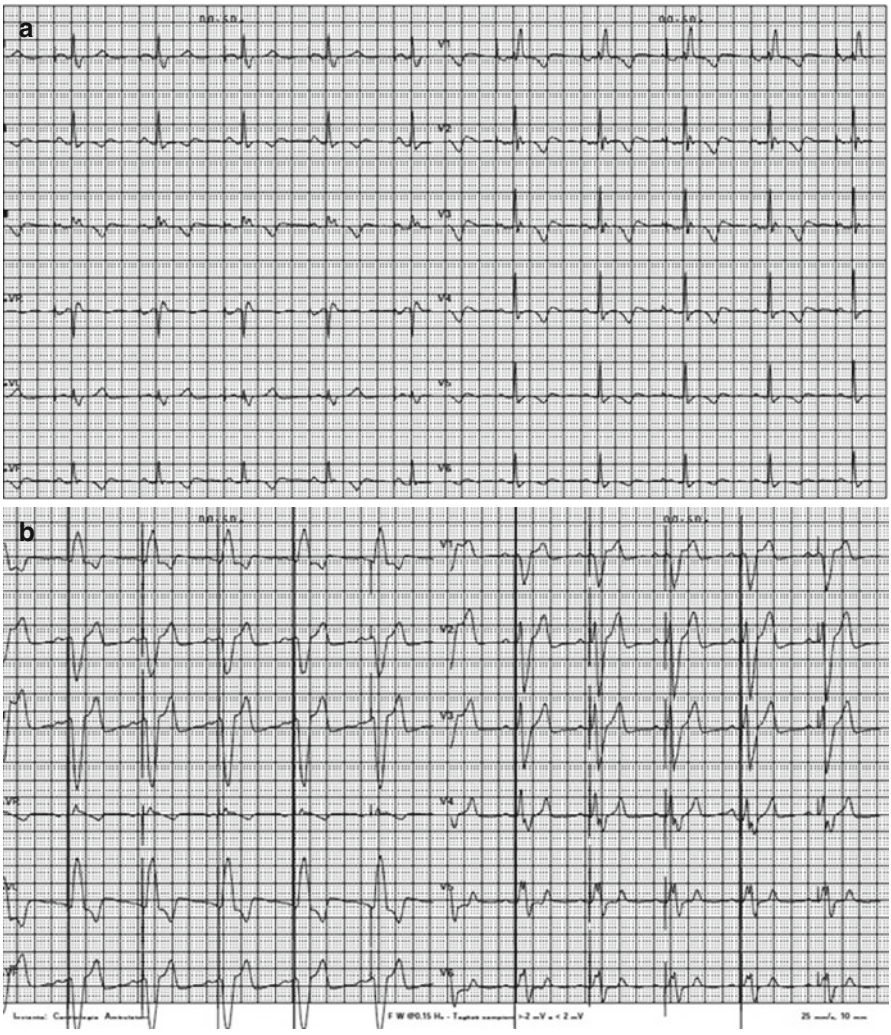

Fig. 11.1 *Top panel* (**a**). DDD pacemaker. Atrial rhythm is paced at 60 bpm. Spontaneous QRS with right bundle branch morphology occurs after 180 ms that inhibits ventricular pacing. This is called atrial-driven rhythm. *Bottom panel* (**b**): spontaneous sinus rhythm is present; each P wave is followed by a ventricular stimulus at the end of the programmed AV delay (120 ms) that captures the ventricular myocardium. The QRS morphology is left bundle branch block with superior axis, typical of right ventricular apical pacing

(d) *Upper rate*: it is the maximum stimulation rate either in case of atrial-driven or sensor-driven stimulation. If the PM stimulates at a rate higher than the programmed upper rate, a hardware/software malfunction is present. This can happen in case of unprotected exposition to strong electromagnetic fields, such as magnetic resonance imaging.

(e) *Algorithms to reduce ventricular pacing:* in order to reduce unnecessary ventricular pacing, several algorithms are present in modern dual chamber PM. Most commonly, only the atrium is stimulated (AAI mode) if atrioventricular conduction is preserved; when one or two (depending on the model and device programming) consecutive A-V blocks occur, the mode of stimulation automatically changes to atrioventricular pacing (DDD mode). Other algorithms prolong the programmed A-V interval up to 400 ms to detect if spontaneous A-V conduction is present. When these algorithms are activated, it is sometimes difficult to understand if the PM is working normally or not, for example, in case of single atrial beats without any ventricular activity; this can be a normal behavior of the device, when followed by DDD pacing, but can be expression of ventricular oversensing. Knowledge of the device programming, PM interrogation, or real-time telemetry can be necessary for the diagnosis.
(f) *Pacing voltage*: this is the voltage of PM stimulus. If it is programmed below the ventricular pacing threshold, spikes will be ineffective leading to an *exit block*.
(g) *Pulse duration*: this is the duration of PM stimulus. If it is programmed too short, spikes could be ineffective leading to an exit block.
(h) *Autocapture*: this algorithms automatically reduce PM output energy to values just above the ventricular pacing threshold. In case the delivered stimulus doesn't capture the ventricle, a second high-energy stimulus is provided: this is a normal behavior of modern PM and not a malfunction.
(i) *Mode switch*: when this algorithms are activated in dual chamber PM, the mode of stimulation automatically switches from DDD(R) to VDI(R) when an atrial tachycardia/fibrillation is detected. If atrial arrhythmia terminates, the mode of stimulation will return from VDI to DDD [1].

11.3 What Cardiologists Should Know

Cardiologists must be familiar with basic PM functions, mode of stimulation, PM algorithms, and interpretation of ECG recordings in PM patients. Modern PMs are very complex, fully programmable devices, with a lot of therapeutic and diagnostic capabilities. PM interrogation, evaluation of battery and lead data, analysis of real-time telemetry, and stored data are necessary for the final evaluation of PM functions. It would be desirable that cardiologists were trained and capable to use at least basic functions of PM programmers and the meaning and utilization of the following:

(a) *Magnet*: the application of a magnet above the PM pocket induces asynchronous pacing (VOO or DOO in single chamber or dual chamber PM, respectively). In case a PM is apparently not working (because spikes are not evident) but bradycardia (below lower rate, including hysteresis) is present, it is useful to apply a magnet on the PM. If PM spikes appear and capture the ventricle, oversensing inhibiting PM stimulation is likely. When necessary, in this cases magnet function is also useful for emergency treatment of the bradycardia.

(b) *ERI*: this is a message of "low battery charge" (Elective Replacement Indicator), meaning that the device will soon (usually after about 3 months) reaches the complete battery depletion, or EOL (End Of Life); ERT (Elective Replacement Time) and EOS (End Of Service) are synonymous of ERI and EOL, respectively, used by some manufacturers.
(c) *Pacing impedance*: this value is normally in the range between 350 and 900 Ω. Pacing impedance is influenced by the integrity of pacing circuit (conductors and insulation), by the lead model (i.e., active or passive fixation, steroid eluting or normal electrodes), and by electrode endocardial contact surface. When pacing impedance drops below 250 Ω, an insulation failure of the lead is likely. When pacing impedance is above 1500–2000 Ω (depending on the lead model), a conductor fracture or a connection defect is possibly present. In case of an abnormal pacing impedance in bipolar pacing and sensing configuration, PM reprogramming to unipolar pacing and sensing is recommended.

All cardiologists involved in emergency evaluation of PM patients should be trained to recognize the most commonly PM malfunctions, i.e., undersensing, oversensing, and exit block [1–3].

11.3.1 Undersensing in Cardiac Pacemakers

Undersensing occurs when the PM fails to sense the spontaneous atrial or ventricular activity. In this case the PM will ignore the spontaneous activity and pace the heart at the programmed rate as if the patient had no rhythm. This results in the so-called "asynchronous" pacing, that is, pacing competitive with spontaneous cardiac activity. Ventricular pacing during the vulnerable period of cardiac cycle (T wave) can occur, triggering ventricular arrhythmias including ventricular fibrillation [1–3].

An example of ventricular undersensing is illustrated in Fig. 11.2.

11.3.1.1 Causes of Undersensing

Causes of undersensing include lead failure, pacemaker failure, and environmental and physiologic changes. Lead failure is the most frequent cause of under- and oversensing in current CIEDs. Both insulation failure and lead fracture are able to induce undersensing, so it is pivotal to interrogate the pacemaker to evaluate pacing impedance. An increase of pacing impedance > 2000 Ω is diagnostic of conductor damage. A decrease of pacing impedance below 250 Ω is diagnostic of insulation failure. A connection defect is usually associated with a high pacing impedance, >3000 Ω, and this must be distinguished from conduction fracture in the presence of high pacing impedances. To identify a connection defect, chest X-ray is useful, as it can show the lead connector incompletely inserted into the PM head. An example of connection defect is illustrated in Fig. 11.3.

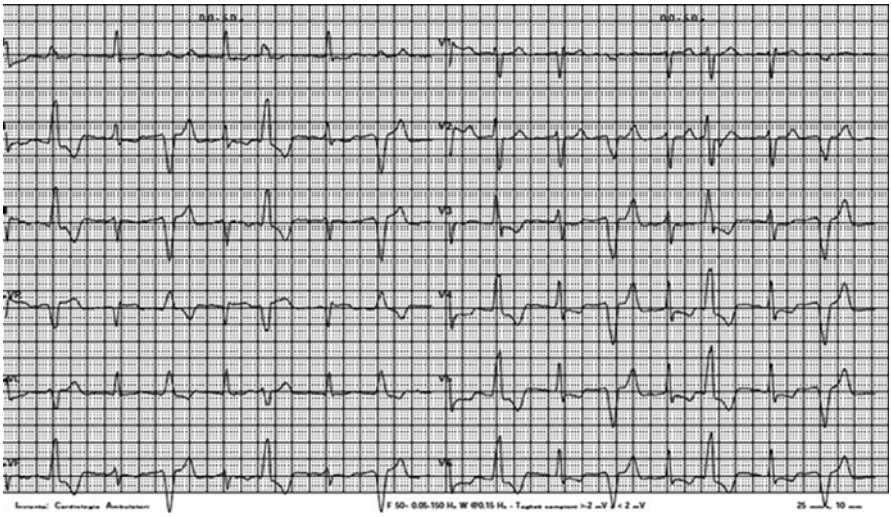

Fig. 11.2 VVI pacemaker. Spontaneous rhythm is present interrupted by premature beats of different morphology. At careful ECG inspection, small pacemaker spikes (bipolar) precede the QRS with left bundle branch morphology and left axis deviation. Other spikes follow spontaneous QRS in random sequence (asynchronous pacing). Undersensing of ventricular activity is present

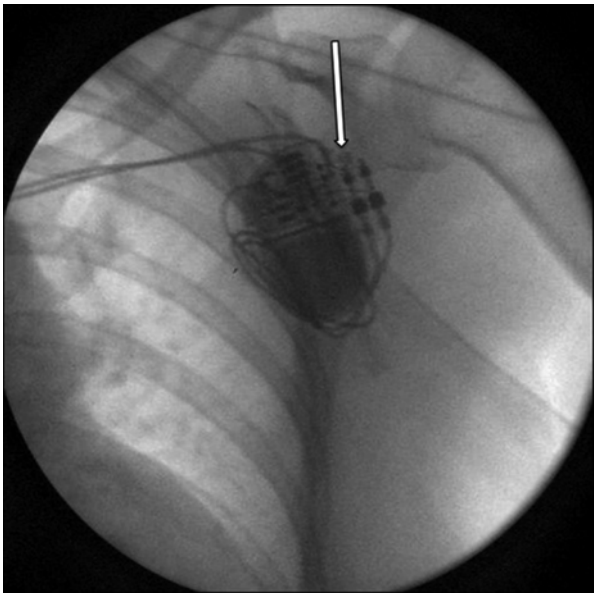

Fig. 11.3 Chest X-ray showing a close-up of pacemaker pocket. Patient had undergone to device replacement 1 week before and presented with high pacing impedance (>3000 Ω), under- and oversensing. The connector of the atrial lead, the lateral one, is completely inserted into the head of pacemaker, and its terminal pin is visible outside the electrode ring. The ventricular connector (*arrow*) is incompletely inserted and its terminal end is not visible

Chest X-ray is less useful to detect lead failure as leads seem apparently intact in most cases.

Pacemaker failure can cause undersensing. The most frequent situation is battery depletion (end of service, or EOL message at telemetry interrogation is displayed): this switches the mode of stimulation to asynchronous pacing.

Environmental causes of undersensing are strong magnetic fields, such as anti-theft devices, great motor engines, the application of a magnet on the pacemaker pocket, and magnetic resonance imaging. A frequent environment cause of undersensing is cardiac defibrillation. In this case undersensing but also an exit block with lack of ventricular capture can occur due to tissue damage at the myocardium-tip electrode interface.

Physiologic cardiac and noncardiac changes can facilitate undersensing, reducing the amplitude of cardiac sensed signals. New bundle branch block, myocardial infarction, hypokalemia and other ionic abnormalities, and old age of the implanted lead, associated with fibrous tissue growing around the electrode tip, are all situations associated with PM undersensing.

11.3.1.2 Treatment of PM Undersensing

In the case of reduced amplitude of sensed signals (measured by telemetry), it's possible to increase the PM sensing function by reprogramming, even if this in turn increases the risk of oversensing, in particular for unipolar leads. PM or lead replacement is the only way to correct the malfunction when battery depletion or lead failure is present [1–3].

11.3.2 Undersensing in ICDs

Undersensing in ICDs recognizes the same causes as in cardiac PM. Lead failure, either insulation or conductor defects, is the most dangerous situation in ICD patients, and it must be excluded in the presence of undersensing or oversensing. In ICDs either lead-related undersensing or oversensing may be intermittent, making diagnosis more difficult. A "physiologic" degree of undersensing is frequently observed in ICDs due to low voltages of cardiac signals during ventricular tachycardia and fibrillation, but this is rarely a clinical problem. Otherwise, prolonged ventricular undersensing during ventricular fibrillation (VF) could result in patient death, and the only possible treatment is an external rescue shock. However, in ICDs the most frequent cause of ventricular tachycardia (VT) undersensing is a programming "error," that is, the cutoff detection rate set at values above the rate of spontaneous VT. Reprogramming of VT detection rate will correct the problem [1].

11.3.3 Oversensing in Cardiac Pacemakers

Oversensing occurs when a PM senses noise, artifacts, or physiologic cardiac or noncardiac signals different from the atrial or ventricular depolarization and classifies such signals as atrial or ventricular depolarizations. The result will be inhibition of ventricular pacing when oversensing occurs at ventricular level or unnecessary ventricular pacing when oversensing occurs at atrial level. Pacing during oversensing is erratic, irregular, and completely unrelated with the programmed lower rate. In the case of prolonged pacing inhibition in PM-dependent patients, asystole will occur [1–3].

11.3.3.1 Causes of Oversensing

Lead failure is by far the most frequent cause of oversensing. Insulation failure, conductor fracture, and lead dislodgement are all able to induce oversensing of noise. Lead problems are identified by means of pacing impedance measurements, as described for undersensing. High pacing impedance is diagnostic of conductor problems, low impedance of insulation defect. Lead dislodgement and connection defect are often visible on X-ray imaging.

Environmental electromagnetic interferences (EMI) are the second more frequent cause of oversensing. They can reach the distal dipole of PM leads because electromagnetic currents flow through the patient's body, which acts as a volume conductor. Electrocautery, extracorporeal shock lithotripsy, and MRI (when CIED presence is ignored) are frequent causes of oversensing in the hospital setting. Noise signals can also originate from metal to metal friction in patients with multiple implanted pacemaker or defibrillation leads.

Myopotential oversensing can occur at pocket level (pectoral muscle oversensing), especially when programmed unipolar sensing, but more frequently the PM can sense the diaphragmatic respiratory activity.

T wave oversensing is the most common situation of oversensing of cardiac physiologic signals; it leads to a decrease of pacing rate as the escape interval is reset by the T wave sensing [1–3].

11.3.3.2 Treatment of Oversensing

The application of a magnet on the pocket will immediately induce (in PM, not in ICDs) atrial and ventricular asynchronous pacing. In the emergency setting this is the only maneuver that must be immediately applied to the patient, especially if symptomatic bradycardia is present.

If the PM programmer is available, sensing function must be reprogrammed to decrease PM sensitivity. In the case of unipolar sensing, the change of sensing configuration to bipolar, if a bipolar lead is implanted, will reduce or even could completely correct the oversensing of muscle potentials. In case T wave oversensing is present, longer ventricular refractory periods must be programmed.

The switch of pacing mode to VOO, or asynchronous, is the safest option in PM-dependent patients with oversensing due to lead problems to correct the bradycardia. In this case replacement of the failing lead is mandatory [1–3].

11.3.4 Oversensing in ICDs

Oversensing is the second leading cause of inappropriate detection and therapy of arrhythmias, including inappropriate shocks after atrial tachyarrhythmias. Lead failure must be suspected in any case of inappropriate shocks and noise stored in device memories. Several algorithms have been developed for early detection of lead failure based on the presence of very short intervals between sensed signals. The presence of a connection defect must always be considered as an alternative source of noise oversensing. Failing ICD leads must be replaced, with or without lead extraction based on careful evaluation of individual risk/benefit profile of lead extraction.

When noise oversensing is due to interference between implanted leads, lead extraction is mandatory [1–4].

11.3.5 Problems with Pacing

The most frequent situation is the presence of pacemaker spikes visible on monitor screens or ECG recordings, not followed by ventricular or atrial depolarizations (exit block). The failure to capture must be immediately recognized as it is a life-threatening malfunction.

In Fig. 11.4 an example of failure to capture is shown. PM spikes are delivered by pulse generator, not followed by ventricular depolarization [1–3].

Fig. 11.4 Patient with PM presenting to the emergency room after a syncope. 12-lead ECG shows several pacemaker spikes not followed by ventricular depolarization (exit block). A failure to capture is certainly present. Real-time telemetry showed high pacing impedance (2500 Ω). Combining the two findings of exit block plus high pacing impedance, the diagnosis of lead fracture was made. Lead replacement was necessary in this case

11.3.5.1 Causes of Failure to Capture

In the period just following pacemaker implantation, lead dislodgement and cardiac perforation are the most common causes of failure to capture. Chest X-ray is necessary for the diagnosis, and reintervention for lead repositioning must be performed as soon as possible. Sometimes perforation is subtle, and a CT scan can be helpful to identify the relationship and exact position of the electrocatheter tip and the pericardium.

If the exit block occurs several weeks after implantation (the most frequent situation), it is usually due to an increase in stimulation threshold because of fibrosis maturation close and around to the electrode tip. Steroid-eluting leads are less frequently involved, while the risk is higher for active fixation leads, where an increase of pacing threshold frequently occurs during the first weeks after implantation. Such increase is usually transient, although it can rarely persist or even worsen (especially in young people) during follow-up.

Failure to capture can be also caused by too low voltage and/or duration of the stimulus emitted by the pacemaker in proximity of battery end of life or in the case of battery failure, but usually it depends by an inappropriate PM programming. Autocapture algorithms in modern pacemaker ensure ventricular capture.

Cardiac defibrillation and strong electromagnetic fields emitted by MRI can cause exit block due to tissue damage by current flow through the lead up to the electrodes, a sort of inadvertent tissue ablation, in particular when insulation failure is present.

Lead failure, in PM and especially in ICDs, is very often associated with deterioration of pacing and sensing thresholds, in addition with under- and oversensing [1–3].

11.3.5.2 Treatment of Failure to Capture

Acute perforation usually presents as an emergency in operating room. It requires pericardiocentesis and immediate lead repositioning.

Subacute and chronic perforation may be difficult to recognize. Symptoms may be minor; pericarditis, chest pain, diaphragmatic stimulation, and sometimes pneumothorax may be present. Perforation may occur at both atrial and ventricular levels. Loss of capture is almost always present together with sensing problems. Device reprogramming can transiently be useful to correct sensing and pacing abnormalities, but again lead revision/repositioning is absolutely required to solve the problem once the diagnosis is made.

When failure to capture occurs due to increased pacing thresholds, device reprogramming and selection of higher energy output, in terms of pulse voltage and duration, are the solutions in the acute setting. However, in current pacemaker technologies, the programmation of high pacing energies, i.e., voltage amplitude of 5–6 V and pulse duration of 1–2 ms, is associated with a marked reduction of battery longevity, up to less than two years. Lead revision, reposition, or replacement must be considered in pacemaker-dependent and/or young people with high pacing threshold.

Failure to capture occurring after MRI or cardiac defibrillation requires lead revision.

11.4 False Malfunctions

In modern devices, the complexity of some algorithms can sometimes make the ECG interpretation and the distinction between normal behavior and malfunctions quite difficult.

For this reason, to reach a correct ECG interpretation, it is necessary to know the model and the programming of the device, because what can be considered a normal behavior in some models and with some programming can be a malfunction in other cases [5].

- For example, a spontaneous rate below the lower rate programmed can be normal when a hysteresis is programmed, but a marker of oversensing in the absence of this function.
- In order to prevent sudden changes of the heart rate, an algorithm called "rate smoothing", "flywheel" or "ventricular rate stabilization," according to the manufacturer, can be enabled. In this case, stimulation can transiently occur beyond the lower rate, even if a rate response function is not present, just after a spontaneous fast activity, allowing a "smooth" reduction of heart rate. This can frequently happen during atrial fibrillation with very irregular rate, after ectopic ventricular beats or at the end of a tachycardia.
- Convincing data have shown that stimulation of the right ventricle is hemodynamically unfavorable and can sometimes cause or worsen congestive heart failure. In some devices, algorithms for minimizing ventricular pacing are enabled. In this case it is possible to observe an extremely long PQ interval, or even two consecutive P waves (spontaneous or stimulated) not followed by any ventricular activity, before the automatic switch from AAI (or ADI) to DDD mode occurs (Fig. 11.5).

Finally, a very short paced AV interval (about 100 ms) can sometimes be observed.

This is due to a function called "ventricular safety pacing," which consists in the delivery of a ventricular stimulus when a signal is detected in the ventricular channel immediately after an atrial stimulation. As in practice, the device is not able to distinguish whether the signal is derived by the artifact of atrial pacing detected at ventricular level (crosstalk) or a real ventricular beat (as an ectopic ventricular beat), so it immediately delivers a ventricular stimulus ensuring stimulation (in the presence of crosstalk) but with an interval short enough to fall, in the presence of a beat of ventricular origin, in its refractory period, avoiding the risk of triggering dangerous arrhythmias. Ventricular safety pacing can be present even in case of a lack of atrial sensing, when the atrial stimulus coincides with the spontaneous QRS complex, as in the course of sinus rhythm and normal AV conduction.

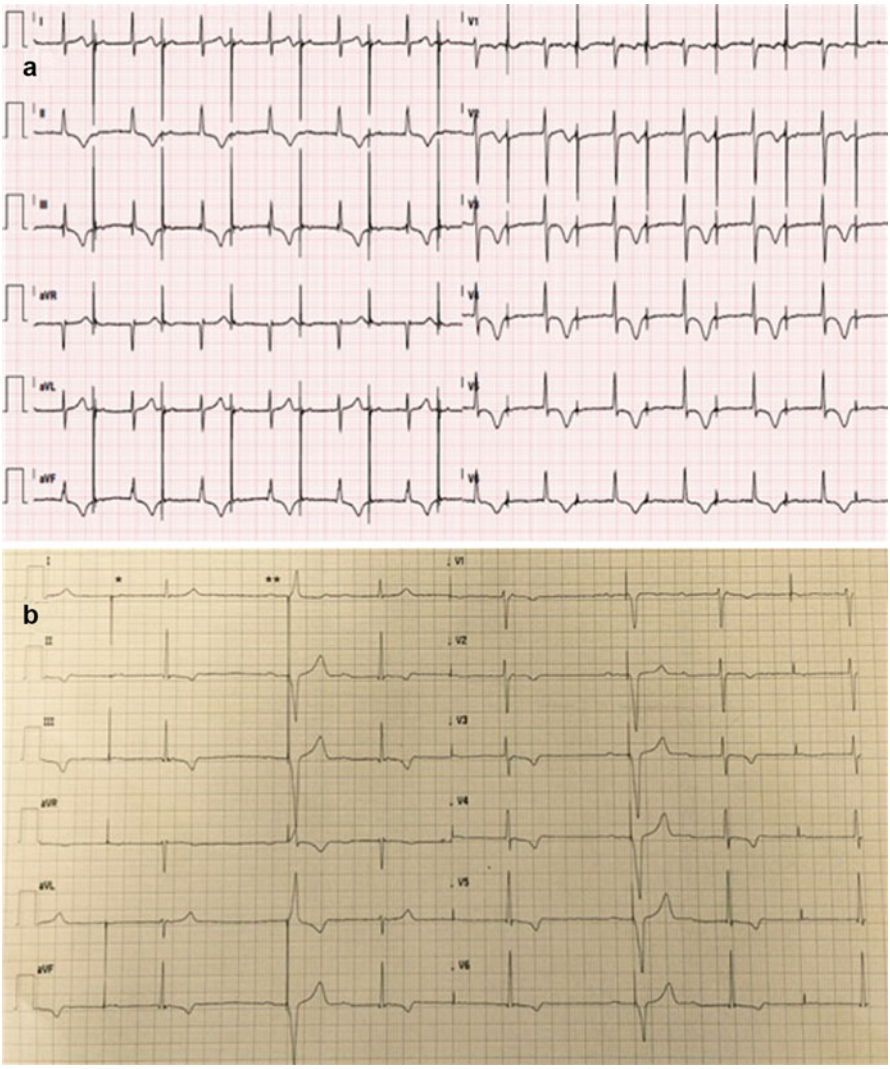

Fig. 11.5 Apparent malfunctions due to algorithm for reduction of ventricular pacing. (**a**) Atrial stimulation with spontaneous AV conduction with very long (440 ms) PQ interval. (**b**) Alternation of AAI (*) and DDD (**) mode, resulting in excessively low ventricular rate

11.5 What to Do in Case a Pacemaker Malfunction Is Suspected

If a PM malfunction is suspected, the patient must be immediately monitored and a complete standard 12-lead ECG obtained.

If artifacts of stimulation are not visible on ECG recording, a magnet must be applied on the device pocket. This will induce asynchronous pacing in both the

atrium and ventricle (VOO, DOO). If pacemaker stimuli become visible, it will be possible to evaluate if they capture the heart (paced P waves and QRS).

If the bradycardia is corrected by magnet application, oversensing is present and lead failure must be considered the most likely cause. The main differential diagnosis is with the presence of a connection defect, especially if the patient has recently undergone PM replacement.

If PM artifacts are visible but fail to capture, either constantly or intermittently even with magnet application, lead dislodgment, cardiac perforation, lead failure, high pacing thresholds, tissue ablation, and programmation errors are the possible causes of the exit block.

Device control by means of real-time telemetry is essential for the final diagnosis. Pacing impedance instant value and trends must be examined. High or low pacing impedances (>2000 or <250 Ω) are diagnostics of lead failure. As they can be intermittent, the temporal impedance trends must be obtained as well. The presence of even only one out-of-range value allows the diagnosis of lead failure. Pacing and sensing thresholds may be evaluated in real time and temporal trends examined.

Battery level is immediately displayed on programmer screen after interrogation, and a message of alert is displayed if battery level is low (ERI, EOS, EOL messages).

Chest X-ray must be obtained to check for connection defects or visible lead fracture, in particular in ICDs recipients. If cardiac perforation is suspected, an echocardiogram and CT scan are recommended.

If a malfunction of the generator is present, like battery exhaustion, PM replacement is necessary. Lead revision/replacement reposition is necessary in most of the other cases as discussed above.

Management of the Electrical Storm in Patients with ICD

12

Daniele Muser, Domenico Facchin, Luca Rebellato, and Alessandro Proclemer

12.1 Focusing on the Issue

Current definition of electrical storm (ES) is the occurrence of three or more episodes of sustained ventricular tachycardia (VT) or ventricular fibrillation (VF) within 24 h requiring appropriate medical intervention. The same definition applies in implantable cardioverter-defibrillator (ICD) carriers in which ES is defined by three or more appropriate and separate (at least 5 min) device interventions in 24 h, either with antitachycardia pacing (ATP) or shock [1].

Current guidelines recommend ICD implantation for secondary prevention of sudden cardiac death (SCD) in survivors of cardiac arrest with no correctable causes and in patients with sustained symptomatic VT of different etiology. They also recommend ICD implantation for primary prevention in patients with ischemic or non-ischemic dilated cardiomyopathy and ejection fraction equal or lower than 35 % after at least 3 months of optimized medical therapy [2] and in other less frequent inherited arrhythmogenic syndromes.

Considering that approximately 1–2 % of the adult population in developed countries suffer from heart failure (HF) and that at least half of these patients have a low ejection fraction [3], the number of ICD carriers is wide spreading. Moreover, the improving therapies of HF ensure a long survival of patients making them older and affected by more comorbidities. For these reasons, ES is an increasingly

frequent cause of access to emergency department (ED). It is estimated that about 25 % of ICD carriers experience at least one ES episode per year follow-up [4]. ES is definitely a medical emergency requiring a multidisciplinary approach.

12.2 What Physicians Working in ED and Anesthesiologists Should Know

12.2.1 How Is an ICD Made and How Does It Work?

The ICD is a subcutaneous implantable device able to monitor cardiac rhythm and terminate potentially life-threatening arrhythmias. It consists of two main components:

- The *generator* that contains the battery, all the circuits that run the device, and the operator communicating system. It is implanted in a subcutaneous pocket, usually under the left clavicle.
- The *leads* that reach heart chambers through the venous system and allow the device to either monitor heart electrical activity and deliver therapies. The ICDs have a lead implanted in the right ventricle apex able both to record ventricular activity and release therapies like pacing and/or direct current shock. In adjunct some ICDs have another lead implanted in the right atrium to record atrial electrical activity, improving discrimination between supraventricular arrhythmias (SVA) and ventricular ones and to pace the atrium (ICD-DR). ICDs with cardiac resynchronization therapy (CRT-D) have a third lead that paces the left ventricle, through the coronary venous system, synchronously to the right ventricle improving contractility. Some recent devices are implanted entirely subcutaneously, leads included (subcutaneous ICD), and can deliver high-energy shocks only (without long-term pacing capabilities) without a direct contact with the heart chambers and no leads inserted in the venous system.

ICDs use mathematical algorithms defined by the manufacturer to discriminate life-threatening ventricular arrhythmias from SVA and deliver appropriate therapy. Sometimes correct recognition fails, and in this case the therapy delivered is defined *inappropriate*. In other cases the delivered therapy may not be able to terminate the ventricular arrhythmia, and in this case it is called *ineffective*:

- The operator interfaces with the ICD through a programmer able to communicate with the device. Each manufacturer uses a different programmer, so it is imperative *to know the manufacturer and use the right equipment*. The programmer establishes an initial connection with the device through a head which must be positioned on the skin above the ICD. Usually green lights turn on to indicate the head is in the right place. At this point, depending on the features of the device, it may be necessary to maintain the head above the ICD throughout the query to allow communication, or, in some devices, the head can be removed since the communication continues via Wi-Fi.

The programmer allows the operator to visualize all the data stored in the device such as:

- *Arrhythmic events*: the device registers all arrhythmic events recognized as such on the basis of user-defined criteria. Each event provides endocavitary (or external for subcutaneous ICDs) electrocardiogram lead recording and therapies delivered.
- *Battery status*.
- Information about *lead integrity*.

On the basis of stored data, the operator may decide to change some settings such as:

- Arrhythmia recognition criteria (heart rate, time before treatment, algorithms for SVT recognition, etc.) and intervention criteria
- Type and characteristics of therapies delivered

12.2.2 How Does the ICD Recognize and Treat Arrhythmias (Appropriate Therapies)?

VT recognition is primarily based upon tachycardia cycle length (to distinguish from normal sinus rhythm) and duration (to detect non-sustained episodes). Both of these parameters are tailored on the patient's characteristics. Thus, ICD uses ventricular rate zones for rhythm classification. The boundaries between zones are defined by two main principles:

- The recognition of unstable fast VT/VF must be highly sensitive even at the cost of inappropriate rapid SVA treatment.
- The recognition of slower VT (generally better tolerated) has to be more specific to avoid inappropriate therapies even at the cost of some delay in detection.

The ICDs treat ventricular tachyarrhythmias by:

- *Antitachycardia pacing* (*ATP*): it is a brief ventricular pacing (6–8 beats) with a cycle length slightly lower (thus at a faster rate) of the arrhythmia (usually 81–88 %), in the attempt of resetting the reentrant circuit and interrupting the arrhythmia. Sometimes the paced cycle shortens from beat to beat, and in this case it is referred as ATP ramp.
- *Direct current shock* (*DC shock*): it is a biphasic electrical shock provided between the generator case and the coil localized on the right ventricular lead. The energy released may vary, reaching up to 40 J with the latest generation high-energy devices.

Basing on several studies [5–7], ICD programming should empirically involve the use of three rate zones:

- A slow VT zone up to 320 ms cycle length (<188 bpm)
- A fast VT zone from 320 to 240 ms (188–250 bpm)
- A VF zone from 240 ms (>250 bpm)

In both VT zones, a variable number of ATP attempts precede shocks delivery. In the slow VT zone, a greater number than in fast VT zone are usually programmed (e.g., 3 ATPs followed by 3 ATP ramps), as fast arrhythmias are usually less tolerated.

In the VF zone, the hemodynamic instability of the arrhythmia and its high life-threatening potential require an immediate shock delivery (usually at the maximum energy from the beginning). In modern devices an ATP during capacitor charging (usually requiring less than 10 s) is delivered, avoiding the shock in the case of arrhythmic interruption.

VT/VF detection not only is based upon ventricular rate but also requires a programmable duration of the arrhythmia to avoid detection of non-sustained episodes. Usually a VT/VF is detected when a certain percentage of ventricular sensed beats meets cycle length criteria. The type of counting used varies between detection zones and among manufacturers. In order to improve sensibility, according to some manufacturers, the arrhythmia is detected when a certain percentage of beats (not necessarily consecutive) falls in VF zone, while consecutive interval counting is required in the VT zone, increasing specificity. The time to detection in the VT zone should be longer enough to allow spontaneous termination of non-sustained episodes [6, 8].

12.2.3 Inappropriate Therapies

Inappropriate therapies (especially shocks) are one of the main issues to be avoided as they cause patient discomfort, are potentially proarrhythmic, and reduce battery life.

The two main causes of inappropriate shock are failure in discriminating SVA and signal misinterpretation.

Frequently SVA is associated with a fast ventricular response leading ventricular rate to fall into VT/VF detection zone causing inappropriate therapy release. This problem occurs more frequently with single-chamber ICDs that do not have atrial sensing capabilities. Dual-chamber devices can compare atrial and ventricular rates to set the origin of the. ICDs use a variety of algorithms to discriminate SVA from VT; major ones are listed below:

- *Atrioventricular rate comparison*: applies only in dual-chamber ICDs; when the ventricular rate is faster, the diagnosis is VT. When atrial and ventricular rates are equal, additional criteria are required for discrimination.
- *Onset*: useful for discrimination of gradually accelerating sinus tachycardia from sudden-onset VT. It applies when the RR interval shortens by a programmed percentage if compared with the average number of preceding beats. May fail in case of VT occurring during sinus tachycardia.
- *Stability*: useful for discrimination of fast response AF. It evaluates RR variability; when greater than a programmed percentage (e.g., 20 %), AF is supposed. It may fail in the case of very fast AF in which there is a pseudo-regularization of ventricular rate, in atrial flutter or in irregular VT.

- *Morphology*: it compares endocavitary electrocardiograms recorded during sinus rhythm and during VT. It is useful in single-chamber ICDs lacking of atrial information but may fail in intraventricular conduction delays and in rate-dependent conduction delays.
- *Rate duration*: it is an extreme lifesaving measure. It results in shock delivery after a programmable time interval even if the episode is classified as SVA; this algorithm is usually activated when there is a high risk of undertreatment of VT erroneously recognized as SVA, but it increases the risk of overtreatment.

Signal misinterpretation is the other big deal leading to inappropriate shocks. It may depend on some programmed variables; easily editable, external, and far-field interferences; or device/lead failure that usually requires an interventional approach. Main causes of signal misinterpretation are listed below:

- *T wave oversensing*: it happens when a high amplitude T wave is erroneously recognized as an R wave. It may happen because of the low ventricular sensing threshold necessary to recognize even low-amplitude VF. This problem can be solved by increasing sensing threshold, lengthening refractory period, or changing sensing decay parameters to suppress T wave detection.
- *Electromagnetic external interference*: external electromagnetic fields can be mistaken for intracardiac signals resulting in inappropriate arrhythmic detection and therapy. Common household appliances are not generally a problem, but some high-intensity fields such as high-voltage power lines, electric motors, magnetic resonance imaging, TENS units, electrocautery during surgery, neurostimulators, and radiotherapy should be avoided.
- *Myopotentials*: far-field myopotential recording may lead to inappropriate arrhythmic detection. This problem occurred in the past with unipolar leads using large sensing fields (from the lead tip to the generator case) and is now largely avoided with the modern bipolar leads, recording more localized signals only.
- *Lead failure*: lead fracture or insulation loss of continuity may cause external noise recording and inappropriate detection. In these cases lead extraction and/or new lead insertion is the only choice. Modern devices usually provide alerts for lead integrity.

12.2.4 Electrical Storm

12.2.4.1 Incidence and Clinical Predictors

Several studies examined the incidence of ES in ICD recipients, although ES definition was not standardized and the inclusion criteria and follow-up period were not homogeneous. Considering current definition, the incidence varies from 4 to 28 % in a follow-up period between 1 and 3 years [9]. In the sub-analysis of the AVID trial [10], including 499 patients treated for secondary prevention, the rate

of ES was 20 % at 3-year follow-up. Of note, the incidence of ES in primary prevention trials appears lower (4 % in MADIT II), and in our experience [11], after a mean 2-year follow-up, only 13 patients (2 %) experienced an ICD treatment configuring an ES.

A recent meta-analysis [9] evaluated the real weight of ES as a risk factor and its clinical predictors. On the basis of 13 studies, a trend toward an increased prevalence of ES was associated with advanced age and male gender. Other factors related to ES in ICD carriers were heart failure-related clinical variables (as lower ejection fraction), an ICD implant for secondary prevention, the presence of monomorphic VT as triggering arrhythmias instead of polymorphic VTs and VF, and the treatment with class I antiarrhythmic drugs but not with amiodarone and beta-blockers. On the contrary, no significant differences between patients with ischemic or nonischemic dilated cardiomyopathy were reported. After meta-regression analysis, no significant interaction between any of the examined clinical variables and the increased risk of ES was confirmed.

The main clinical characteristics and clinical predictors of ES in the group of patients treated with a CRT-D have been considered in a multicenter experience including 631 patients, with a mean follow-up of 19 ± 11 months. In this study VT or VF episodes were detected and treated in 141 patients (22 %), and ES occurred in 45 (7 %). At univariate analysis, the only predictors of ES were the nonischemic etiology of cardiomyopathy and secondary prevention indication, while other common variables such as age, male gender, ejection fraction lower than 25 %, and advanced NYHA class did not correlate.

Our experience included 62 patients (mean age 66 years, 90 % male) admitted for ES during the period 2006–2012. The mean interval from implant to ES was 47 months. Ischemic heart disease was present in 30, nonischemic cardiomyopathy in 11, and other etiologies in 14, and 60 % of patients had been treated with ICD for secondary prevention. Mean ejection fraction was 35 %. In 23 patients the arrhythmia at admittance was incessant VT, while the remaining 39 experienced several VT/VF episodes, with a mean number of 6 shocks per patient. In more than half of patients (31), there wasn't a clear trigger and the ES rises from a primitive electrical instability. In the remaining the most frequent triggers were worsening heart failure, electrolyte imbalances, myocardial ischemia, and proarrhythmic drug side effects.

12.2.4.2 Prognosis

The majority of papers evaluating the role of ES as a mortality risk factor showed that it was associated with a threefold risk of death. ES maintained a significant value as risk factor even when compared with unclustered sustained VT/VF [9]. For the composite end point of all cause mortality, heart transplantation and hospitalization for heart failure ES was associated with a 3.39-fold increased risk.

The reported mortality among large series [12] of patients with ES treated by catheter ablation appeared extremely variable between 15 and 29 % during a follow-up ranging from 1 to 2.5 years. In our series, including patients treated not exclusively by catheter ablation, the overall survival of patients experiencing their first ES episode was 60 %, 50 %, and 44 % after 1, 2, and 3 years, respectively.

Considering that ES is associated with increased SCD and non-sudden cardiac mortality, Guerra et al. evaluated the association between ES and heart failure in patients with chronic heart failure and ICD. They reported that during 5-year follow-up, the survival estimates were not significantly different between patients with ES and HF worsening (36.4 vs. 38.5 months), while it was significantly lower in comparison to survival of patients with unclustered VT/VF episodes (49.2 months). The primary mortality cause in ES group was refractory heart failure (59 %), followed by noncardiac conditions and by SCD in only two patients. Even hospitalization-free rate was lower in both ES and HF worsening groups in comparison to patients with unclustered VT/VF episodes (15.4 vs. 20.1 vs. 36.1 months), while the hospitalization rates were not significantly different between ES and HF worsening groups. The conclusions of the authors were that heart failure patients admitted for ES show important outcome analogies with patients admitted for acute heart failure and that ES should be identified as an important clinical consequence of heart failure decompensation.

12.3 What the Cardiologist Should Know

ES is a medical emergency potentially leading to acute cardiac failure and cardiogenic shock and requiring a multidisciplinary approach.

Initial diagnostic workup includes physical examination, electrocardiogram (ECG), chest X-ray, echocardiogram, blood gas analysis, electrolytes, serum creatinine evaluation, and ICD interrogation.

The first issue to assess in a patient with multiple ICD shocks is to seek ICD intervention causes.

In case of appropriate therapies due to VT/VF, it is necessary first of all to rule out reversible causes of ES including electrolyte imbalances, acute ischemia, worsening heart failure, infective state, hyperthyroidism, and proarrhythmic drugs. In a large series reversible causes of ES account for no more than 10 % of cases referred to EP labs [4].

Following initial evaluation, an accurate patient's risk stratification should be made according to hemodynamic tolerance of the clinical VT and comorbidities [13]. Hemodynamic decompensation defined as sustained hypotension (i.e., systolic blood pressure <80–90 mmHg) despite increasing doses of vasopressors and requiring mechanical hemodynamic support (i.e., intra-aortic balloon pump, left ventricular assist devices, or extracorporeal membrane oxygenation) [14] makes the patient at high risk by itself and in some cases even at the temporary restoration of sinus rhythm. In case of hemodynamically tolerated VT, the presence of at least one comorbidity such as left ventricular ejection fraction less than 30 %, serum creatinine level >1.5 mg/dl, chronic occlusion of left anterior descending coronary artery, and severe chronic lung disease makes the patient particularly high risk [13]. All high-risk patients should be admitted to intensive care unit (ICU) and, if necessary, undergo circulatory and/or ventilatory support and/or hemodialysis.

All the efforts should be made to reduce VT/VF episodes to avoid further shocks considering even in combination of a complex strategic approach including antiarrhythmic drug therapy, device reprogramming, deep sedation/mechanical assistance, and catheter ablation.

12.3.1 Antiarrhythmic Drugs

Initial treatment of ES usually involves the use of antiarrhythmic drugs, weighing their proarrhythmic risk and negative inotropic effect, to prevent arrhythmic recurrences.

The cornerstone of antiarrhythmic therapy still remains sympathetic blockade with *beta-blockers* to suppress the adrenergic drive to VT recurrence [15]. Although all beta-blockers are able to reduce susceptibility to VT/VF as class action, most of the studies analyzed *propranolol*. In patients with HF, propranolol resulted to be more effective than *metoprolol* in reducing sympathetic tone due to its capability of blocking both β1 and β2 receptors and to its lipophilic nature that enables penetration within the central nervous system blocking also presynaptic adrenergic receptors [16, 17]. Sympathetic blockade is able not only to suppress ES [18] but also to improve short-term survival more than the combined antiarrhythmic therapy with lidocaine, procainamide, and bretylium [15]. In severely compromised patients, intravenous short-acting drugs like *esmolol* should be preferred [19]. The first-choice antiarrhythmic drug should be *amiodarone*, even in combination with propranolol that effectively controlled ES and improved survival [15, 18]. When amiodarone is administered intravenously, it reduces adrenergic tone, blocks sodium and L-calcium channels without prolonging ventricular refractoriness, and, when administered, orally prolongs ventricular refractory period [20, 21]. When ineffective alone or in combination with beta-blockers, amiodarone may be helpful even in adjunct to other agents [22]. Even patients who previously keep amiodarone may beneficiate from a reloading dose/therapy adjustment if serum levels of amiodarone/desethil-amiodarone are under therapeutic levels. The acute administration is relatively safe even in patients with depressed ejection fraction due to its low inotropic negative effect. It can increase the defibrillation threshold, making potentially ineffective ICD therapy; consequently ICD defibrillation energy should be re-tested or re-evaluated. Long-term amiodarone assumption is burdened by several side effects like thyroid, liver, and lung toxicity, sometimes forcing to therapy discontinuation. In case of amiodarone failure, other additionally drugs may be considered such as procainamide both orally or intravenously. The use of multiple antiarrhythmic drugs makes the drug-to-drug interaction unpredictable, potentially increasing the side effect occurrence. The use of *lidocaine* is limited by its relatively incapacity to terminate scar-related VT [23]. Lidocaine is a sodium rapid channel blocker that binds to channels in a use-dependent way. During ischemic VT, the altered membrane potential as the pH reduction [24] increases the rate of drug binding, making lidocaine effective in terminating arrhythmias. The pharmacodynamic proprieties

make lidocaine not so effective in settings different from ischemic arrhythmias, maintaining a role only for the treatment of polymorphic VT associated with ischemia (IIb recommendation according to the American College of Cardiology/American Heart Association guidelines [25]).

Procainamide (not available in all countries) is another IC class antiarrhythmic drug commonly used as second- or third- line therapy in refractory VTs. Procainamide acts as fast sodium channel blocker, while its active metabolite N-acetylprocainamide blocks potassium channels and accounts for much of the antiarrhythmic effect in vivo as well as side effects like QT interval prolongation. Care must be taken in administering the drug in patients with low ejection fraction due to the high risk of hypotension.

12.3.2 Device Reprogramming

Several studies demonstrated that repeated ICD shocks are associated with increased mortality as well as with a reduction of quality of life [10]. For these reasons optimization of ICD programming in order to avoid unnecessary shock is mandatory in patients experiencing ES. As stated above, arrhythmic detection and treatment by ICD is a step process including several variables such as heart rate threshold, number of intervals to detect, discrimination of SVA, and type and number of therapies released. Each of these steps can be tailored upon patient characteristics to avoid unnecessary treatment.

12.3.2.1 Higher Heart Rate Threshold

Usually patients treated with ICD for primary prevention tend to develop fast VT, while patients treated for secondary prevention usually have slower VT with a wider overlap with SVA [26]. On this basis, the first may benefit from higher rate detection zones, while the latter needs slower rate detection zones and improved SVA discriminating algorithms. Even better, rate detection zones can be tailored upon patient's clinical history when previous arrhythmia episodes occurred. In three trials (PREPARE, MADIT-RIT, and PROVIDE), higher rate detection zones demonstrated reduce ICD shocks without increasing both syncope and death risk.

12.3.2.2 Longer Detection Period

The effect of prolonging arrhythmic detection time is well studied especially in the primary prevention setting with lower data available in the setting of secondary prevention.

The REVELANT study showed that a higher number of intervals for arrhythmic detection (30/40 vs. 12/16) significantly reduced the incidence of ICD intervention without increasing syncope or death in patients with ICD for primary prevention and nonischemic cardiomyopathy. MADIT-RIT trial showed a reduction of both inappropriate therapy and all-cause mortality with a 60-s delay at 170–199 bpm, a

12-s delay at 200–249 bpm, and a 2.5-s delay at ≥250 bpm vs. conventional programming. These results were recently confirmed by ADVANCE III trial [27] in which the combination of a higher number of intervals to detection (30/40 vs. 18/24) with ATP therapy during charge significantly reduced either appropriate or inappropriate therapies regardless of ICD type and indication. Even in the PROVIDE trial, multi-parametric programming including higher detection rate, longer detection intervals, and optimized SVA discriminating algorithms was associated with better overall survival and reduction of ICD shocks without increasing arrhythmic syncope risk, and the PainFree SST trial confirmed that longer detection intervals are safe in terms of risk of syncope. Of all these studies, only ADVANCE III and the PainFree SST included patients with both primary and secondary preventions for ICD, while the remaining trials focused only on patients treated for primary prevention.

12.3.2.3 Improving ATP Programming

ATP therapy demonstrated to be highly effective in terminating VTs, reducing unnecessary shocks and consequently improving survival, quality of life, and generator life. In several studies 85–90 % of "slow" VTs (<188–200 bpm) [28] and 54–72 % of "fast" VTs (188–250 bpm) [29, 27] were terminated by ATP. As stated before, ATP therapy can be administered as *bursts or ramps* on the basis of the pacing cycle length variations. Bursts and ramps proved similar efficacy in treating slower VTs [28], while fast VTs (>200 bpm) were best treated by bursts that also showed a lower risk of arrhythmic acceleration than ramps. Due to less efficacy of ATP in terminating fast VTs (>200 bpm) and the negative hemodynamic consequences of such arrhythmias, usually in the fast VT and VF zone, *ATP is delivered during capacitor charge* to avoid any delay in shock therapy. The majority of VTs were effectively interrupted by one or two ATP attempts with only a minority of patients responsive to more than three attempts [30, 31], and for this reason programming more than three ATP attempts should be discouraged. In CRT-D recipients, biventricular ATP should be preferred to right ventricular ATP due to its higher efficacy and safety [32, 33]. The last key point in ATP programming is burst cycle length that can be empirically programmed at 85–90 % of the arrhythmic cycle length for fast VTs and at 70–80 % for slower ones. When ATP appears ineffective in VT termination, the analysis of the post pacing interval can allow tailoring ATP programming upon patient characteristics, for example, by shortening drive cycle length or by increasing the number of paced beats [34].

Accordingly to all these data, the increase of detection time and threshold rate in patients experiencing ES helps to prevent both inappropriate and unnecessary shocks, making ICD reprogramming a mandatory step in the clinical workup of ES.

In case of inappropriate therapies, specific measures must be taken: e.g., change ICD detection parameters, enhance drug therapy, or consider catheter ablation in case of SVA; temporarily turn off the device before lead replacement in case of lead fracture/failure.

12.3.3 Sedation, General Anesthesia/Mechanical Ventilation, and Mechanical Hemodynamic Support

The sympathetic adrenergic activation in patients experiencing multiple shocks due to ES may perpetuate VT/VF [35] and render the arrhythmias life threatening and refractory to several maneuvers. Therefore, some patients with ES should be sedated or even undergo general anesthesia to reduce sympathetic tone and suppress ventricular electrical instability. *Propofol* has been reported to suppress ES [36, 37], but this beneficial effect may be offset by the inotropic negative effect. In this regard, only few data are available in literature about the effect of deep sedation/general anesthesia on the prognosis of ES patients, and most of them are extrapolated from patients undergoing catheter ablation to treat ES. Drugs inducing general anesthesia should be considered with attention because they can exacerbate hypotension and depress cardiac function [14]. Deep sedation with *remifentanil* even in association with a *benzodiazepine* like midazolam should be preferred as it is able to reduce sympathetic hypertone and provide analgesia avoiding dangerous negative inotropic effects [38–40]. A valuable alternative may be *dexmedetomidine* [41], an α2 presynaptic adrenergic receptor agonist able to markedly reduce sympathetic tone by both enhancing central vagal tone [42] and inhibiting presynaptical adrenaline release [43]. However, it has important side effects like hypotension and bradycardia [44] that should be rigorously monitored during its usage.

General anesthesia and mechanical ventilation should be reserved only to patients with hemodynamically non-tolerated arrhythmias refractory to all therapies. Such patients may benefit from hemodynamic mechanical support like *intra-aortic-balloon pump* (IABP), *left ventricular assistance devices* such as the Impella (Abiomed Inc., Danvers, MA) [45–47], and even *extracorporeal membrane oxygenation* (ECMO) [48, 49]. These devices can not only suppress ischemic VTs by increasing coronary perfusion but can be effective in suppressing ES reducing LV afterload and wall tension [50] as well as prevent multiple organ failure sustaining organ perfusion. Last but not least, they have a key role in mapping and ablating unstable VTs. Some patients experiencing refractory unstable arrhythmias should also be carefully evaluated for urgent check for cardiac transplantation.

12.3.4 Neuraxial Modulation (Thoracic Epidural Anesthesia, Cardiac Sympathetic Denervation)

Given the importance of the autonomic nervous system in triggering and maintaining ventricular arrhythmias, sympathetic neuromodulation through thoracic epidural anesthesia [51], cardiac sympathetic denervation (CSD), and spinal cord stimulation may help in reducing arrhythmic burden in selected patient with ES refractory to multiple antiarrhythmic drugs and catheter ablation. CSD is usually performed via video-assisted thoracic surgery and consists of removal

the lower third of the stellate ganglia (to avoid Claude-Bernard-Horner syndrome) as well as T2–T4 thoracic ganglia. The resection is usually performed on the left side, reserving bilateral CSD for selected cases. The procedure should be performed in referral centers only, due to special anesthesiology skills required such as selective bronchus intubation management. Most of what we know about the results of the procedure results from case reports [52, 51, 53], but in a prospective study of 41 patients with ES refractory to medical therapy and catheter ablation, CDS demonstrated to be effective in prolonging ICD shock-free survival at 1-year follow-up with greater effect of bilateral CDS compared to left CDS only [54].

12.3.5 Catheter Ablation

Currently, radiofrequency catheter (RF) ablation represents the mainstay treatment of recurrent VTs and even of ES. Several studies demonstrated how catheter ablation may prevent VT recurrence as well as improve survival of ES patients with a growing effectiveness due to technological improvement and deeper knowledge of arrhythmogenic substrate [14]. In the past, RF ablation was considered as the last chance treatment in patients refractory to multiple antiarrhythmic drugs, but in the last decade there has been a growing evidence for early referral to RF ablation in case of recurrent ICD therapies or even prophylactically [55–57]. RF ablation showed to be highly effective in suppressing refractory VTs in the acute management of ES, reaching an acute success rate of 80 % in the largest series [40, 12, 58, 59], especially when the end point of non-inducibility of all clinical VTs was reached [12]. As stated before, patients with unstable hemodynamic VTs should be referred for mechanical assistance in order to allow mapping and ablation but also those with apparently stable arrhythmia may develop acute hemodynamic decompensation during RF ablation procedure. In a preliminary study, a simple score named PAINESD taking in account patient's baseline comorbidities (Pulmonary chronic obstructive disease, Age older than 60, Ischemic cardiomyopathy, NYHA class III or IV, Ejection fraction lower than 25 %, Storm at presentation, and Diabetes mellitus) was tested to predict acute decompensation during VT catheter ablation in order to select patients who may benefit prophylactic mechanical support [14] (Fig. 12.1).

12.4 Indication for Follow-Up and Referral

All patients who experienced an ES episode remain at high risk of recurrences even if effectively treated with catheter ablation and multiple antiarrhythmic drug prophylaxis. Often ES is the expression of worsening of the underling heart disease. For these reasons all patients who developed at least one episode of ES

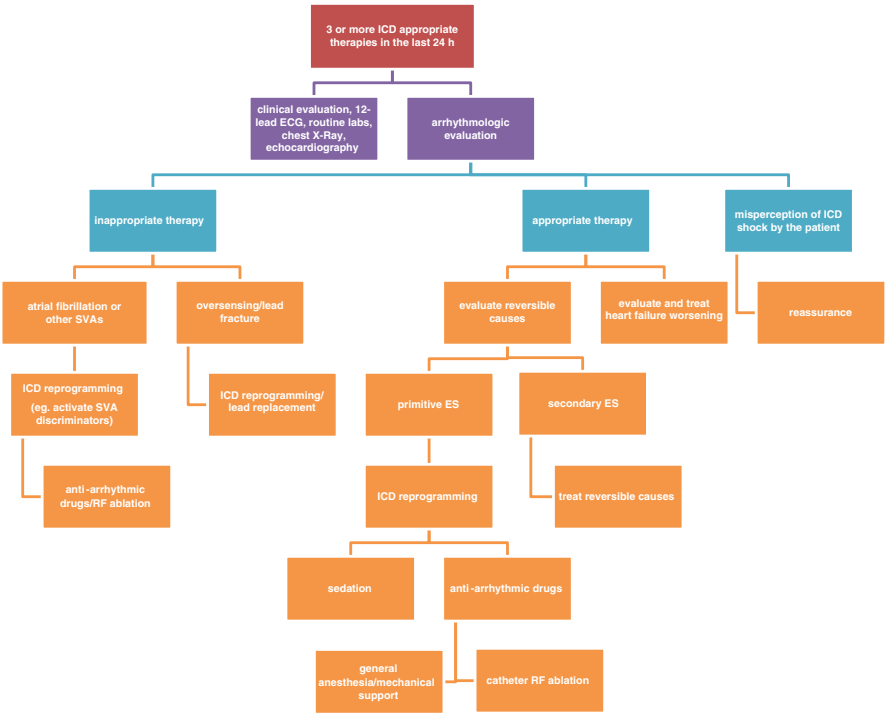

Fig. 12.1 A suggested algorithm/pathway for diagnosis and treatment of ES

should be referred both to a heart failure specialist and proper electrophysiological management in order to optimize the heart failure therapy and evaluate indication to heart transplantation or left ventricular assistance devices both as a bridge to transplant and as destination therapy. Arrhythmic follow-up may be best done with home monitoring of the ICD that allows a prompt evaluation of arrhythmic events.

Emergency Surgery and Cardiac Devices

13

Massimo Zecchin, Luigi Rivetti, Gianfranco Sinagra, Marco Merlo, and Aneta Aleksova

13.1 Focusing on the Issue

The number of patients with CIED (Cardiac Implantable Electric Devices) who need emergency surgery has been increasing in the last decades, considering the spread of ICD (Implantable Cardiovetrer-Defibrillator) and CRT (Cardiac Resynchronization Therapy) implantations for sudden death prevention and heart failure treatment.

It is estimated that about three million patients worldwide have a pacemaker (PM) and about 500,000 patients have an ICD [1]. According to EUCOMED data, in Europe nearly 1000 PM and 170 ICD new implantations were performed every million inhabitants in 2012. Although the implant rate of PMs has not significantly changed, there has been an increase of ICD and CRT implantations in the last decade, after the publication of several trials proving their efficacy. Despite some regional differences, this trend can be observed in most western countries.

In case of urgent surgical intervention, patients with CIED (especially ICD) can be considered at high risk for many reasons, mostly due to the underlying cardiac disease, hemodynamic impairment/left ventricular dysfunction (in particular those with ICDs), and the advanced age (in particular those with PMs) [2].

In addition, during surgical interventions, transient or even permanent malfunctions of the device, because of electromagnetic interferences or mechanical damages, are possible [3].

Electromagnetic fields can potentially cause several malfunctions: damage to the CIED circuitry, pacemaker inhibition, noise tracking, asynchronous pacing, communication failure, etc. [4].

An electromagnetic field is characterized by a wavelength, a frequency, and a field strength. The range of frequency emitted by sources such as magnetic resonance imaging (MRI) and electrosurgery is between 0 Hz and 450 MHz. The electric field strength is measured in volts per meter, while the magnetic field intensity components of electromagnetic fields are measured in amperes per meter. Electromagnetic field energy decreases as an inverse squared function of distance from the source, so the risk of exposure is fourfold lower just doubling the distance from the source.

Even static magnetic fields can be a possible cause of CIED malfunction; sterile magnetic drapes, frequently used during surgery to hold metal instruments, can potentially interfere with the function of PM and ICDs if positioned at a distance less than 15 cm [5].

Electrocautery is associated with tissue heating. However, conductive devices and leads, particularly when placed in a loop configuration, can increase the risk of burns due to the inductive heating of the lead conductor from radiofrequency fields.

In recent years, a great effort to minimize CIED has been performed. Generators are shielded by hermetically sealed titanium or stainless steel cases. The extent of shielding varies depending on the manufacturer, weight of the device, and dimensions and usually rejects electric fields >2 MHz.

EMI are also reduced by the use of bipolar sensing and low-pass filters. However, frequencies between 0 and 60 Hz overlaps the cardiac signal range so a "noise reversion feature" is activated when signals are detected in the noise-sampling period of the atrial and ventricular refractory periods, programming the device in asynchronous pacing.

Additionally, lead design was modified to improve shielding from radiofrequency and time-varying gradient magnetic fields.

13.2 What Physicians Working in ED, Anesthesiologists, and Surgeons Should Know

The PM is a pulse generator, generally placed in the left (less frequently right) subclavian region, usually subcutaneously or under the pectoral muscle. It is connected with the heart across the cephalic, axillary, or subclavian vein by one or two leads reaching the right ventricle, the right atrium, or both; in patients with cardiac resynchronization therapy (CRT), another lead is positioned in a branch of the coronary sinus for left ventricular pacing. Depending on the needs of an individual patient and model of the PM, programming and pacing function will differ from one device to another.

The ICDs differ from PMs for their antitachycardia properties, as they can recognize and automatically interrupt (by overdrive pacing or high-voltage DC shock) potentially fatal arrhythmias, as sustained ventricular tachycardias or ventricular fibrillation, the leading causes of sudden death. In patients with left ventricular dysfunction of any origin, as well as in those with other cardiac conditions at high risk of sudden death, treatment with ICD is associated with an improved survival even in

Table 13.1 NASPE code for pacing modalities

S → single (A or V)	S → single (A or V)			

the absence of previous history of ventricular arrhythmias. With the exception of some newly released entirely subcutaneous ICD, without intravascular leads (s-ICD), all ICDs have PM properties. In addition, it is possible to program the minimum rate and duration of arrhythmias required to be recognized and treated, to avoid unnecessary therapies in the case of slow and/or brief self-terminating tachycardias.

13.2.1 PM Programming Modes

Pacing modalities are expressed according to the North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group (NASPE/BPEG) revised code (see Table 13.1) [6]. The first letter indicates the chamber in which pacing occurs, while the second indicates the chamber with sensing capabilities. The third letter indicates the effect of sensing on the triggering or inhibition of subsequent pacing stimuli. The fourth and the fifth letter, not always used in clinical practice, respectively indicate the presence (R) or absence (O) of an adaptive-rate mechanism and whether multisite pacing (as in CRT) is present.

13.2.2 Unipolar Versus Bipolar Leads

Artifacts during electrocauterization can be erroneously considered by the CIED as spontaneous fast electrical activity of the heart (oversensing) [7]. Nearly all leads implanted in the last decade are bipolar, meaning that both the cathode and the anode are on the tip of the catheter, reducing the inter-electrode distance and the likelihood of external interferences. However, in some patients, especially with less recent implantations, unipolar leads can still be present. In these patients, the risk of oversensing is particularly high, as the sensed field is included between the tip of the lead (functioning as a cathode) and the generator (anode).

13.2.3 Unipolar Versus Bipolar Electrocautery

Electrosurgery current usually occurs in the frequency range between 100 and 5000 kHz and is typically delivered in a unipolar configuration between the

cauterizing instrument and ground electrode. Bipolar electrosurgery involves the use of an electrical forceps where each limb is an electrode; it is used far less commonly because it is useful only for coagulation and not dissection. Bipolar systems deliver the current between two electrodes at the tip of the instrument, reducing the likelihood for EMI with CIEDs. Therefore, malfunctions are associated with unipolar electrocautery only, while bipolar electrosurgery does not cause EMI when not directly applied to CIED.

EMI usually occur when electrosurgery is performed within 8–15 cm from the device. Electrosurgery below the umbilicus with the grounding pad placed on the thigh is therefore unlikely to result in EMI with thoracic CIEDs.

EMI are more likely with the cutting mode rather than with the coagulation mode of surgical electrocautery, probably because of the higher power and the longer period of time applied for tissue cutting than coagulating a bleeding vessel.

The use of a harmonic scalpel, an ultrasonic cutting and coagulating instrument, can avoid surgical diathermy, according to some data [8].

13.2.4 Effects of EMI on CIED: General Considerations

Depending on the type of devices and lead, the programming of the devices and the type of surgery, different malfunctions can be found.

The possible effects of EMI can be transient (due to oversensing) or permanent (initiation of noise reversion, electrical reset mode, or increase of pacing thresholds).

Permanent damages are extremely rare, unless the energy is applied directly to the pulse generator or system electrode. There are some old reports of various serious effects, such as failure to pace, system malfunction, and even inappropriate life-threatening uncontrolled pacing activity [3]. However, because of the advances in lead and generator technology, most recent reports suggest that nowadays these effects infrequently occur.

13.2.4.1 Reset

Resetting of PMs has been reported in presence of energy coursing through the pulse generator (i.e., when the electrocautery touches, or is very close to, the generator) and simulates the initial connection of the power source at the time of manufacture. During reset, pacing parameters are automatically programmed in VVI mode with a lower rate from 60 to 70/min (depending on the manufacturer) and high output energy. For ICD, beside a VVI 60–70/min pacing mode, a fixed antitachycardia therapy (with lower rate cutoff ranging from 146 to 190/min according to the manufacturer) is programmed.

13.2.4.2 Generator Damages

The application of electrosurgery either in immediate close proximity or directly to the pulse generator can cause failure or permanent damage to a CIED, especially to older pacemakers (with voltage-controlled oscillators, no longer manufactured).

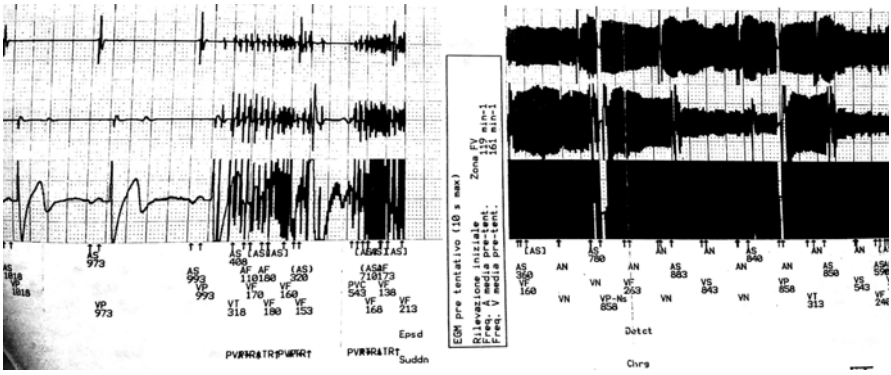

Fig. 13.1 Ventricular oversensing during thoracic surgery leading to ICD charge

ICDs may be more resistant, but energy can still enter the pulse generator in presence of breaches of lead insulation.

13.2.4.3 Lead-Tissue Interface Damage

Damage to the lead-myocardial interface is unlikely to occur with modern devices, but monopolar electrosurgery pathways crossing a pulse generator can produce enough voltage to create a unipolar current from the pulse generator case to a pacing electrode in contact with myocardium. This can result in a localized tissue damage with an increase in pacing threshold and possible loss of capture [9].

13.2.4.4 Oversensing

The most frequent CIED interaction with EMI is oversensing, leading inappropriate inhibition of pacing output and false detection of a tachyarrhythmia, with possible inappropriate CIED therapy (Fig. 13.1).

Electrosurgery applied below the umbilicus is much less likely to cause PM or ICD interference than when applied above the umbilicus. However, endoscopic gastrointestinal procedures that use electrosurgery may result in interference (Fig. 13.2). In a recent analysis on 71 subjects with ICD, EMI were recorded in 50 % of thoracic and head or neck procedures, 22 % of upper extremity procedures, 7 % of abdominal/pelvic procedures (laparoscopic cholecystectomies only), and 0 % of lower extremity procedures. No EMI in any lower abdominal procedures were recorded [10].

13.2.4.5 Pacemaker Response to EMI

When programmed in inhibited pacing modes (AAI, VVI, or DDI), pacing inhibition can occur in presence of EMI, with consequent bradycardia or asystole in PM-dependent patients. When programmed in tracking mode (DDD), sensing of EMI in the atrial channel (more likely to occur, because of the higher sensitivity necessary to detect atrial signals) could result in increased rate of ventricular pacing or false atrial arrhythmia detection and consequent "mode-switch" to inhibited pacing modes (VDI, VVI, or DDI).

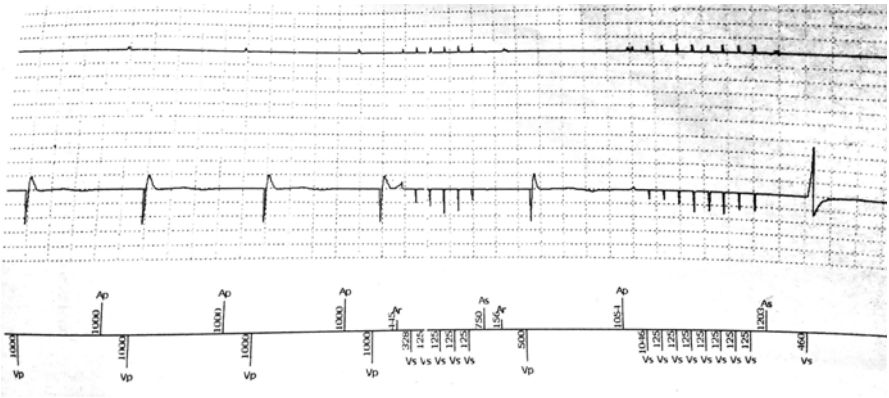

Fig. 13.2 EMI during polypectomy

For a patient with spontaneous underlying rhythm, pacing inhibition does not have any consequences, while in PM-dependent patients, a prolonged (>4–5 s) pacing inhibition can result in significant hemodynamic compromise. Therefore, *limiting electrosurgery usage to shorter bursts* is desirable and may be a safer approach than either reprogramming the CIED or placement of a magnet over the pulse generator [3].

In patients with cardiac resynchronization therapy (CRT), ventricular stimulation is, or should be, always present at surface ECG; however, these patients are not usually pacemaker dependent, so will not experience hemodynamic difficulties if biventricular pacing is transiently interrupted, with the exception of patients with advanced spontaneous AV block and those treated with AV node ablation ("ablate and pace").

13.2.4.6 ICD Response to EMI

The ICDs require a certain duration (several seconds) of continuous high-rate sensing to satisfy arrhythmia detection criteria and consequently start the treatment (antitachycardia pacing or DC shock). Therefore, short bursts (<5 s) of electrosurgery alternating with pauses lasting some seconds are unlikely to result in false tachyarrhythmia detection and inappropriate antitachycardia therapies.

Inappropriate ICD shocks, although painful in nonsedated patients, should not be necessarily considered a serious danger for both the patient (apart from skeletal muscle contraction even if the patient is paralyzed by curare) and the people surrounding, who will not experience any shock. There is, however, a rare but possible proarrhythmic effect of DC shocks, which can initiate ventricular fibrillation.

13.2.5 Effects of the Magnet

A simple magnet (typically 90 G) should always be present in the operating room when a patient with a CIED undergoes a procedure potentially causing EMI. However, the effect of the magnet positioned on the skin just above the device (Fig. 13.3) differs between pacemakers and ICDs.

Fig. 13.3 A magnet placed on the CIED pocket

13.2.5.1 Pacemakers

When a magnet is applied on a pacemaker, it usually causes "asynchronous pacing" (generally VOO or DOO), meaning that pacing at a fixed rate is provided, independently from any sensed activity, ensuring cardiac stimulation (or avoiding inappropriate triggered activity) even in the presence of persistent artifacts. The pacing rate in the presence of a magnet is CIED characteristic and varies according to the battery charge.

If spontaneous ventricular activity is adequate, asynchronous pacing (provided by the magnet or by CIED reprogramming) can be unnecessary or even inappropriate and potentially dangerous, as the magnet rate may compete with the patient's rate; however, the risk that asynchronous pacing in patients with intrinsic rhythm can potentially induce atrial or ventricular arrhythmias, although widely feared, is very low [11].

13.2.5.2 Implantable Defibrillators

In ICDs, arrhythmias detection or tachycardia therapy can be disabled by magnet application and is automatically re-enabled when the magnetic field is removed. In some elderly Boston Scientific (former Guidant) ICDs, antitachycardia therapy may be permanently, and not transiently, deactivated by magnet application, necessitating reprogramming of the device or magnet repositioning to restore prior function. For this reason, and because it is possible to turn off magnet response in some devices, careful monitoring is required during the procedure to determine the effects of cauterization.

If inappropriate antitachycardia therapies (shock or antitachycardia pacing) should be delivered despite the magnet, shorter bursts (<5 s) with pauses between bursts, or bipolar cautery, are mandatory. On the other side, when true sustained

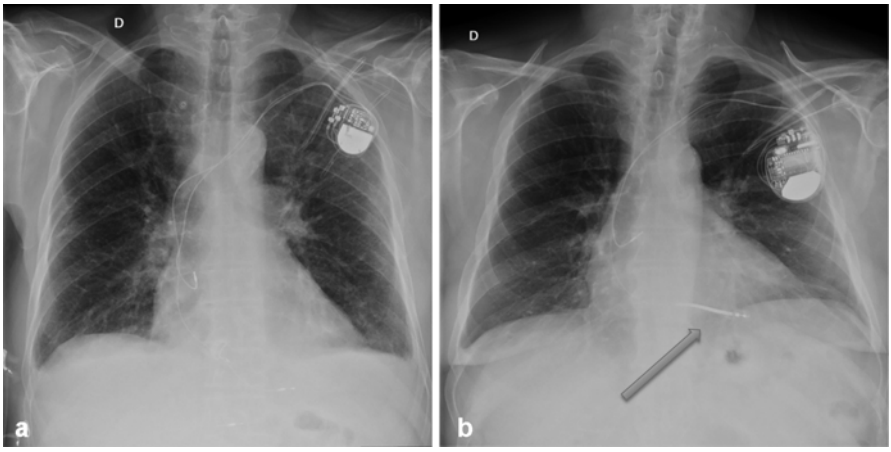

Fig. 13.4 Posterior anterior thoracic X-ray in a patient with a pacemaker (**a**) and an ICD (**b**). The shocking coil along the right ventricular lead in the ICD patient is indicated by the *arrow*

ventricular arrhythmias occur, appropriate antitachycardia therapies can be delivered by the device by just removing the magnet or by using an external defibrillator. In this case, external pads should be placed in the anteroposterior rather than anterolateral position, ensuring the anterior (apical) pad is at least 5 cm away from the device.

Differently from PM, the *magnet does not affect ICD antibradycardia pacing functions*. As a consequence, *in PM-dependent patients with ICD, reprogramming is more desirable* to avoid pacing inhibition when EMI are expected to be significant.

13.2.6 How to Recognize that a Patient Has a CIED and if Is PM Dependent

When data from medical history or files are not available, a CIED can be easily recognized by the presence of the wound in the infraclavicular region, more frequently on the left side. In less skinny patients, some devices, as some recent PMs, cannot be always detected because of the small dimensions and the position, sometimes several centimeters away from the original site under the wound.

All patients should always carry a device identification card, necessary to understand the type (PM, ICD, or CRT) and devices' manufacturer; these information are particularly important, as every device can be interrogated by the programmer from its manufacturer only. In emergency situations, chest radiograph is useful to distinguish a PM from an ICD, as the latter presents a shocking coil (section of the lead which are wider and more radiodense) along the right ventricular lead, close to the tip (Fig. 13.4). Sometimes another coil is present along the same lead, more proximally, in the superior vena cava. In addition, chest X-ray often allows the recognition of the model and even the device's serial number.

A patient with spontaneous activity is not, by definition, PM dependent. Even if the risk of bradyarrhythmias can be present, the occurrence of pauses contemporary to the inhibition of pacing during EMI is very unlikely. Therefore, PM reprogramming or magnet positioning is usually unnecessary in these patients, when the CIED is not an ICD.

When feasible, in paced patients, the PM dependence should be evaluated by the cardiologist during a preoperative PM evaluation, reprogramming the device at a low (usually 30 or 40/min) rate to detect spontaneous activity. This is particularly important in patients with CRT, where 100 % biventricular pacing is usually present, even in the absence of bradyarrhythmias. When interrogation cannot be performed before the operation, all patents with constant paced rhythm should be considered as PM dependent.

Routine PM check is usually performed every 6–12 months (3–6 for ICD). Therefore, most patients should have been evaluated in the past year; in addition, an increasing number of devices are regularly followed by "remote monitoring": using a base unit (similar to a modem), connected to the internet (via a standard phone line connection or a cell phone communication technology) and communicating wirelessly with the CIED, most information available during routing ambulatory evaluation are transmitted to designed servers and can be viewed by authorized personnel whenever desired. Data are automatically sent according to fixed intervals, in the presence of significant events (as arrhythmias or malfunctioning) or manually by the patient. Current systems, however, do not permit remote device reprogramming.

13.2.7 How to Minimize the Risk

The risk of EMI is greatest when the current field crosses the CIED or the leads or is closer than 15 cm from the CIED. During electrosurgical application, the return electrode should be placed on the ipsilateral heel or flank; however, for operations involving the ipsilateral arm of the CIED, the return electrode should be placed on the same arm to avoid the full exposure to the electrosurgical energy.

The umbilicus can be not a precise anatomical landmark especially in obese patients and many abdominal laparoscopic surgical procedures go through the umbilicus. Therefore, *iliac crest as the landmark below which no magnet or reprogramming need to be performed should be recommended. Utilization of the magnet, rather than turning off the ICDs, significantly reduces the time of exposure to the risk of untreated life-threatening arrhythmias* [10].

In addition, there is a potential risk of not re-enabling tachycardia therapies after the surgical intervention, leaving the patient unprotected in the case of ventricular arrhythmias, as demonstrated by a report on 67,410 remote follow-up patients in which the most common "red alert" was that detections and therapies for ventricular fibrillaton were "off".

Equipment for urgent cardioversion, defibrillation, and emergent pacing should be immediately available. It is important to remember, however, that artifacts can be also present at surface ECG, and arrhythmias can be difficult to detect by

electrocardiographic monitoring during electrosurgical application. Therefore, cardiac activity should be monitored with other modalities, like invasive or noninvasive continuous arterial pressure monitoring or pulse oxymeter.

Therefore, *application of short burst of electrocautery (<5 s), with some seconds of pause, is the best mode to minimize the risk* of both significant bradyarryhythmias in PM-dependent patients and inappropriate antitachycardia therapy in patients with an ICD.

13.3 What the Cardiologist Should Know

When an urgent or emergent surgical intervention is needed, a cardiologist may not be immediately available, and not all cardiologists are practical with CIED programming. However, whenever possible, the cardiologist or, better, an electrophysiologist should be involved in the management of the patient, especially in case of thorax, head, or upper limbs surgery.

Clearly, the cardiologist should be aware of the patient's cardiac problems, including the reason for CIED implantation, whether the patient is PM dependent, and the model, the manufacturer, and the programming of the CIED, as responses to EMI and to magnet application vary among different CIED and according to the programming. For example, in impedance-based rate responsive systems (as in minute-ventilate sensors), EMI may result in pacing at the sensor-triggered upper rate limit if rate response is activated.

In the presence of significant EMI, a "noise reversion" may occur, during which time the CIED paces asynchronously and tachyarrhythmia therapy is suspended. Noise reversion mode is an algorithm designed to minimize the effects of EMI, and, differently from reset, it is automatically disabled once the noise is no longer present. However, noise reversion algorithms are manufacturer specific and can be useful mainly in the presence of persistent EMI; they may not provide an adequate protection in presence of sporadic and/or transient EMI, as encountered in the operating room; therefore, transient inhibition of pacing or inappropriate pacing at the programmed upper rate is more likely in this context.

13.3.1 Magnet Responses

Magnet responses vary according to different manufacturers, and different models continuously change as manufacturers release new devices. In addition, pacing rate is different at beginning of life (BOL) and at elective replace indicator (ERI).

13.3.2 Pacemakers

In PM, the magnet generally causes asynchronous pacing by closing a magnetic switch.

At BOL, VOO or DOO pacing rate vary from 85/min (Medtronic) to 100/min (Boston Scientific and S. Jude. At ERI, it decreases to lower values (Medtronic 65/min, Sorin and Biotronik 80/min, S. Jude 85–86.3/min). Other different responses can be found when magnet response is programmable (Biotronik, Boston, S. Jude).

In some devices with atrial antitachycardia therapies (Medtronic AT500), antitachycardia pacing only is suspended, but there is no conversion to an asynchronous pacing mode.

Rate response is always suspended.

In some devices (Biotronik, Boston Scientific and Medtronic), pacing amplitude remains unchanged as programmed, while if autocapture algorithm is operating, the output is usually reset above the autocapture threshold value.

13.3.3 ICD

In all ICDs, antitachy-therapy is suspended while PM functions are usually unchanged; only in Sorin devices pacing rate changes (96/min at and 80/min at ERI), continuing in demand mode (therefore, not switching in asynchronous pacing).

In some models (Boston and S. Jude), it is possible to disable magnet response to ICD.

When placing the magnet on the device, tones can be audible in some models (R wave-synchronized beep in Boston devices, steady tone in Medronic devices). However, if the device continues to emit a tone after magnet removal, it should be interrogated because of a possible fault.

13.4 A Suggested Algorithm/Pathway for Diagnosis and Treatment

13.4.1 Preoperative/Preanesthesia Assessment

In urgent/emergent setting, a preoperative assessment, as required in elective procedures, may be difficult to achieve. However, information available in the patient's records should be sufficient to generate most perioperative prescriptions, as most patients are regularly followed by ambulatory or remote evaluations.

If such evaluation has not been performed in the appropriate time frame (12 months for PM, 6 months for ICD/CRT), a consultation with an available CIED team is desirable prior to the procedure, when feasible.

13.4.2 Before Surgery

See Table 13.2

13.4.3 During Surgery

See Table 13.3

Table 13.2 Before Surgery

	What to do	How to do
All patients	Identify CIED patient	Check medical records, physical examination
	Identify the device (PM, ICD, CRT), manufacturer, and model (always)	Check medical records, patient card, or chest X-ray
	Verify CIED indications (whenever possible)	Check medical records or patient card
	Verify PM dependency (whenever possible)	Preoperatory ECG; in absence of evident spontaneous activity at surface ECG, check medical records or assume PM dependency when preoperatory interrogation and programming is not feasible
Patients with pacemaker		
PM-dependent patients *and* procedures *above* the umbilicus or iliac crest, unipolar cautery necessary	Verify underlying rhythm and spontaneous heart rate (whenever possible)	Preoperatory interrogation and transient programming at the lower rate (if not recently performed during PM routine evaluation)
	Heart rate monitoring (always)	Monitor patient with plethysmography or arterial line rather than ECG only
	Verify response to magnet placement (always)	Verify heart rate during magnet placement
	Alternative stimulation mode available (whenever possible)	Transcutaneous pacing available
Patients with ICD		
All procedures	Heart rate monitoring (always)	Monitor patient with pulse oxymeter or arterial line rather than ECG only
Procedures *under* the umbilicus or iliac crest; bipolar cautery	No reprogramming required	
Procedures *above* the umbilicus or iliac crest, unipolar cautery necessary		
Magnet available and device accessible during the operation (non PM-dependent patients)	Disable antitachycardia therapies (always)	Position a magnet over the device
Magnet unavailable/device *not accessible* during the operation (but CIED personnel readily available)	Disable antitachycardia therapies (always)	Disable tachyarrhythmia therapies by programming and *ensure postoperative reprogramming*

(continued)

Table 13.2 (continued)

	What to do	How to do
PM-dependent patients (and CIED personnel readily available)	Ensure adequate heart rate	Preoperatory reprogramming in asynchronous mode (VOO or DOO) at appropriate rate and *ensure postoperative reprogramming*
PM-dependent patients; magnet unavailable/device *not accessible* during the operation; *no CIED personnel readily available*	Extreme attention to minimize EMI during electrocautery (always)	Electrosurgical return electrode placed on the ipsilateral heel or flank (or the same arm for operations involving the ipsilateral arm)

Table 13.3 During Surgery

	What to do	How to do
All procedures	Heart rate monitoring (always)	Monitor patient with pulse oxymeter or arterial line rather than ECG only
	Avoid magnetic fields (if possible)	Position sterile magnetic drapes >15 cm far from the CIED
Procedures *under* the umbilicus or iliac crest or bipolar cautery	No reprogramming required	
Procedures *above* the umbilicus or iliac crest, unipolar cautery necessary		
All patients, but particularly PM-dependent ICD patients (even with the magnet applied) ICD patients, no magnet applied PM-dependent PM patients, no magnet applied (*and* CIED personnel not readily available)	Minimize EMI during electrocautery (always)	Short electrosurgical bursts (<5 consecutive sec) with pauses >5 s
PM-dependent PM patients (magnet applied)	Verify response to magnet (always)	Verify heart rate during cauterization (with and without magnet placement)
ICD patients (therapies disabled by the magnet)	Ensure proper treatment in the case of intra-procedure ventricular arrhythmias (always)	Remove the magnet to enable tachycardia therapies
ICD patients (therapies disabled by reprogramming)		External DC shock

13.4.4 After Surgery

After surgery, CIED personnel should be contacted as soon as possible when:

- Reset of the CIED occurred during surgery.
- Reprogramming (asynchronous pacing in PM-dependent patients, disabling of antitachycardia therapy in ICD patients) before surgery was performed.
- Significant brady- or tachyarrhythmias occurred during the operation.

Preface

The third edition of this book has been updated to reflect changes in guidelines and practice since the last edition. The aim of the book remains the same: to help those certifying or recertifying prepare for the cardiovascular board examination. As in prior editions, we have included subjects, images, and tracings that are important not only for examinations but also relevant to clinical practice. The questions are presented in formats that are commonly used on the boards.

We would like to thank all of the contributors to this and prior editions, our colleagues and fellows from whom we learn on a daily basis, and especially our families who support and encourage our academic activity in addition to our busy clinical practices. We hope you enjoy the book and find it helpful.

IVC	inferior vena cava
JNC	Joint National Committee
JVP	jugular venous pulse
LA	left atrium(-al)
LAD	left anterior descending artery
LBBB	left bundle branch block
LCC	left coronary cusp
LCx	left circumflex artery
LDL	low-density lipoprotein
LDH	lactate dehydrogenase
LMWH	low-molecular-weight heparin
LV	left ventricle(-ular)
LVEF	left ventricular ejection fraction
LVH	left ventricular hypertrophy
LVOT	left ventricular outflow tract
MAT	multifocal atrial tachycardia
MET	metabolic equivalents
MI	myocardial infarction
MR	mitral regurgitation
MRA	magnetic resonance angiography
MRI	magnetic resonance image(-ing)
MS	mitral stenosis
MTHFR	methylenetetrahydrofolate reductase
MV	mitral valve
MVP	mitral valve prolapse
NCC	noncoronary cusp
NSAID	nonsteroidal anti-inflammatory drug
NSR	normal sinus rhythm
NTG	nitroglycerin
OR	odds ratio
P	pulse
PA	pulmonary artery
PAD	peripheral arterial disease
PCI	percutaneous coronary intervention
PCWP	pulmonary capillary wedge pressure
PDA	patent ductus arteriosus
PE	pulmonary embolus
PEA	pulseless electrical activity
PET	positron emission tomography
PFO	patent foramen ovale

PJRT	permanent junctional reciprocating tachycardia
PMI	point of maximum impulse
PO	oral(-ly)
PT	prothrombin time
PTCA	percutaneous transluminal coronary angioplasty
PVARP	post-ventricular atrial refractory period
PVC	premature ventricular contraction
QOL	quality of life
RA	right atrium(-al)
RAO	right anterior oblique
RAS	renal artery stenosis
RBBB	right bundle branch block
RCA	right coronary artery
RCC	right coronary cusp
RR	risk ratio
RT-PCR	reverse transcriptase-polymerase chain reaction
RUSB	right upper sternal border
RV	right ventricle(-ular)
RVH	right ventricular hypertrophy
RVSP	right ventricular systolic pressure
SAM	systolic anterior motion
SBE	subacute bacterial endocarditis
SC	subcutaneous(-ly)
SERCA2	sarcoplasmic-endoplasmic reticulum calcium ATPase type 2
SL	sublingual(-ly)
SSS	sick sinus syndrome
STEMI	ST-segment elevation myocardial infarction
SVR	systemic vascular resistance
SVT	supraventricular tachycardia
TAO	thromboangiitis obliterans
TdP	torsades de pointes
TEE	transesophageal echocardiography
TIA	transient ischemic attack
TID	transient ischemic dilation
TIMI	thrombolysis in myocardial infarction
tPA	tissue plasminogen activator
TR	tricuspid regurgitation
TTE	transthoracic echocardiogram
TVR	target vessel revascularization
UA	unstable angina
UA/	unstable angina and non–ST-segment elevation NSTEMI myocardial infarction
UFH	unfractionated heparin

VF	ventricular fibrillation
VSD	ventricular septal defect
VT	ventricular tachycardia
VTE	venous thromboembolism
VTI	velocity time integral

Arrhythmia

Bryan J. Baranowski

QUESTIONS

1. Which of the following antiarrhythmic medications would be the best choice for treatment of a patient with atrial fibrillation (AFib) and significant renal insufficiency?

   a. Propafenone
   b. Sotalol
   c. Dofetilide
   d. Flecainide

2. Which of the following antiarrhythmic medications has active metabolites?

   a. Amiodarone
   b. Sotalol
   c. Dofetilide
   d. Flecainide

3. A patient arrives at the emergency department with symptomatic narrow complex tachycardia. The patient is hemodynamically stable. The decision is made to administer intravenous (IV) adenosine. Under which of the following circumstances should the dosage of adenosine be reduced?

   a. The patient is taking theophylline.
   b. The patient is taking dipyridamole.
   c. The patient has significant valvular regurgitation.
   d. The patient has a significant left-to-right shunt.

4. Which of the following medications is contraindicated for use with dofetilide?

a. Digoxin
b. Diltiazem
c. Verapamil
d. Propranolol

5. Which of the following antiarrhythmic drugs may be more likely to have proarrhythmia at increased heart rates?

a. Sotalol
b. Flecainide
c. Quinidine
d. Dofetilide

6. Which of the following statements i s true regarding antiarrhythmic drugs with reverse-use dependence?

a. Antiarrhythmic drugs with reverse-use dependence have greater efficacy for arrhythmia prevention than termination and have less risk for ventricular proarrhythmia at slower heart rates.
b. Antiarrhythmic drugs with reverse-use dependence have less efficacy for arrhythmia prevention than termination and have greater risk for ventricular proarrhythmia at slower heart rates.
c. Antiarrhythmic drugs with reverse-use dependence have greater efficacy for arrhythmia prevention than termination and have greater risk for ventricular proarrhythmia at slower heart rates.
d. Antiarrhythmic drugs with reverse-use dependence have less efficacy for arrhythmia prevention than termination and have less risk for ventricular proarrhythmia at slower heart rates.

7. Which of the following is true regarding the Cardiac Arrhythmia Suppression Trials (CAST I and II)?

a. The treatment drugs increased mortality for patients without heart disease.
b. All class IC antiarrhythmic drugs were found to decrease mortality.
c. The treatment drugs effectively suppressed premature ventricular complexes (PVCs).
d. The antiarrhythmic drugs studied were flecainide, propafenone, and moricizine.

8. Which of the following antiarrhythmic drugs is the most potent sodium channel blocker?

a. Flecainide
b. Lidocaine

c. Disopyramide
d. Procainamide

9. Which of the following effects is expected when administering adenosine to a patient with recent cardiac transplantation (denervated heart)?

a. No effect
b. Diminished effect
c. Enhanced effect
d. Delayed effect

10. A patient presents with regular narrow QRS tachycardia. A 12-lead electrocardiogram (ECG) demonstrates an r' in lead V_1 that was not seen on ECG when the patient was in sinus rhythm. An esophageal electrode shows a 1:1 atrial-to-ventricular relationship during tachycardia. The ventriculoatrial (VA) interval is measured as 55 milliseconds. Which of the following is the most likely diagnosis?

a. Orthodromic atrioventricular reentrant tachycardia (AVRT)
b. Atrial tachycardia
c. AV nodal reentrant tachycardia (AVNRT)
d. Permanent junctional reciprocating tachycardia (PJRT)

11. A 17-year-old patient who is known to have Wolff-Parkinson-White syndrome presents with a regular narrow complex tachycardia with a cycle length of 375 milliseconds (160 bpm) that occurred with a sudden onset. You note that there is a 1:1 atrial-to-ventricular relationship and that the RP interval is 100 milliseconds. The best initial treatment is

a. IV procainamide.
b. atropine.
c. vagal maneuvers.
d. catheter ablation.

12. A 25-year-old patient presents with the sudden onset of tachycardia and is found to have a regular narrow QRS tachycardia with a cycle length of 340 milliseconds (176 bpm). An ECG appears to show P waves visible just after each QRS complex. You place an esophageal electrode and confirm a 1:1 atrial-to-ventricular relationship with a VA interval of 110 milliseconds. During the tachycardia, there is spontaneous development of left bundle branch block (LBBB), and a slower tachycardia with a VA interval of 150 milliseconds is now seen. What is the most likely diagnosis for the second tachycardia?

a. AVNRT

b. Orthodromic AVRT using a right-sided accessory pathway
c. Orthodromic AVRT using a left-sided accessory pathway
d. Ventricular tachycardia (VT) with 1:1 VA conduction

13. A 65-year-old man presents after an arrest while eating at a local restaurant. On arrival, paramedics documented ventricular fibrillation (VF), and he was successfully resuscitated. He has a history of myocardial infarction (MI) and congestive heart failure (CHF). Serum electrolytes are remarkable only for mild hypokalemia. MI is ruled out by ECG and serial blood tests of myocardial enzymes. Subsequent evaluation includes cardiac catheterization, which shows severe three-vessel coronary artery disease (CAD) and severe left ventricular (LV) systolic dysfunction. A nuclear myocardial perfusion scan shows a large area of myocardial scar without significant viability in the territory of the left anterior descending coronary artery. The decision is made to treat the CAD medically. Which of the following is the best management strategy for his arrhythmia?

a. PO amiodarone
b. Implantable cardioverter defibrillator (ICD) implantation if an electrophysiologic (EP) study shows inducible VT or VF
c. ICD implantation
d. β-Blocker medication

14. A 55-year-old woman has CAD and moderately severe LV systolic dysfunction (LV ejection fraction, 34%). Routine ambulatory Holter monitoring shows asymptomatic frequent ventricular ectopy with PVCs and occasional runs of nonsustained VT. Which of the following statements about the management of this patient is true?

a. Implantation of an ICD is indicated.
b. Implantation of an ICD is indicated if an EP study shows inducible VT.
c. Treatment with amiodarone is indicated, and if the arrhythmia recurs, then an EP study is indicated.
d. No treatment is indicated unless the arrhythmia becomes symptomatic.

15. A patient arrives at the emergency department after experiencing multiple shocks from his ICD. The shocks were not preceded by any symptoms. He is noted to be in sinus rhythm on presentation, and, while on the monitor, he receives several more shocks from the ICD without any arrhythmias noted. Which of the following is the most appropriate initial step in the management of this patient?

a. Immediately arrange for a programmer for interrogation and reprogramming of the ICD.
b. Arrange for urgent surgery in the EP laboratory.

c. Initiate antiarrhythmic drug therapy.
d. Place a "donut" magnet over the ICD site.

16. Which of the following is most important for successful resuscitation of an adult patient with out-of-hospital cardiac arrest?

a. IV epinephrine
b. Early direct current (DC) shock defibrillation
c. IV antiarrhythmic drugs
d. Early intubation

17. Which of the following rhythms documented at the time of resuscitation from cardiac arrest carries the poorest prognosis for long-term survival?

a. Asystole
b. Electromechanical dissociation (EMD) or pulseless electrical activity (PEA)
c. VF
d. VT

18. Which of the following rhythm disturbances is most commonly documented for an adult with out-of-hospital sudden cardiac death resuscitated within the first 4 minutes after arrest?

a. Asystole
b. EMD or PEA
c. Monomorphic VT
d. VF

19. Which of the following treatment options has been most consistently shown to be effective for the primary prevention of sudden cardiac death in patients with CAD and recent MI?

a. D-Sotalol
b. β-Blocker medications
c. Amiodarone
d. Dofetilide

20. Which of the following is the most common condition associated with sudden cardiac death in the United States?

a. Hypertrophic cardiomyopathy
b. CAD
c. Valvular heart disease

d. Dilated cardiomyopathy

21. A 55-year-old man is referred for recurrent syncope. The episodes consist of a prodrome of weakness and nausea followed by loss of consciousness. Physical examination is unremarkable. ECG and exercise treadmill stress test were normal. Which of the following is the most appropriate next step?

a. EP study
b. Signal-averaged ECG
c. Head-upright tilt-table testing
d. Ambulatory Holter monitoring

22. A 40-year-old woman presents to the emergency department with tachycardia. An ECG shows regular narrow complex tachycardia at 160 bpm. Atrial activity is difficult to discern in the tracing, but during tachycardia, there appears to be an "r'" in lead V_1 that is not present on an ECG during sinus rhythm recorded a few months earlier. Which of the following is the most likely diagnosis?

a. AVNRT
b. AVRT
c. Atrial tachycardia
d. Atrial flutter

23. An 80-year-old man with chronic AFib of 15 years' duration is admitted with recurrent episodes of dizziness and a recent episode of syncope. He has normal LV function and no evidence of CAD. In-hospital telemetry confirms the presence of slow ventricular rate and frequent pauses (4 seconds) that correlate with his lightheadedness. His medications consist of warfarin sodium (Coumadin). The most appropriate course of action includes which of the following?

a. Reassuring the patient and instructing him to come back if he has recurrence of syncope
b. Prolonged monitoring with a loop recorder
c. EP testing to evaluate for ventricular arrhythmia
d. Permanent pacemaker implant
e. ICD implant

24. A decision was made in the previous case to proceed with a permanent pacemaker. Which would be the most suitable pacing modality?

a. Dual-chamber system programmed to DDDR
b. Dual-chamber system programmed to DDDR with mode switching
c. Dual-chamber system programmed to DDIR

d. Single-chamber system in the ventricle programmed to VVIR
e. Single-chamber system in the atrium programmed to AAIR

25. Which one of the following is true about "pacemaker syndrome"?

a. Symptoms usually include fatigue, dizziness, and hypotension.
b. It occurs equally in atrial-based and ventricular-based pacing systems.
c. It does not occur in patients who have 1:1 VA conduction.
d. It can be treated with fludrocortisone.
e. It is treated by increasing the VVI baseline pacing rate.

26. Of the following patients, who is the most likely to carry the diagnosis of sick sinus syndrome (SSS)?

a. A 65-year-old woman with a resting sinus arrhythmia varying from 70 to 85 bpm
b. A 30-year-old with sinus pauses 1.5 seconds in duration
c. A 20-year-old athletic man with sinus bradycardia at 25 bpm while sleeping
d. A 73-year-old man with persistent AFib and a ventricular rate of 40 bpm during peak treadmill test
e. A 70-year-old with sinus bradycardia and AV block secondary to a β-blocker overdose

27. A 76-year-old patient with dilated cardiomyopathy and LBBB on baseline ECG is undergoing evaluation for syncope. Placement of a catheter near his bundle during EP testing is most likely to

a. induce AFib.
b. induce VT.
c. perforate the atrium.
d. perforate the ventricle.
e. induce complete heart block (CHB).

28. A 25-year-old patient with a history of depression is brought to the emergency room after ingesting some of her mother's prescription medications, including diltiazem and metoprolol. Her pulse rate is 25 bpm, and her BP is 90/50 mmHg. Her ECG shows sinus bradycardia and high-grade AV block. In preparation for temporary pacemaker placement, which of the following is most likely to be effective?

a. IV calcium gluconate
b. Isoproterenol infusion
c. IV atropine
d. IV magnesium sulfate
e. IV glucagon

29. A young patient is admitted to the intensive care unit with amitriptyline overdose. Three hours after gastric lavage, he develops hypotension and wide complex tachycardia that is recurrent despite cardioversion. Appropriate management includes which of the following?

a. IV bretylium
b. Temporary pacemaker with overdrive pacing
c. IV calcium gluconate
d. IV hypertonic sodium bicarbonate
e. IV magnesium sulfate

30. An 80-year-old undergoes dual-chamber pacemaker placement for CHB. Excellent ventricular and atrial capture thresholds were obtained at the time of the implant. The pacemaker programmed parameters are as follows: mode, DDD; lower rate, 70 bpm; upper rate, 130 bpm; atrial sensitivity, 0.25 mV (most sensitive setting); ventricular sensitivity, 1.00 mV; AV delay, 175 milliseconds; pace/sense configuration, bipolar. The next day, the following rhythm strip was recorded (Fig. 1.1): This rhythm strip shows

a. normal pacemaker function for the programmed parameters.
b. atrial noncapture.
c. ventricular noncapture.
d. atrial undersensing.
e. ventricular undersensing.

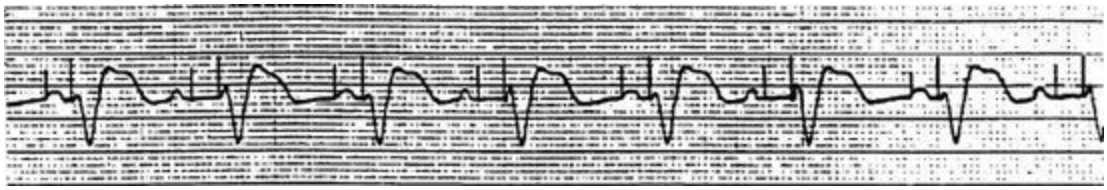

Figure 1.1

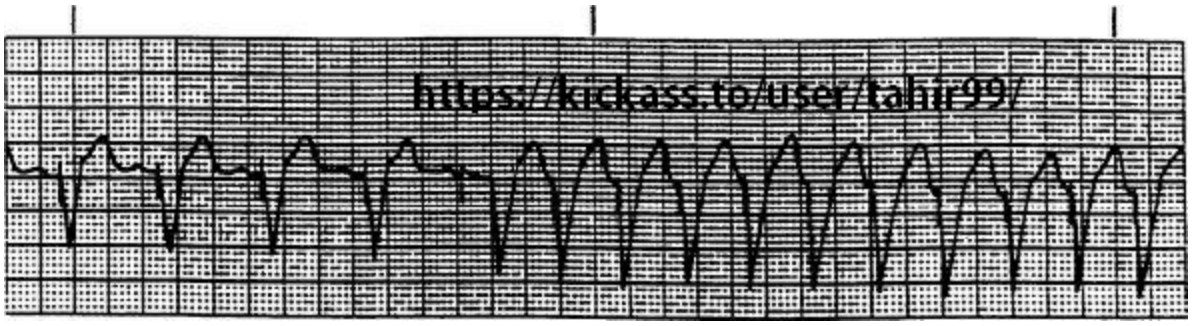
31. A 50-year-old man with chronic obstructive pulmonary disease related to chronic smoking presents to the emergency room with palpitations. ECG shows narrow QRS tachycardia at 165 bpm. His BP is 125/60 mmHg. Expiratory wheezes are heard on lung examination. His medications include albuterol inhaler and theophylline. The most appropriate initial treatment includes which of the following?

a. Adenosine IV bolus
b. Digoxin loading over 6 hours
c. Verapamil IV bolus

d. Propafenone IV bolus
e. Immediate cardioversion

32. A 55-year-old woman returns to the clinic after a recent dual-chamber pacemaker placement. She reports frequent palpitations and fatigue. These episodes last for several minutes before stopping. A Holter monitor recorded the following rhythm (Fig. 1.2): The pacemaker is programmed to mode DDD; lower rate, 80 bpm; upper rate, 150 bpm; AV delay, 200 milliseconds; postventricular atrial RP, 150 milliseconds. The latter part of this rhythm strip shows

a. VT induced by the pacemaker.
b. initiation of atrial tachycardia with atrial tracking.
c. pacemaker-mediated tachycardia.
d. pacemaker function failure with inappropriate rapid ventricular pacing.
e. artifact.



https://kickass.to/user/tahir99/

Figure 1.2

33. An 82-year-old man receives a dual-chamber pacemaker for SSS. Routine transtelephonic check (without and with magnet) shows the following strips (Fig. 1.3). Which of the following is true?

a. The pacing mode is VVI secondary to automatic mode switch.
b. There is consistent atrial capture on the magnet strip.
c. There is consistent ventricular capture.
d. Ventricular sensing cannot be determined by the available strips.
e. Atrial sensing cannot be determined by the available strips.

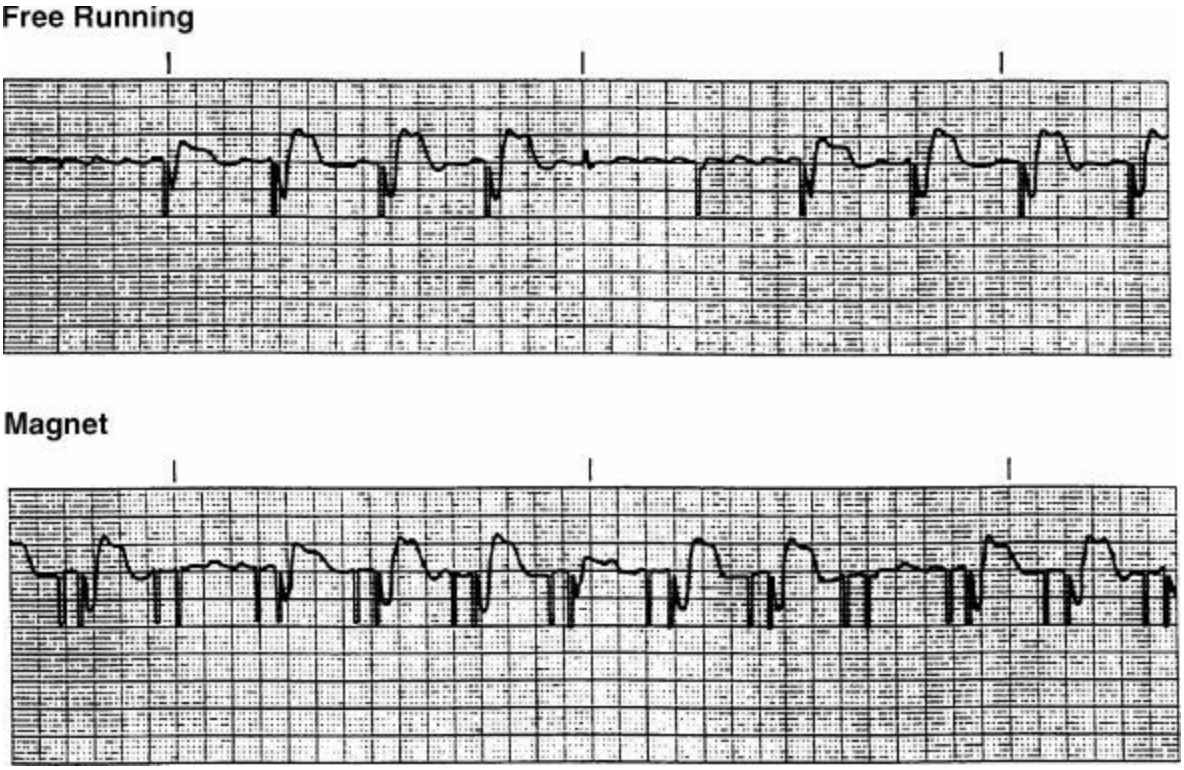


Figure 1.3

Questions 34–37

The following tracings (Figs. 1.4, 1.5, 1.6, and 1.7) are obtained during EP evaluation of AV conduction in different patients. HRA (high right atrium) and HBE (His bundle electrogram) are the intracardiac electrograms, recording from the high right atrium and the His bundle regions, respectively. Which of the following is true for these tracings?

Figure 1.4

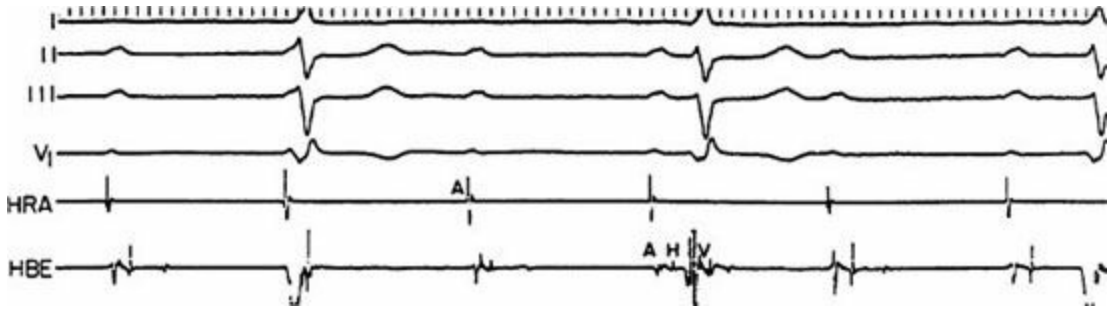

Figure 1.5

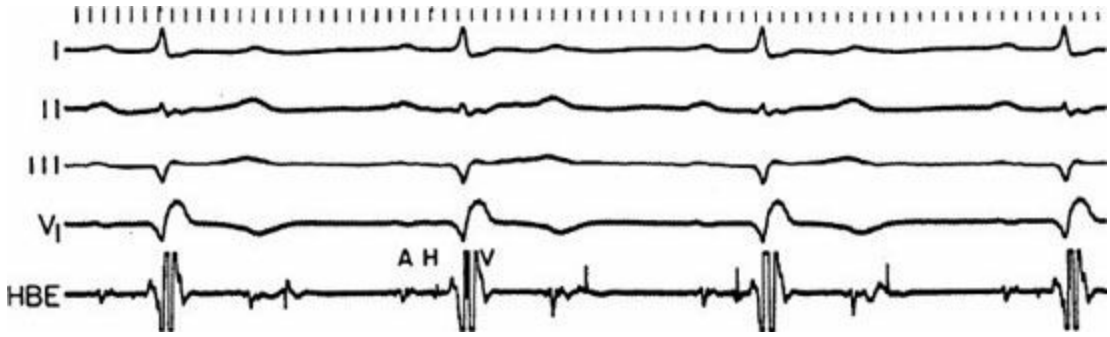

Figure 1.6

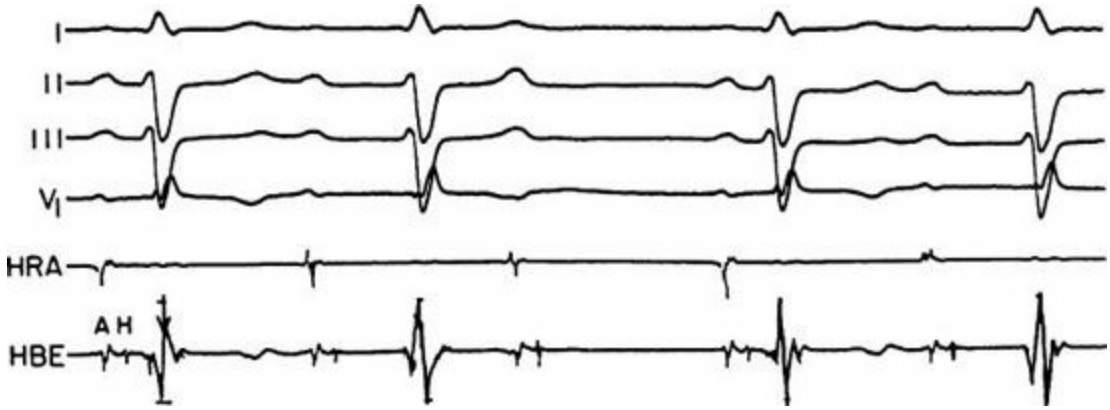

Figure 1.7

a. CHB at the level of the AV node
b. CHB at the infra-Hisian (below the His bundle) level
c. Second-degree AV block at the AV node level
d. Second-degree AV block at an infra-Hisian level
e. First-degree AV block

38. A 38-year-old woman with congenital CHB undergoes a dual-chamber permanent pacemaker. A 12-lead ECG obtained after the procedure shows normal sinus rhythm (NSR) with atrial tracking (a sense–V pace behavior). The ventricular-paced complex has a right bundle branch block (RBBB) morphology. Further

evaluation should include

a. obtaining a portable anteroposterior chest X-ray (CXR) to evaluate lead position.
b. obtaining a two-view (anteroposterior and lateral) CXR to evaluate lead position.
c. repeating the 12-lead ECG.
d. requesting a pacemaker interrogation.
e. reassuring the patient without ordering further tests.

39. Which of the following is true regarding EP testing of the conduction system?

a. It is indicated in patients with symptomatic third-degree heart block to identify the level of block.
b. An abnormal sinus node recovery time is an indication for pacemaker placement.
c. A normal sinus node recovery time rules out the diagnosis of SSS.
d. Patients with evidence of infra-Hisian block during EP testing should be considered for permanent pacing.
e. Ambulatory ECG is less reliable than EP testing in evaluating SSS.

40. Which of the following statements is true regarding Brugada syndrome?

a. It is characterized by ST elevation and a pseudo-RBBB pattern in the right precordial leads with persistent ST elevation.
b. The ECG manifestations can be exacerbated by sotalol.
c. It is the leading cause of death in young men in the Middle East.
d. AFib is the most frequently reported arrhythmia.
e. It is effectively treated with β-blockers.

41. In patients with long-QT syndrome

a. EP testing is indicated to evaluate for inducible ventricular arrhythmias.
b. the mechanism of torsades de pointes (TdP) is believed to be related to early afterdepolarization.
c. sotalol is effective for the treatment of the associated ventricular tachyarrhythmias.
d. hyperkalemia increases the risk of TdP.
e. cardiac arrest typically occurs at rest in LQT1 syndrome.

42. A 75-year-old man is admitted with upper gastrointestinal (GI) bleeding. His ECG shows sinus rhythm at 90 bpm, with a PR of 220 milliseconds, RBBB, and left anterior fascicular block. He had one episode of near syncope 2 days before this admission. His current hematocrit is 20. You are consulted regarding the need for a

pacemaker. Which of the following is true?

a. You should proceed with permanent pacemaker placement in the setting of bifascicular block.
b. You should proceed with ICD placement.
c. You should perform EP testing to evaluate the AV conduction system.
d. You should reassure the patient and suggest no further testing.
e. You should prescribe β-blockers to slow down the sinus rate.

43. Which of the following criteria is most helpful in differentiating supraventricular tachycardia (SVT) from VT in a patient presenting with wide complex tachycardia?

a. The patient is older than 65 years.
b. The tachycardia rate is >160 bpm.
c. The patient is awake with a BP of 110/65 mmHg.
d. There is an RS pattern in V_2.
e. There is AV dissociation.

44. A 76-year-old man walks into the emergency room reporting palpitations and dizziness. A 12-lead ECG shows wide complex tachycardia at a rate of 160 bpm. His BP is 110/50 mmHg. He reports that he recently sustained an MI. He has not had any similar symptoms before. Which of the following should be included in further evaluation and treatment of his arrhythmia?

a. Verapamil, 10-mg IV bolus, to treat SVT with aberrancy, as the patient is hemodynamically stable
b. Immediate DC cardioversion
c. Procainamide, 15 mg/kg IV over 30 to 60 minutes
d. Immediate cardiac catheterization and angioplasty, as needed
e. Digoxin, 1 mg IV over 6 hours in four divided doses

45. A 55-year-old man had a pacemaker initially implanted 8 years ago over the left prepectoral area. Two months earlier, his old pacemaker reached end-of-life, and he underwent replacement of the pacemaker using the existing leads. He is presenting now with dull pain, swelling, and mild erythema over the pacemaker pocket site that started 1 week earlier, together with low-grade fever. He reports some purulent drainage from the incision site. Blood cultures were drawn. The best course of action is

a. to prescribe PO antibiotics for 2 weeks.
b. to admit the patient for IV antibiotics and pacemaker-system extraction.
c. to prescribe long-term suppressive PO antibiotics, as the pacemaker and leads system are too old to be extracted.

d. to remove the recently implanted pulse generator on the left, leaving the old leads in place, and implant a new pacemaker system on the right prepectoral area.
e. to incise and drain the pacemaker pocket and allow it to heal with secondary intention with daily change of dressing.

46. Which of the following is a correct statement concerning external cardioversion of AFib?

a. Acute MI is a contraindication to cardioversion, as it results in further myocardial damage.
b. A nonsynchronized shock should be delivered because the rhythm is irregular.
c. Inadequate synchronization may occur with peaked T waves, low-amplitude signal, and malfunctioning pacemakers.
d. Digoxin therapy should be discontinued for 48 hours before elective cardioversion.
e. Patients with pacemakers should not undergo cardioversion because of the risk of pacemaker damage.

47. In patients with Wolff-Parkinson-White syndrome, with which of the following is acute pharmacologic treatment of AFib best achieved?

a. Diltiazem
b. Lidocaine
c. Verapamil
d. Procainamide
e. Adenosine

48. A 75-year-old patient with a history of ischemic cardiomyopathy develops worsening heart failure symptoms during episodes of AFib despite a controlled ventricular rate. Which of the following is included in a reasonable trial of pharmacologic therapy?

a. Flecainide
b. Sotalol
c. Verapamil
d. Disopyramide
e. Amiodarone

49. Which of the following is true regarding the use of digoxin in AFib?

a. It is superior to placebo for the acute conversion of AFib.
b. It controls ventricular rate during exercise in most patients.

c. It can control ventricular rate at rest in many patients.
d. It effectively maintains sinus rhythm after cardioversion.
e. Because of its hepatic clearance, it is safe to use in patients with renal insufficiency.

50. Which of the following statements regarding flecainide as a treatment of AFib is true?

a. It may contribute to an increase in the digoxin level.
b. It may be used without an AV nodal blocking agent because of its potent effect on the AV conduction system.
c. It has been shown to be effective and safe for use in patients with hypertrophic cardiomyopathy.
d. It has no effect on the acute conversion of AFib but only on maintenance of sinus rhythm postcardioversion.
e. It is used for the treatment of AFib but not atrial flutter.

51. Which of the following mechanisms is responsible for AFib occurring in the immediate postoperative period after a maze procedure?

a. Change in the atrial refractory period as a result of the surgical manipulation
b. Autonomic imbalance as a result of the surgical intervention
c. Misplacement of a suture line
d. An incomplete or omitted suture line
e. Inhibition of atrial natriuretic peptide secretion as a result of the surgical manipulation

52. The following tachycardia was induced during EP testing of a 36-year-old woman with recurrent palpitations (Fig. 1.8). Which of the following is the most likely diagnosis?

a. AVNRT
b. Orthodromic reentrant tachycardia
c. Antidromic reentrant tachycardia
d. VT
e. Idiopathic left VT

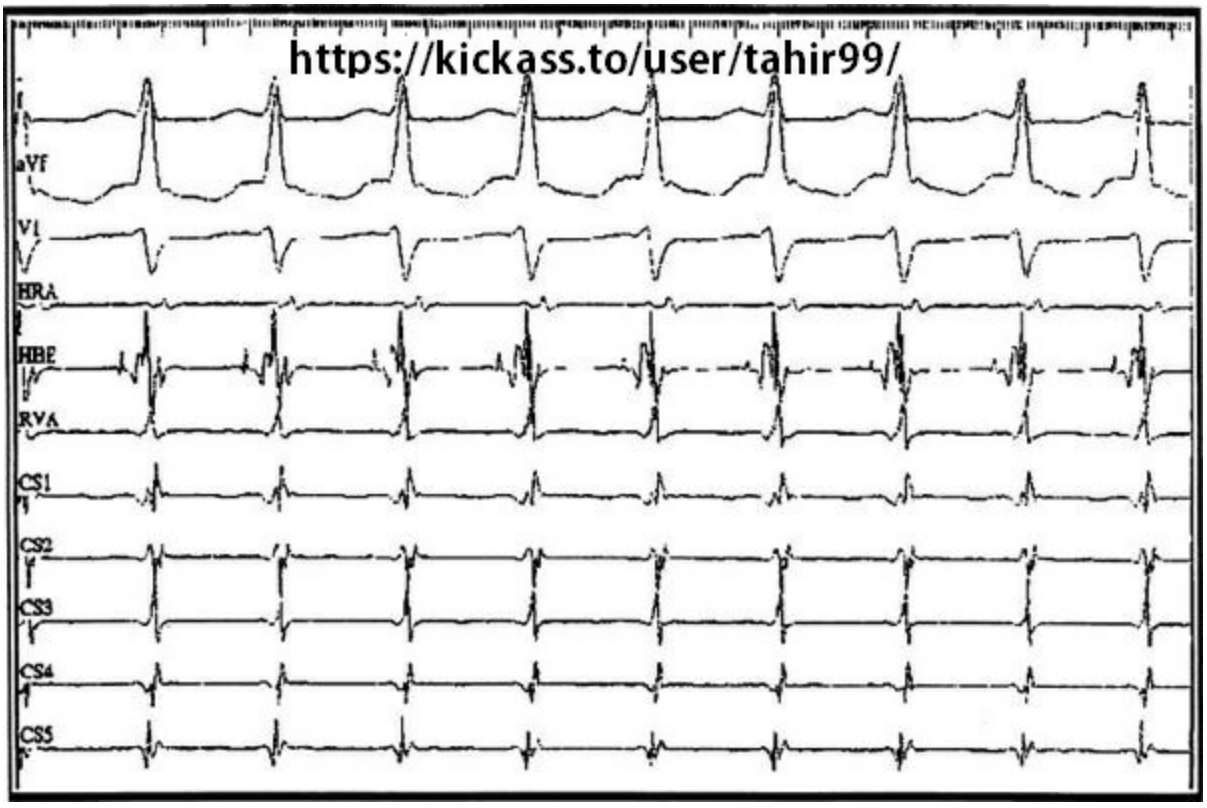

Figure 1.8

ANSWERS

1. **a.** Propafenone. Sotalol and dofetilide are primarily excreted by the renal route and should be used cautiously, if at all, in patients with significant renal insufficiency. Flecainide primarily undergoes hepatic elimination (approximately 70%) but has 25% renal elimination. The route of elimination for propafenone is 99% hepatic.

2. **a.** Amiodarone. Sotalol, dofetilide, and flecainide do not have significant active metabolites. Amiodarone is metabolized to the active metabolite desethylamiodarone.

3. **b.** The patient is taking dipyridamole. Dipyridamole potentiates the effect of adenosine by interfering with metabolism; therefore, a reduced dose of adenosine is recommended. Although not a part of this question, it is important to remember that adenosine also needs to be used with extreme caution in heart transplant patients as a markedly exaggerated response to adenosine can be seen in the denervated heart. An increased dose of adenosine is recommended in the presence of methylxanthines such as theophylline, which antagonizes the effect of adenosine (blocks receptors), and other factors such as slow circulation time, valvular regurgitation, and left-to-right shunts that reduce the effectiveness of adenosine.

4. **c.** Verapamil. Verapamil may increase serum levels of dofetilide because of interference with renal excretion and hepatic metabolism.

5. **b.** Flecainide. Flecainide is a class IC antiarrhythmic drug, and these agents exhibit "use dependence." This refers to the property of increased drug effect at increased heart rates. Sotalol and dofetilide are class III antiarrhythmic drugs that exhibit "reverse-use dependence"—that is, greater drug effect at slower heart rates. Quinidine has effects on both sodium and potassium channels. While the effects on the sodium channels are use dependent, it is far less pronounced compared with the Ic agents such as flecainide. The potassium-blocking properties and resulting QT prolongation are more pronounced at slower heart rates— reverse-use dependent.

6. **c.** Antiarrhythmic drugs with reverse-use dependence have greater efficacy for arrhythmia prevention than termination and have greater risk for ventricular proarrhythmia after AFib termination (at slower sinus rates) than during AFib. Antiarrhythmic drugs with use dependence, such as sotalol and dofetilide, have greater antiarrhythmic effect at slower heart rates. Consequently, drug efficacy is enhanced at the relatively slower rates in sinus rhythm, making these drugs more effective for prevention of AFib than those drugs with use dependence. Likewise, for proarrhythmia, the antiarrhythmic drugs with reverse-use dependence are more likely to produce ventricular proarrhythmia after conversion to sinus rhythm at the relatively slower sinus rate or with a postconversion pause.

7. **c.** The treatment drugs effectively suppressed premature ventricular complexes (PVCs). CAST studied the concept that PVC suppression in the postinfarction period would reduce the incidence of sudden cardiac death. Patients without heart disease were, therefore, excluded from these studies. CAST I studied flecainide, encainide, and moricizine versus placebo. Demonstration of effective suppression of PVCs by one of the drugs was necessary before a patient could be randomized to drug or placebo treatment. Propafenone, another class IC antiarrhythmic drug, was not studied. CAST I was prematurely terminated by the safety committee after only a 10-month average follow-up because of significantly increased incidence of arrhythmic death and nonfatal cardiac arrests in the flecainide and encainide treatment groups. CAST II was a continuation of the study with only moricizine versus placebo, but this study was also terminated early because of an increased incidence of cardiac arrest in the moricizine treatment group.

8. **a.** Flecainide. All of these drugs are class I antiarrhythmic medications and have sodium channel–blocking properties to various degrees. Class IC agents, such as flecainide, have the most potent sodium channel–blocking effects, and class IB

agents, such as lidocaine, have the least potent sodium channel–blocking effects.

9. **C.** Enhanced effect. Patients with denervated hearts are supersensitive to the effects of adenosine.

10. **C.** AV nodal reentrant tachycardia (AVNRT). Atrial tachycardia and PJRT are long RP tachycardias and, therefore, would not have such a short VA interval. PJRT is a special type of orthodromic AVRT that involves a posteroseptal accessory pathway with decremental (AV nodal-like) conduction properties and, hence, has a long RP (long VA) interval. Because of the time required to reach the accessory pathway for the retrograde portion of the arrhythmia circuit, orthodromic AVRT generally has a VA interval longer than 70 milliseconds. Therefore, a VA interval shorter than 70 milliseconds excludes orthodromic AVRT and makes AVNRT the most likely diagnosis. A small r' wave (pseudo r' wave) can sometimes be seen at the terminal portion of the QRS (usually best in lead V_1). This deflection represents retrograde activation of the atrial (a retrograde P wave) occurring shortly after the QRS complex.

11. **C.** Vagal maneuvers. A sudden onset of a regular narrow complex tachycardia with a cycle length of 375 milliseconds and an RP interval of 100 milliseconds is a short RP tachycardia (the PR interval would be 375 milliseconds – 100 milliseconds = 275 milliseconds, so the RP is shorter than the PR). This patient most likely presents with orthodromic AVRT, a reciprocating tachycardia circuit that involves antegrade conduction through the AV node and retrograde conduction through the accessory pathway (however, AVNRT is also possible). As the AV node is a necessary component of the arrhythmia circuit, AV nodal blockade effectively terminates this type of tachycardia. Vagal maneuvers, such as Valsalva, coughing, or carotid sinus massage, may be quite effective and avoid the potential risks associated with administration of medications. Verapamil and other drugs that block AV conduction, such as β-blockers and adenosine, may be quite useful for termination of AVRT. This should not be confused with the management of AFib in the setting of Wolff-Parkinson-White syndrome, in which administration of AV nodal blocking drugs, such as verapamil, is contraindicated due to a concern for uninhibited and thus rapid AV conduction of the AP, which if rapid enough can induce ventricular fibrillation. When AV conduction is occurring through both the AV node and AP, retrograde, concealed conduction into the AP can limit its antegrade conduction properties. If preexcited, AFib with IV procainamide or DC cardioversion is the correct management. A precautionary note regarding the use of adenosine for regular narrow QRS tachycardia in patients with Wolff-Parkinson-White syndrome: Adenosine may precipitate AFib and result in a very rapid

ventricular response (preexcited tachycardia). Atropine has no role in the treatment of these types of arrhythmia. Catheter ablation is not generally an acute treatment option for this arrhythmia, although this approach may be an excellent option for chronic treatment (cure).

12. **c.** Orthodromic AVRT using a left-sided accessory pathway. A regular narrow QRS tachycardia that has VA interval prolongation with the development of bundle branch block is most consistent with an orthodromic AVRT using an accessory pathway ipsilateral to the bundle branch. During AVRT, the antegrade limb of the circuit is the AV node and His-Purkinje/bundle branch system, and the retrograde limb is the accessory pathway. Block in a bundle branch ipsilateral to an accessory pathway creates a larger circuit, as the antegrade limb must now use the contralateral bundle branch, and therefore, the VA interval increases. This results in an increase in the tachycardia cycle length (a slower tachycardia). Of note, a slower tachycardia with bundle branch block itself does not necessarily have the same significance. Other types of tachycardia may slow because of a change in conduction of other components of the tachycardia circuit, such as the conduction through the AV node (A–H interval). Thus, it is important to demonstrate VA interval prolongation during bundle branch block to implicate an ipsilateral accessory pathway participating in AVRT.

13. **c.** ICD implantation. Cardiac arrest with VT or VF in the absence of reversible causes (e.g., MI, severe electrolyte or metabolic disorders) is a class I indication for ICD implantation. ICD implantation for such patients is superior to amiodarone drug therapy, as demonstrated in the Antiarrhythmics Versus Implantable Defibrillator (AVID) trial. The Canadian Implantable Defibrillator Study examined a similar population of patients and, although not statistically significant, showed a strong trend for the superiority of ICDs. Demonstration of inducible VT or VF in these types of patients is not necessary.

14. **b.** Implantation of an ICD is indicated if an EP study shows inducible VT. The Multicenter Automatic Defibrillator Implantation Trial (MADIT) evaluated patients with CAD, ischemic cardiomyopathy with an LV ejection fraction of <35%, and nonsustained VT. This study showed that for patients with inducible VT at baseline EP study and after administration of IV procainamide, treatment with an ICD was superior to treatment with antiarrhythmic drugs. A follow-up study, MADIT II, assessed the role of ICD implantation in patients with an ischemic cardiomyopathy and an ejection fraction ≤30%. Nonsustained VT was not required to undergo ICD implant, nor was an EP study. The study was terminated early after an average follow-up of 20 months because the ICD significantly reduced all-cause mortality

(14.2% versus 19.8% for conventional therapy). This study helped expand ICD implant indications. This is a class I indication for ICD implantation.

15. **d.** Place a "donut" magnet over the ICD site. The patient is having inappropriate or spurious shocks from the ICD, most likely caused by detection of electrical noise from a malfunction of the ICD lead. It is imperative that further shocks be prevented immediately, not only for patient comfort but also to prevent induction of life-threatening ventricular arrhythmias (including ventricular arrhythmia storm) caused by the ICD shocks. The most effective action at this point is placement of a magnet over the ICD site. This prevents the ICD from delivering any therapies. It would not be optimal to delay the prevention of further shocks while waiting for an ICD programmer. Of note, unlike pacemakers, ICDs do not have an asynchronous pacing response to application of a magnet.

16. **b.** Early direct current (DC) shock defibrillation. The two most crucial factors that determine the value of out-of-hospital resuscitation for patients who experience sudden cardiac death are citizen-bystander cardiopulmonary resuscitation and early DC shock defibrillation.

17. **a.** Asystole. EMD or PEA and, in particular, asystole tend to be found in increasing proportions as the time since arrest increases. This is likely caused by degeneration of prolonged VF. When VF is the documented rhythm at the time of resuscitation, the long-term survival is approximately 25%. When EMD or PEA is the documented rhythm, the long-term survival rate drops to approximately 6%, and it drops even further, to approximately 1%, when asystole is documented.

18. **d.** VF. The initial rhythm documented in a patient who undergoes sudden cardiac death is dependent on the time elapsed since the arrest. Most episodes of sudden cardiac death (approximately 65% to 85%) that are documented electrocardiographically are caused by malignant ventricular arrhythmias such as VF. Monomorphic VT is uncommonly documented as a cause of out-of-hospital sudden cardiac death, perhaps caused by degeneration of unstable VT to VF. Asystole and EMD or PEA are found in greater proportions as the time since arrest increases, as these rhythms are likely the result of prolonged VF.

19. **b.** β-Blocker medications. Several randomized trials of the use of β-blocker medications for patients after MI have shown efficacy for the prevention of sudden cardiac death (including propranolol, timolol, metoprolol, and acebutolol). Trials of amiodarone in this setting have provided mixed results. Two large randomized trials, the European Myocardial Infarct Amiodarone Trial (EMIAT) and the

Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT), examined the use of amiodarone in patients after MI and did not show a reduction in overall mortality with the use of amiodarone. The Polish Amiodarone Trial showed that amiodarone improved survival only in patients with preserved LV function after MI. The Survival with Oral D-sotalol (SWORD) trial studied the use of the D-isomer of sotalol (D-sotalol) in patients with recent MI and LV dysfunction. This study found worse survival in the group treated with D-sotalol than in the group treated with placebo. The Danish Investigations of Arrhythmias and Mortality on Dofetilide (DIAMOND) studies showed that dofetilide had a neutral effect on total mortality compared with placebo in the treatment of post-MI patients with LV dysfunction.

20. **b.** CAD. CAD is the predominant disease process associated with sudden cardiac death in the United States, accounting for 64% to 90% of cases. The other cardiomyopathies, such as dilated and hypertrophic cardiomyopathies, together account for approximately 10% to 15% of cases of sudden cardiac death.

21. **c.** Head-upright tilt-table testing. Syncope in the absence of structural heart disease is most likely neurally mediated (vasovagal). The head-upright tilt-table test is the most appropriate test to evaluate for this condition. This test initiates the vasovagal episode by maximizing venous pooling, sympathetic activation, and circulating catecholamines. In general, the test involves at least 30 minutes of 70-degree head-up tilt angle without a saddle support. An addition of a catecholamine challenge with isoproterenol is sometimes used. Among symptomatic patients, the sensitivity of the head-upright tilt-table test is approximately 85%. The specificity of the head-upright tilt-table test is good, with the frequency of an abnormal tilt-table test in control subjects being 0% to 15%. In the absence of structural heart disease, EP study, ambulatory Holter monitoring, and the signal-averaged ECG are low yield.

22. **a.** AVNRT. An "r'" in lead V_1 during regular narrow complex tachycardia that is not present during sinus rhythm indicates the inscription of the P wave in the terminal QRS, is consistent with a very short VA interval, and is very specific for AVNRT.

23. **d.** Permanent pacemaker implant. This patient has evidence of symptomatic bradycardia on Holter monitoring, which constitutes a class I indication for permanent pacemaker placement. He has AV conduction system disease with no obvious reversible causes, which is most probably caused by idiopathic fibrosis (Lev disease). Prolonged monitoring will probably show more episodes of bradycardia, which was already seen during telemetry, and which places this elderly patient at risk for syncope and injury. EP testing for ventricular arrhythmia

is not indicated in view of the absence of structural heart disease. Likewise, ICD is not indicated.

24. **d.** Single-chamber system in the ventricle programmed to VVIR. This patient is in chronic AFib, and, therefore, physiologic pacing in the atrium cannot be achieved. Furthermore, conversion and long-term maintenance of sinus rhythm in this situation are very unlikely. Therefore, there is no indication for placement of an atrial lead. DDDR with mode switching and DDIR will behave like a VVIR system in this patient, at the expense, however, of an additional lead (atrial) and a more expensive dual-chamber pacemaker.

25. **a.** Symptoms usually include fatigue, dizziness, and hypotension. Pacemaker syndrome is caused by pacing the ventricle asynchronously, which results in AV dissociation or VA conduction. Symptoms consist of fatigue, dizziness, dyspnea, and weakness, with or without hypotension. The mechanism is believed to be related in part to atrial contraction against a closed AV valve and release of atrial natriuretic peptide. It occurs with ventricular pacing and therefore is worsened by increasing pacing rate and relieved by allowing intrinsic conduction (if present) by lowering the pacing rate, programming rate hysteresis, or upgrading to a dual-chamber system. Therapy with fludrocortisone and other volume-expansion modalities is not helpful.

26. **d.** A 73-year-old man with persistent AFib and a ventricular rate of 40 bpm during peak treadmill test. The 73-year-old man with AFib and slow ventricular rate during exercise is the classic example of SSS. This usually indicates degenerative disease of the cardiac conduction system involving the AV node as well as the sinus node. Function of the sinus node can only be assessed after AFib has been terminated, usually by DC cardioversion. In this patient's case, it would not be uncommon to manifest a long postconversion pause, followed by either marked sinus bradycardia or complete sinus node arrest with a resulting junctional or ventricular escape rhythm (hopefully) following cardioversion. The finding of sinus arrhythmia varying by 15 bpm in an older patient, the profound nocturnal bradycardia in young athletes, and the sinus pauses in young patients are related mostly to a high vagal tone and do not indicate sinus node disease.

27. **e.** Induce complete heart block (CHB). Patients with true complete LBBB are at risk for developing transient CHB during catheter manipulation in the septal region of the tricuspid valve. This is caused by transient traumatic block of the right bundle branch. A similar scenario can result when placing a Swan-Ganz catheter in patients with LBBB.

28. **e.** IV glucagon. This patient has an overdose of diltiazem and metoprolol. These drugs slow sinoatrial and AV conduction. Calcium and magnesium have no effect in reversing these bradycardic effects. Isuprel and atropine are not likely to overcome the β-blockade of metoprolol. IV glucagon acts on a specific receptor. This results in an increase in intracellular cyclic adenosine monophosphate, which enhances both sinoatrial and AV node conduction despite the presence of β-blockade.

29. **d.** IV hypertonic sodium bicarbonate. Amitriptyline has sodium channel–blocking properties and induced QRS widening and VT. Increasing the extracellular sodium concentration by the administration of sodium bicarbonate decreases the association of this drug with the sodium channel.

30. **d.** Atrial undersensing. This rhythm shows evidence of atrial undersensing. The pacemaker is programmed to DDD. In this mode, an appropriately sensed P wave should cause inhibition of the atrial spike; a ventricular spike is then delivered after the programmed AV interval or inhibited by an intrinsic R wave. In this strip, the P wave is present in each complex. However, in complexes 2, 4, 6, and 8, an atrial spike follows the intrinsic P wave because the intrinsic P wave was not appropriately sensed by the pacemaker. The noncapture of the atrium following the atrial spike on complexes 2, 4, 6, and 8 is anticipated as the atrium would still have been refractory from the preceding P wave. Capture of the atrium on complexes 1, 3, 5, and 7 is suggested by the P wave that is different in morphology (wider) than the intrinsic P wave. Atrial undersensing occurring early after implantation may be the result of lead dislodgment. A CXR should be obtained to assess lead position. Other possibilities include inappropriate programmed sensitivity, which can be assessed on a device check. Finally, inflammation at the lead tip–endocardium interface can result in a decrease in sensing amplitude. This may improve over several weeks as the lead matures and inflammation resolves.

31. **c.** Verapamil IV bolus. Adenosine is commonly used to terminate SVT. However, this patient is on theophylline, which is an effective blocker of the adenosine receptor. Propafenone might be poorly tolerated by this patient because of its associated β-blocking activity, which might increase airway resistance. Digoxin shortens the refractory period of the atrium and might potentially accelerate an atrial tachycardia. Immediate cardioversion is not needed, as the patient appears hemodynamically stable, and it would be reasonable to attempt pharmacologic therapy initially with verapamil.

32. **c.** Pacemaker-mediated tachycardia. In this strip, there is evidence of atrial undersensing (fifth complex). As a result, the fifth ventricular-paced beat comes

"late" relative to atrial activation. This allows enough time to go by for the AV node to recover its conduction properties. This allows retrograde P-wave conduction following ventricular pacing, which is sensed by the pacer (because of short programmed postventricular atrial refractory period [PVARP]), and results in ventricular triggered pacing, causing a pacemaker-mediated tachycardia or endless-loop tachycardia. Acute treatment of this condition includes the application of a magnet to inhibit atrial sensing, thereby breaking the tachycardia loop. The spontaneous termination of these episodes in this patient is most probably related to intermittent atrial undersensing, which interrupts the tachycardia loop. Further prevention of these episodes includes reprogramming the PVARP, AV delay, or atrial sensitivity. Pacemaker-mediated tachycardia is an abnormal consequence of normal pacemaker function.

33. **a.** The pacing mode is VVI secondary to automatic mode switch. The initial rhythm strip shows background AFib with VVI pacing, most probably related to automatic mode switch. The absence of atrial pacing suggests adequate atrial sensing (of the fibrillation), which resulted in the mode switch behavior. Atrial pacing cannot be determined in the presence of AFib. There is adequate ventricular sensing, as determined on the nonmagnet strip (fifth complex—the small intrinsic QRS is sensed by the pacemaker which results in inhibition of pacing); however, there is intermittent ventricular capture noted (ventricular pacing spike followed by a lack of ventricular depolarization).

34. **a.** CHB at the level of the AV node. In this tracing, there is NSR with CHB and a narrow escape rhythm that is junctional in origin. This is apparent in the HBE tracing, in which the atrial deflections are completely dissociated from the H–V deflections. Therefore, the atrial impulse entering the AV node is not conducting down to the His bundle (A is not followed by His potential), indicating that the level of block is at the level of the AV node.

35. **b.** CHB at the infra-Hisian (below the His bundle) level. In this tracing, there is NSR with CHB and a relatively wide escape rhythm. In the HBE tracing, each atrial deflection is followed by an initial His deflection and a third, smaller deflection, H', indicating that there is conduction delay within the His bundle itself. This is suggestive of significant His-Purkinje conduction disease. Therefore, the atrial impulse enters the AV node, conducts down to the His bundle (normal AH interval), where it encounters conduction delay (a "split" His made up of both an H and an H'), and then fails to propagate to the ventricle, indicating that the level of block is at or below the level of the bundle of His. There is obvious AV dissociation with a ventricular escape rhythm.

36. **d.** Second-degree AV block at an infra-Hisian level. In this tracing, the surface ECG shows NSR with 2:1 AV block. The HBE tracing shows constant AH with 2:1 block below the level of the His bundle.

37. **d.** Second-degree AV block at an infra-Hisian level. In this tracing, the surface ECG shows NSR with second-degree type I AV block (Wenckebach). This pattern of block is usually localized to the AV node. However, in rare circumstances the block can occur within or below the His bundle. The wide QRS seen on the surface leads are a clue in this case that the patient has conduction disease below the level of the AV node; however, the site of block can only be determined by reviewing the His bundle recordings. In this situation, the HBE tracing shows progressive prolongation in the HV interval before it blocks in a 3:2 conduction pattern. Therefore, the conduction delay is not at the level of the AV node but at or below the His bundle. As opposed to Wenckebach in the AV node, which is usually benign in nature, this type of infra-Hisian block indicates His-Purkinje conduction system disease and is an indication for pacemaker placement, as it may progress to CHB.

38. **b.** Obtaining a two-view (anteroposterior and lateral) CXR to evaluate lead position. The presence of an RBBB-paced QRS complex pattern suggests that the ventricular lead may be in the LV. The lead may enter the LV through an atrial septal defect or ventricular septal defect or via perforation of the interventricular septum. It may also be inadvertently introduced into an artery and passed retrogradely through the aortic valve. Another possibility is placement into one of the LV branches of the coronary sinus. Although sometimes an apical position in the RV in a rotated heart can potentially give an RBBB-paced pattern, a two-view CXR should be obtained to rule out LV positioning. A single-view portable AP will not distinguish an LV from an apical RV placement. If LV placement is confirmed on the lateral radiograph, repositioning of the lead is indicated.

39. **d.** Patients with evidence of infra-Hisian block during EP testing should be considered for permanent pacing. Patients with symptomatic CHB do not need EP testing because the decision for a permanent pacemaker is already made. The sensitivity and specificity of sinus node recovery time are approximately 70%, making this test less than ideal; in most cases, the decision as to whether to implant a pacemaker in cases of suspected sinus node dysfunction depends on symptoms and correlation with ambulatory monitoring rather than results of EP testing. Patients with infra-Hisian block tend to have an unpredictable course and should be considered for permanent pacing.

40. **a.** It is characterized by ST elevation and a pseudo-RBBB pattern in the right

precordial leads with persistent ST elevation. Brugada syndrome has been described worldwide but is most common in Asian countries and is the leading cause of death in young men in part of Thailand. It is characterized by ST-segment elevation and a pseudo-RBBB pattern in the right precordial leads with persistent ST elevation. These features can be induced with sodium channel blockers such as flecainide and ajmaline. (Sotalol is a potassium channel blocker.) It is related to a mutation in the sodium channel gene. Mutations in SCN5A, which encodes the α-subunit of the cardiac sodium channel gene, have been found in up to 30% of families with Brugada syndrome. It is associated with a high incidence of sudden cardiac death resulting from VF. Risk assessment and therapy remain poorly defined at this time, but the implantation of an ICD has been advocated in patient with a Brugada pattern on their ECG and additional risk factors including a history of syncope or sudden cardiac death.

41. **b.** The mechanism of torsades de pointes (TdP) is believed to be related to early afterdepolarization. The pathognomonic arrhythmia associated with long-QT syndrome is TdP. The mechanism is believed to be related to early afterdepolarization and triggered activity. Sotalol causes QT prolongation and is contraindicated in patients with long QT. Hypokalemia, not hyperkalemia, is associated with an increase of TdP in this situation. EP testing is of no value and is not indicated for the risk stratification of patients with long-QT syndrome. Cardiac arrest occurs typically with vigorous activity and infrequently during sleep in LQT1 syndrome. Acute arousal events (emotion or noise) are much more likely to trigger events in LQT1 and LQT2 than LQT3. Events in LQT3 syndrome are common during sleep.

42. **c.** You should perform EP testing to evaluate the AV conduction system. The patient had an episode of near-syncope, which could be related to his GI bleeding, but the possibility of intermittent heart block in the setting of bifascicular block cannot be ruled out. This is a class I indication for EP testing to evaluate AV conduction. If there is evidence of abnormally prolonged HV interval, then a permanent pacemaker should be considered. If the syncopal episode was remote from the GI bleeding and based on the clinical history of the events there was a concern for intermittent high-degree AV block causing symptoms, then empiric placement of a PPM without an EP study prior would carry a class IIa indication. There is no indication for ICD placement in this setting. β-Blockers would blunt a reactive tachycardia resulting from the patient's anemia.

43. **e.** There is AV dissociation. In patients presenting with wide complex tachycardia, the presence of AV dissociation is highly specific for VT. All the other listed

parameters suffer from significant overlap between SVT and VT.

44. **c.** Procainamide, 15 mg/kg IV over 30 to 60 minutes. Wide complex tachycardia occurring after MI is most likely to be VT. Verapamil is contraindicated in this setting, as it might lead to hypotension and VF. DC cardioversion can be used if the patient does not respond to antiarrhythmic therapy or if he becomes hemodynamically unstable. Procainamide is the drug of choice because it treats ventricular as well as supraventricular arrhythmia. There is no role for digoxin and no need for urgent cardiac catheterization in this situation.

45. **b.** To admit the patient for IV antibiotics and pacemaker-system extraction. This presentation is consistent with pacemaker-system infection, which occurred following the recent pulse generator replacement. Antibiotics PO or IV without extraction of the pacemaker system have limited efficacy in eradicating the infection. The patient should undergo pacemaker-system extraction, followed by IV antibiotics, until negative blood cultures are obtained. A new pacemaker system can then be implanted on the right side.

46. **c.** Inadequate synchronization may occur with peaked T waves, low-amplitude signal, and malfunctioning pacemakers. Cardioversion is the delivery of electric energy synchronized on the R wave. A synchronized shock should be used in AFib. A nonsynchronized shock may result in VF if they fall near the middle of the T wave when there is a marked dispersion of refractoriness within the ventricle. Improper synchronization may occur in a situation in which more than one peaked signal exists, such as with pacemakers and peaked T waves. On the other hand, a low QRS signal may not synchronize at all. In patients with pacemakers, the pads are positioned at least 3 inches away from the pulse generator to minimize damage. MI and digoxin intake are not contraindications for DC cardioversion as long as digoxin toxicity is not suspected.

47. **d.** Procainamide. Procainamide can slow down conduction across the accessory pathway and potentially converts AFib. Diltiazem (Cardizem) and verapamil cause hypotension and a reflex increase in sympathetic activation and may result in increased ventricular response and in rare circumstances can lead to VF. Adenosine is of no use in this setting. Lidocaine has little effect on the refractory period of the accessory pathway.

48. **e.** Amiodarone. Amiodarone may allow maintenance of sinus rhythm in patients with AFib and cardiomyopathy. In low doses, the side effects are minimized. Flecainide and disopyramide are not used in patients with cardiomyopathy because of their

potential for proarrhythmia and their negative inotropic effects. Verapamil is not effective for maintenance of sinus rhythm. Sotalol might not be tolerated in patients with heart failure and has the potential for proarrhythmia in patients on diuretics prone to hypokalemia.

49. c. Digoxin can control the ventricular rate at rest in patients with AFib, but not with exercise. It is as effective as placebo for the acute conversion of AFib and does not help in maintaining NSR.

50. a. It may contribute to an increase in the digoxin level. Flecainide (amiodarone, propafenone [Rythmol], and verapamil) can increase digoxin level. Flecainide can regularize and slow the atrial rhythm in patients with AFib and can, therefore, lead to increased ventricular response because of improved conduction of the atrial impulses through the AV node. It is, therefore, important to use an AV nodal blocking agent in patients with AFib treated with flecainide. It is used for AFib as well as flutter; however, it needs to be used with caution in atrial flutter patients, as it may slow the cycle length of the flutter circuit and result in more rapid conduction to the ventricle. There are no definite data on its safety in patients with hypertrophic cardiomyopathy. It is effective for acute conversion as well as maintenance of NSR postconversion.

51. a. Change in the atrial refractory period as a result of the surgical manipulation. The occurrence of AFib post-cardiac surgery is believed to be related to shortening of the refractory period of atrial tissue as it recovers from surgical manipulation, cardioplegia, and, potentially, ischemia. This nonuniformity of recovery results in reentry as the mechanism of AFib.

52. a. AVNRT. This tracing shows AVNRT. It is a narrow complex tachycardia using the slow pathway of the AV node in the antegrade direction (long AH) and the fast pathway of the AV node in the retrograde direction (short HA). It is unlikely to be orthodromic reentrant tachycardia in which the retrograde limb of the circuit is an accessory pathway, because the QRS-A time is very short (atrium and ventricle are activated almost spontaneously), not long enough to involve ventricular activation as part of the circuit. Because the QRS is narrow, VT is not a likely diagnosis. Idiopathic LV-VT can sometimes be narrow but has an RBBB morphology on the surface ECG.

QUESTIONS

Case 1

A 60-year-old man presents to the emergency room with complaints of weakness, lethargy, and severe dyspnea. One week prior, his family notes that he complained of chest pressure that lasted for several hours. On physical examination, he appears to be in respiratory distress. Blood pressure (BP) is 80/50 mmHg. Heart rate is 130 bpm. His oxygen saturation is 87% on room air. Chest examination reveals diffuse crackles. Cardiac examination reveals a nondisplaced point of maximum impulse (PMI). Third and fourth heart sounds are heard, as is an apical systolic murmur. No thrill is present. Electrocardiogram reveals inferior Q waves without ST-segment elevation. He is urgently intubated and pressors are started. An intra-aortic balloon pump is placed. A surface echocardiogram reveals a normal-sized left atrium and a mild jet of mitral regurgitation (MR).

1. What test do you perform first?

   a. Cardiac catheterization
   b. Transesophageal echocardiography (TEE)
   c. Right heart catheterization with an oxygen saturation run
   d. Administration of thrombolytic therapy

2. A TEE is performed urgently (Fig. 2.1 shows a 3D view of the mitral valve from above). What is the most likely diagnosis?

   a. Endocarditis involving the mitral valve
   b. Posterior papillary muscle rupture as it has a single blood supply
   c. Anterior papillary muscle rupture as it has a single blood supply
   d. Severe mitral valve prolapse secondary to recent myocardial infarction

Case 2

A 65-year-old woman presents to your office for follow-up of a murmur she was told about several years prior. She denies any symptoms, but is not very active. Her past medical history is significant for hypertension and diabetes, both of which have been well controlled. On examination, she is in no acute distress. BP is 125/75 mmHg, with a resting heart rate of 70 bpm. Lungs are clear. Cardiac examination reveals a displaced PMI. S_1 is soft. S_2 reveals an increased P_2 component. There is a right ventricular (RV) lift. An S_3 is present. There is a grade III/VI holosystolic murmur heard at the apex radiating to the base. She has no peripheral edema. Chest X-ray demonstrated cardiomegaly with prominence of the central pulmonary vasculature.

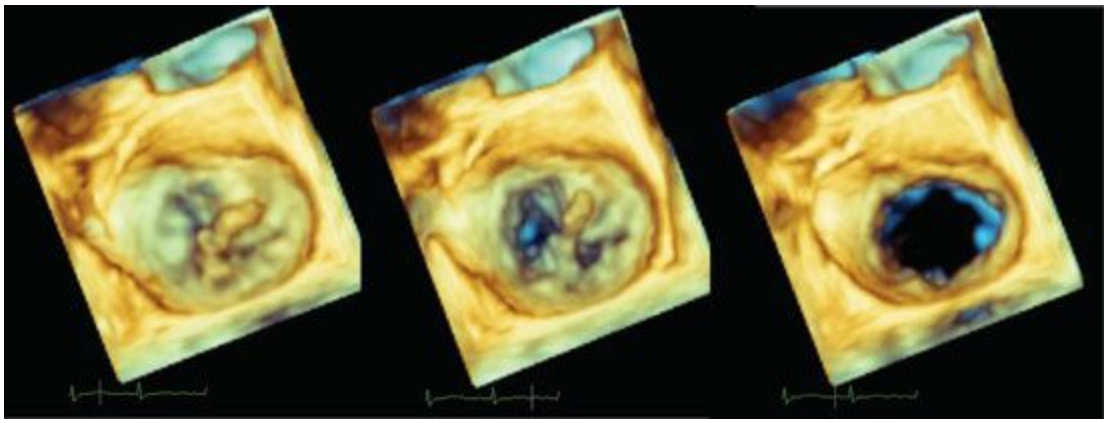

Figure 2.1

3. An echocardiogram is performed on this patient (Fig. 2.2). Left ventricular (LV) systolic dimension is 4.7 cm. Ejection fraction is 45%. There is posterior leaflet prolapse. There is a very eccentric jet of MR, which is read out as 2+. Which of the following is most likely?

    a. MR is unlikely to account for her presentation.
    b. She likely has more severe MR than is evident on the echocardiogram.
    c. Her LV function is better than it appears on the echocardiogram.
    d. TEE is unlikely to be helpful here.

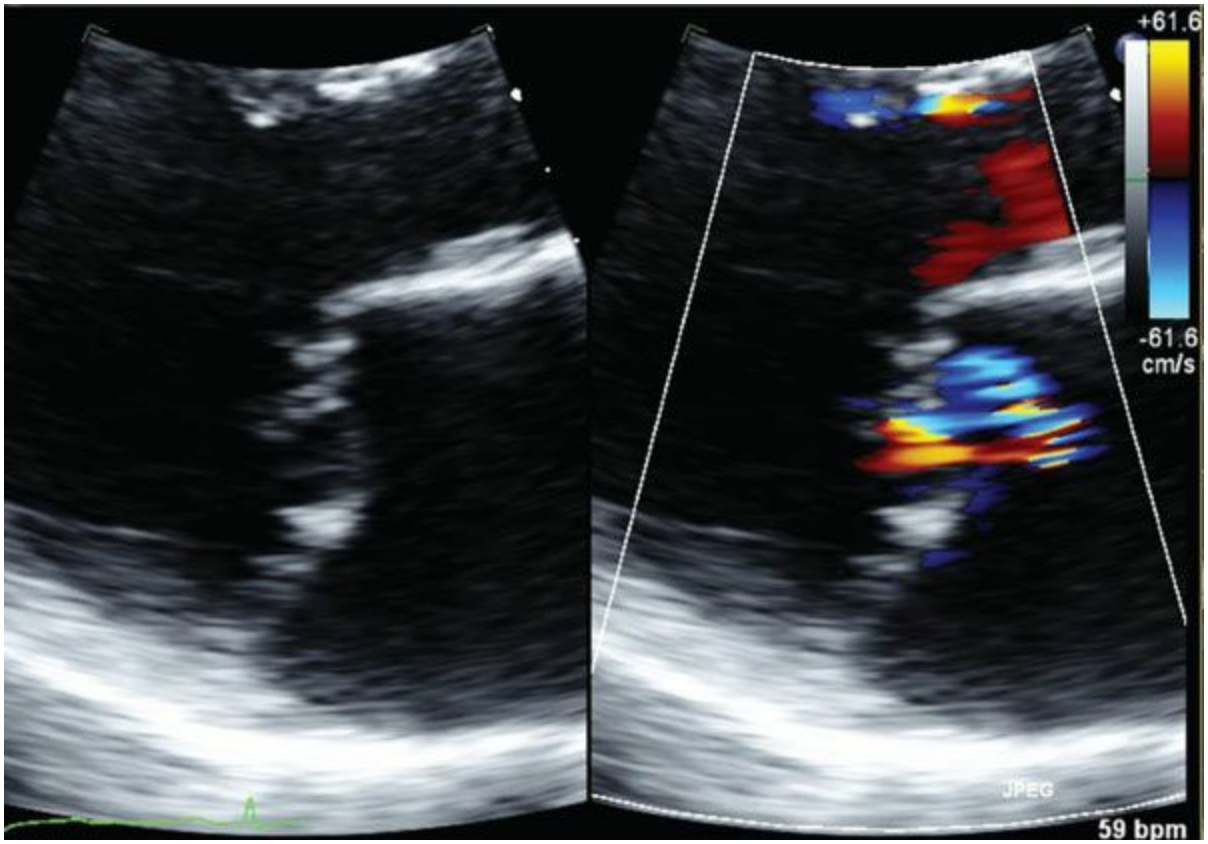

Figure 2.2

4. What do you recommend next?

   a. Stress echo, to assess LV and PA (pulmonary artery) pressures post stress
   b. Mitral valve surgery
   c. Start an angiotensin-converting enzyme inhibitor (ACEI) and reassess in 3 months
   d. Start a β-blocker

Case 3

A 40-year-old woman is referred to your office for evaluation of a murmur heard during a routine physical examination. She is asymptomatic. She used to jog 2 to 3 miles a day without problems but over the past few years has stopped exercising. She had frequent febrile illnesses as a child, but her past medical history is otherwise unremarkable.

Physical Examination

BP 120/70 mmHg, pulse 73 bpm.
She is in no acute distress.
Jugular venous pulse (JVP) is not elevated.
Chest is clear.
Cardiac—PMI not displaced. Regular rate and rhythm. S_1 is increased in intensity.

S_2 is normal. A high-pitched diastolic sound is heard at rest and is heard best between the apex and left sternal border, 0.10 seconds after S_2. This is followed by a low-pitch decrescendo murmur with pre-systolic accentuation.
Abdomen—No organomegaly.
Extremities—No edema. Normal distal pulses. Good capillary refill.

An echocardiogram is performed (Fig. 2.3); proximal flow convergence radius (PFCR) using color 3D across the mitral valve indicates an orifice area of 1.2 cm^2. Resting PA pressures are 35 mmHg. Splittability score is 5. LV size and function are normal.

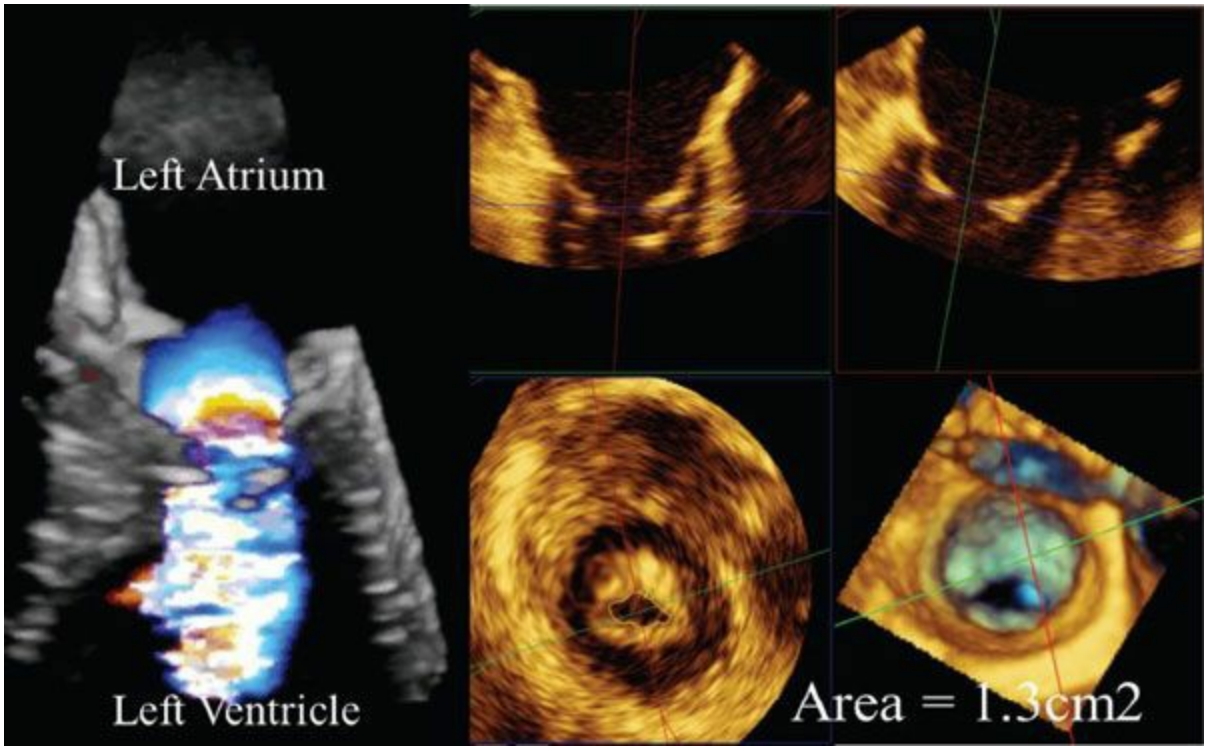

Figure 2.3

5. Which of the following would be the most reasonable next step in management?

   a. Immediate referral for surgery
   b. Immediate referral for percutaneous valvuloplasty
   c. Stress echocardiogram, to assess for mitral pressures post stress
   d. Follow-up in 2 years

6. A stress echocardiogram is performed. Patient exercises for 6 metabolic equivalents (METs). Right ventricular systolic pressure post stress is estimated at 70 mmHg. Which of the following would be an appropriate next step?

   a. Consideration for percutaneous valvuloplasty

b. Mitral valve replacement
c. Start β-blocker and return for follow-up in another 2 years
d. Start digoxin

Case 4

A 50-year-old woman presents to you for evaluation. She complains of easy fatigability, as well as abdominal fullness and right upper quadrant pain. She also notes marked swelling in her legs. She has recently been diagnosed with asthma and is also undergoing evaluation for recurrent diarrhea. On examination, she has a BP of 100/60 mmHg. Heart rate is 96 bpm. There is elevation in jugular venous pressure, with a large a wave and a prominent v wave. Lungs are clear. Cardiac examination reveals a nondisplaced PMI. Rhythm is regular. S_1 and S_2 (including P_2) are normal. A diastolic murmur is heard along the sternal border, which increases with inspiration. A pansystolic murmur is also heard in this area. Hepatomegaly is present, along with ascites and peripheral edema.

7. What is the most likely cause of this patient's signs and symptoms?

a. Rheumatic heart disease
b. Carcinoid
c. Primary pulmonary hypertension
d. Cirrhosis of the liver secondary to chronic hepatitis

Case 5

A 28-year-old man is referred to your office for a second opinion regarding his hypertension. On physical examination, he is in no acute distress. BP is 160/90 mmHg, symmetric in both arms. Pulse rate is 75 bpm. Cardiac examination reveals a nondisplaced PMI. S_1 is normal. It is followed by a high-pitched sound widely transmitted throughout the precordium. A short II/VI systolic ejection murmur is heard. S_2 is normal.

8. What is the most important diagnostic test to perform next?

a. Check plasma catecholamines.
b. Check serum potassium level.
c. Check lower extremity BP.
d. Check plasma cortisol levels.

Case 6

A 59-year-old man presents for further evaluation of recurrent congestive heart failure. He appears to be in no acute distress on your evaluation. BP is 100/60 mmHg. Carotid upstrokes are weak, but not delayed. Chest examination shows minimal bibasilar rales. PMI is displaced and sustained. A summation gallop is present. There is an increased

P_2. There is mild peripheral edema. An echocardiogram reveals a dilated LV with an ejection fraction of 25%. The aortic valve does have some calcification, with restricted leaflet excursion. Peak/mean gradients are 25/15 mmHg. By the continuity equation, the aortic valve area is calculated as 0.7 cm^2.

9. What is your next step?

- **a.** Immediate referral for aortic valve replacement (AVR)
- **b.** Referral for cardiac transplant
- **c.** Dobutamine echocardiogram
- **d.** Start an ACEI

10. With dobutamine echocardiography, the gradients across the valve increase to 60/40 mmHg, and the calculated valve area stays at 0.7 cm^2. What do you recommend?

- **a.** AVR
- **b.** Continued medical management
- **c.** Cardiac transplant evaluation
- **d.** Balloon aortic valvuloplasty

11. Alternatively, how would you interpret the following results: an increase in stroke volume by 5% and an increase in peak/mean gradients to 30/19 mmHg without a significant change in the aortic valve area?

- **a.** Patient has true severe aortic stenosis (AS) and should proceed to surgery.
- **b.** Patient has pseudo-AS and should be managed with medical therapy alone.
- **c.** Patient has a lack of contractile reserve and should be managed with medical therapy alone.
- **d.** Patient has a lack of contractile reserve but should still be considered for AVR.

Case 7

A 32-year-old man with known bicuspid aortic valve is referred to you for management of aortic insufficiency (AI). He is completely asymptomatic and jogs 3 miles a day as well as doing other aerobic exercise for 30 minutes daily. He has a grade III/VI systolic and diastolic murmur at his left sternal border, a collapsing pulse on examination, and his BP 170/70 mmHg. An echocardiogram reveals a mildly dilated LV (end-diastolic dimension of 6.0 cm) with an ejection fraction of 65%. There is prolapse of the conjoined aortic leaflet with 3 to 4+ insufficiency.

12. What is your recommendation?

- **a.** Referral for surgery

b. Addition of vasodilator therapy
c. Observation for now, return for follow-up in 3 years
d. Cardiac catheterization

13. What do you tell him is his yearly risk of sudden death?

a. <1%
b. 2%
c. 3% to 5%
d. >5%

14. The above patient undergoes a gated computed tomography angiography of the thorax (Fig. 2.4), what would you recommend?

a. Observation with echocardiography every 6 months
b. Start a β-blocker and reassess in 6 months
c. Refer to computed tomographic (CT) surgery for surgical replacement of his aortic valve
d. Referral for surgical intervention to repair or replace his aortic valve and to replace his ascending aorta

Case 8

A 76-year-old woman has been accepted for AVR for severe symptomatic AS. Your opinion is sought by the cardiothoracic surgeon regarding best management of reported concomitant valvular lesions. On review of the echocardiogram you confirm severe AS. In addition, you note a morphologically normal mitral valve, mild MR, and moderate tricuspid regurgitation (TR) associated with annular dilation (45 mm). There is also mild pulmonary hypertension.

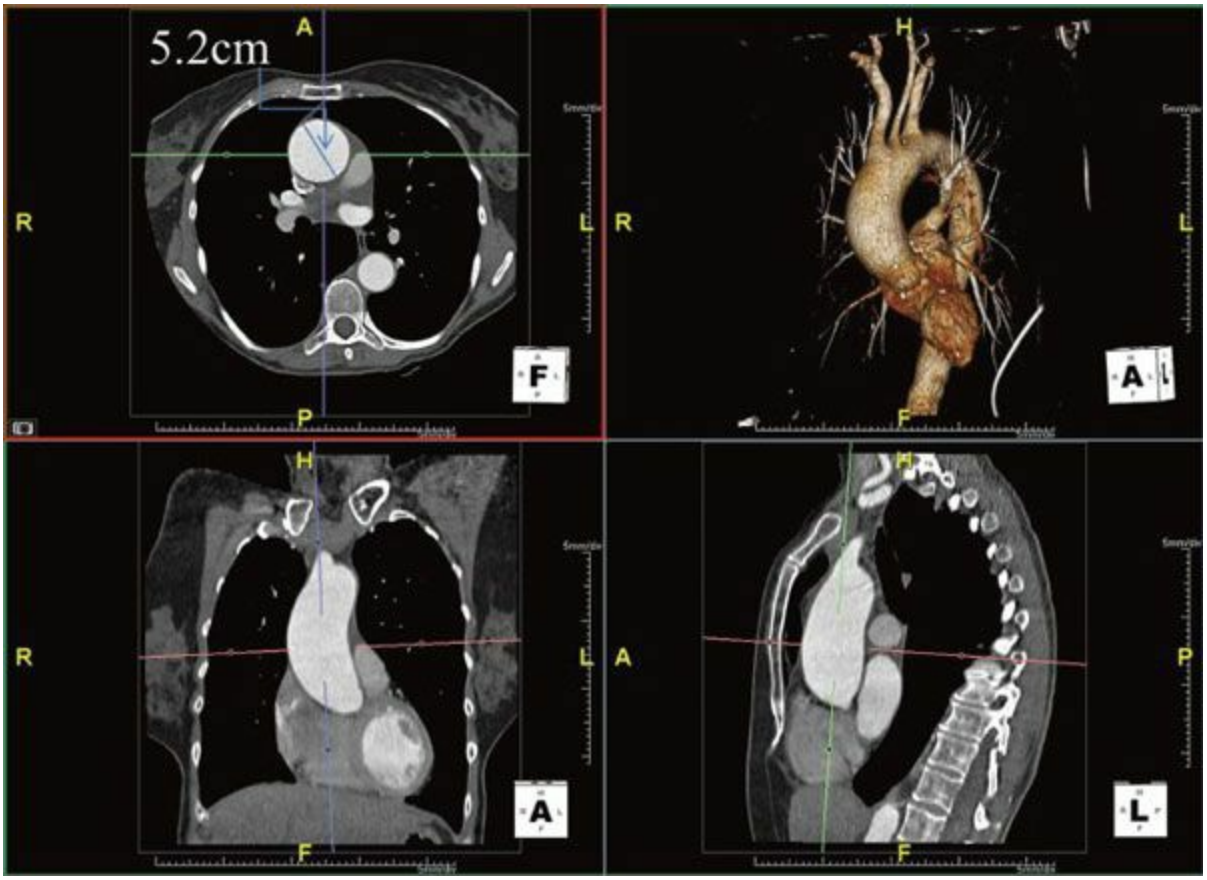

Figure 2.4

15. What do you recommend?

- **a.** AVR alone
- **b.** AVR with mitral and tricuspid valve repair
- **c.** AVR with tricuspid valve replacement
- **d.** AVR with tricuspid valve repair if feasible
- **e.** AVR and mitral valve repair alone

Case 9

A 46-year-old woman with chronic obstructive pulmonary disease is referred by her pulmonologist for evaluation of a murmur and concern that her symptoms of shortness of breath with moderate exertion may be related to severe MR diagnosed on an outside echocardiogram. On examination, her body mass index is 19 kg/m^2, BP is 130/75 mmHg, and her heart rate is 75 bpm and regular. Her apex beat is nondisplaced. On auscultation, S_1 and S_2 are normal; there is a mid-systolic click with a grade IV/VI late systolic murmur heard best at the apex. An echocardiogram is performed (Fig. 2.5A).

16. Assuming an aliasing velocity of 40 cm/s and an MR V_{max} of 5 m/s, based on the PFCR seen here, what is the estimated effective regurgitant orifice area (EROA)?

a. 0.4 cm^2
b. 0.45 cm^2
c. 0.18 cm^2
d. Not enough information to calculate an EROA

17. A continuous-wave signal is provided through the mitral valve (Fig. 2.5B); based on the data provided how would you classify this MR?

a. 1+, mild
b. 2+, moderate
c. 3+, moderately severe
d. 4+, severe

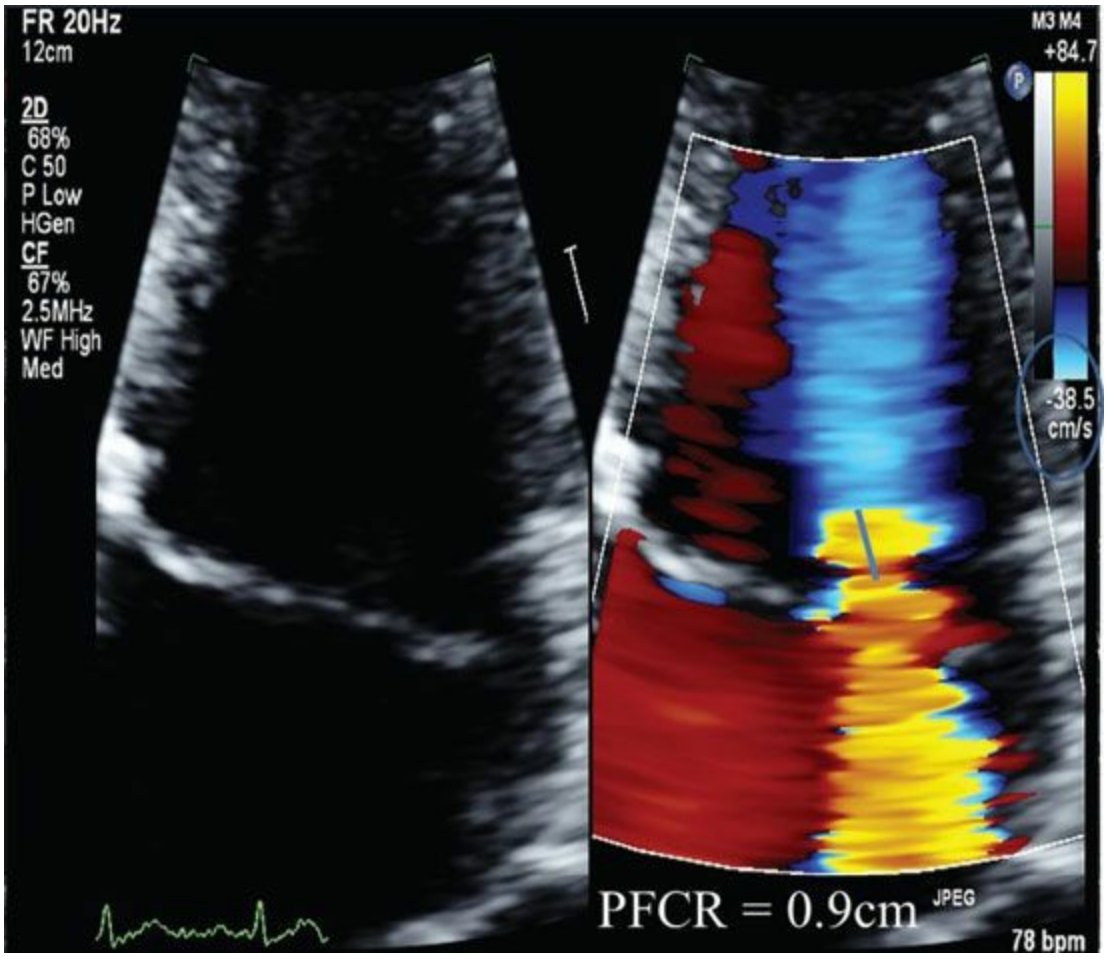

Figure 2.5A

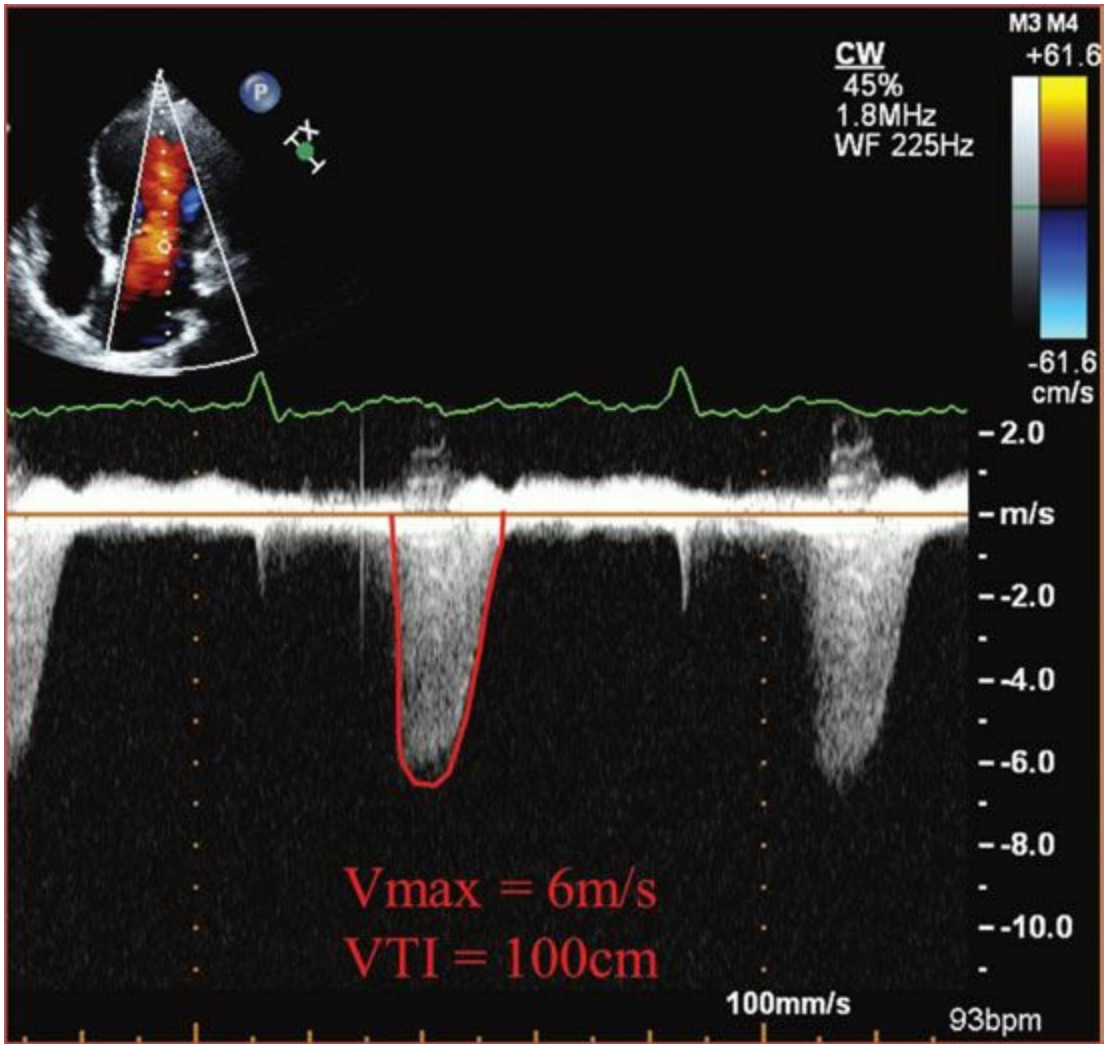

Figure 2.5B

Case 10

A 45-year-old man with rheumatic mitral stenosis presents for further evaluation. In the past 2 to 3 years, he has noted progressive dyspnea with less than moderate activity. He was started on a β-blocker 1 year ago, but remains symptomatic. Echocardiogram reveals a mean mitral gradient of 4 mmHg with a valve area of 1.6 cm^2. As there was a discrepancy between the degree of symptoms and resting hemodynamics you proceed to a stress echocardiogram that revealed a post stress PA pressure of 70 mmHg and a mean transmitral gradient of 17 mmHg. You decide to send this patient for percutaneous intervention.

18. What is the most appropriate test to order at the time of or prior to the valvuloplasty procedure?

a. Transesophageal echocardiogram
b. 24-Hour electrocardiographic monitoring to assess for paroxysmal atrial fibrillation

c. Cardiac CT to assess for aortic calcification
d. Stress nuclear perfusion study

Case 11

A 65-year-old man is referred to you for evaluation of a heart murmur. He denies any symptoms at this time. On physical examination, he is in no acute distress. BP is 135/75 mmHg; pulse is 82 bpm and regular. Carotid upstrokes are diminished. The PMI is sustained and displaced. A_2 is soft. A late-peaking systolic murmur is heard at the base. You order an echocardiogram. This reveals LV hypertrophy with moderate global impairment of LV function, calculated ejection fraction of 35%. There is severe calcific AS, with peak/mean gradients of 75/45 mmHg. Aortic valve area is 0.5 cm^2.

19. What is the role of AVR in this setting?

a. It is absolutely indicated.
b. It is absolutely not recommended.
c. There is some evidence/opinion that would favor valve replacement.
d. Dobutamine echocardiography is needed to determine whether this is truly severe AS.

Case 12

A 76-year-old woman is referred to your clinic with recent onset of exertional chest pain. She has a long-standing history of hypertension and atrial fibrillation. On examination, her body surface area is 2.0 m^2, BP is 150/100 mmHg, and heart rate is 80 to 90 bpm and irregular. The carotid upstroke is delayed and diminished. The apex beat is nondisplaced but sustained. S_1 is normal, and S_2 is soft and paradoxically split. There is a grade II/VI ejection systolic murmur heard best at the right upper sternal border that radiates to the carotids. An echocardiogram reports normal ejection fraction with a stroke volume of 55 mL. The peak and mean gradients across the aortic valve are 44/28 mmHg. The dimensionless index is 0.21 and the calculated aortic valve area is 0.83 cm^2. You review the echocardiogram (Fig. 2.6) and confirm the accuracy of the left ventricular outflow tract (LVOT) diameter and are satisfied that multiple windows were used to obtain the gradients.

20. Which of the following statements is true?

a. The patient has moderate AS confirmed by gradients across the valve and should be followed up in 6 months with a repeat echocardiogram.
b. The echocardiogram shows inconsistent data and should be repeated.
c. This is a definite contraindication to AVR.
d. The rate of mortality, for a patient with these findings, is higher compared with patients with severe AS and high gradients across the aortic valve, but aortic

valve surgery has resulted in better outcomes in these patients.

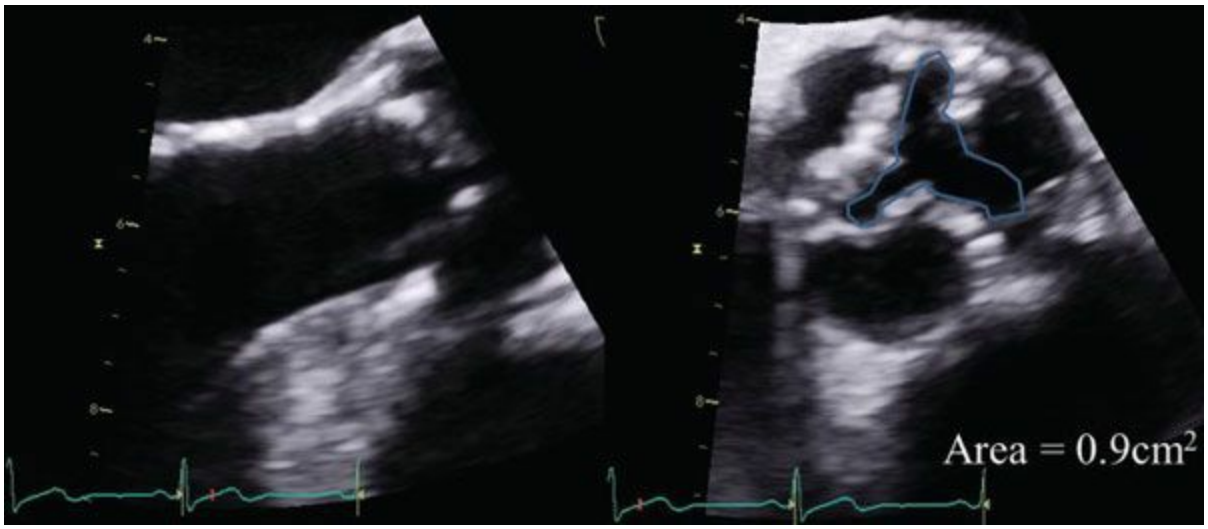

Figure 2.6

Case 13

A 75-year-old man is referred to you for evaluation of aortic regurgitation. He has no symptoms at this time. His past medical history is significant only for hypertension. On physical examination, he is in no acute distress. BP is 170/60 mmHg. Arterial pulses are brisk. A bisferiens pulse is noted in the brachial artery. The apical impulse is displaced and hyperdynamic. S_1 is not loud, and no opening snap is heard. A high-frequency holodiastolic murmur is heard, loudest along the right sternal border. A late diastolic apical rumble is heard as well.

21. You order an echocardiogram. Which of the following are you most concerned about?

- **a.** Aortic valve commissural anatomy
- **b.** Degree of AI
- **c.** Aortic root dimension
- **d.** Mitral valve

22. The above patient returns for follow-up 6 months later. He now reports symptoms of marked exertional dyspnea. An echocardiogram is read as 2+ central aortic regurgitation, with an LV end-diastolic dimension of 6.9 cm and an ejection fraction of 50%. What do you do next?

- **a.** Cardiac catheterization with aortography
- **b.** Start an ACEI, reassess in 6 months
- **c.** Continue observation
- **d.** Start a β-blocker, reassess in 6 months

Case 14

A 56-year-old man presents to the emergency room with the sudden onset of chest pain. He is tachypneic on presentation. O_2 saturation is 82% on room air. BP is 80/60 mmHg. Heart rate is 125 bpm. Lung examination reveals diffuse bilateral crackles. Cardiac examination reveals a nondisplaced PMI. S_1 is soft. P_2 is loud. An S_3 is present. A short decrescendo diastolic murmur is heard at the upper sternal border. Extremities are cool. Electrocardiogram reveals inferior ST-segment elevation. He is promptly intubated, and pressors are started. A brief echocardiogram is performed at the bedside. The study is difficult, but reveals premature closure of the mitral valve. There is hypokinesis of the inferoposterior walls.

23. Which of the following would be your next course of action?

- **a.** Transesophageal echocardiogram, emergent cardiac surgical consultation
- **b.** Intra-aortic balloon pump to stabilize hemodynamics, followed by emergent angiography
- **c.** Administer thrombolytics
- **d.** Send patient for magnetic resonance imaging (MRI)

Case 15

A 77-year-old patient is admitted to the hospital for urosepsis. His past medical history is significant only for having undergone AVR 5 years prior. On examination, he is febrile to 102°F. Heart rate is 106 bpm. Carotid upstrokes are full. Chest examination reveals clear lung fields. Cardiac examination reveals a hyperdynamic apical impulse, which is not displaced. S_1 and S_2 are normal. An early-peaking systolic murmur is heard at the sternal border. No diastolic murmur is heard. An echocardiogram is performed. Peak/mean gradients are 50/30 mmHg. LVOT VTI (velocity time integral) is 36 cm and aortic valve VTI is 78 cm. The aortic valve itself is not well seen. Flow in the descending thoracic aorta is normal. An echocardiogram 2 years prior had revealed peak/mean gradients of 24/12 mmHg. LVOT VTI was 19 cm and aortic valve VTI 41 cm.

24. What do you conclude about prosthetic aortic valve function?

- **a.** He has prosthetic valve stenosis
- **b.** No evidence for dysfunction
- **c.** He has severe prosthetic valve regurgitation
- **d.** He likely has endocarditis

25. The above patient remains febrile despite 1 week of antibiotic therapy. Electrocardiogram reveals a new long first-degree atrioventricular (AV) block. The patient becomes progressively dyspneic. A short, regurgitant murmur is heard.

What do you recommend?

a. TEE with surgical consultation
b. TEE
c. Change antibiotic regimen
d. Monitor closely with daily electrocardiogram

Case 16

A 56-year-old man with mitral stenosis presents for evaluation. He has NYHA class II-III shortness of breath.

Physical Examination

He is in no acute distress.
JVP is mildly elevated.
Pulse is regular at 80 bpm.
Chest is clear.
Cardiac: Nondisplaced PMI. Opening snap heard 0.09 milliseconds after S_2. Long diastolic rumble. No peripheral edema.
Echocardiogram reveals a planimetered mitral valve area of 1.2 cm^2. Mean gradient 10 mmHg. Pressure half-time of 185 milliseconds.
He undergoes percutaneous valvuloplasty. The following morning, on examination, you note that he is comfortable. His oxygen saturation is 100% on room air. Opening snap is 0.12 milliseconds after S_2. A shorter decrescendo diastolic rumble is heard. You obtain a predischarge echocardiogram. The report indicates a pressure half-time of 180 milliseconds.

26. What do you do next based on the echocardiogram?

a. There was a less-than-optimal result from the valvuloplasty. No significant change in mitral valve area was achieved. You plan to send him for another procedure or surgery.
b. There was an error in half-time measurement. You order a repeat assessment of pressure half-time later that day.
c. Repeat echocardiogram with planimetry of mitral valve area.
d. Consider TEE to see the valve opening better.

27. The echocardiogram reveals a small left-to-right shunt at the atrial level by color. What do you recommend?

a. Observation
b. Referral for percutaneous closure
c. Referral for surgical closure

d. Indefinite anticoagulation

Case 17

An 80-year-old man underwent successful AVR with a bioprosthetic valve 4 months ago. He presents to your office for a routine follow-up visit. He is asymptomatic. He is in sinus rhythm. Echocardiogram reveals a normally functioning prosthetic valve. Chamber dimensions are normal with normal biventricular function. He has no clinical history of embolic events.

28. Which of the following should you recommend?

a. Antibiotic prophylaxis, office visits if he feels unwell
b. Antibiotic prophylaxis, with yearly office visits
c. Warfarin therapy indefinitely
d. Clopidogrel therapy indefinitely

Case 18

A 28-year-old 20-week pregnant woman is referred to your clinic after being diagnosed with mitral valve prolapse and severe MR on an echocardiogram ordered by her obstetrician. She reports no symptoms prior to pregnancy but since being told her diagnosis is extremely worried and has noticed some shortness of breath on exertion (New York Heart Association [NYHA] class II). She is clinically euvolemic.

29. What do you recommend?

a. Antibiotics at the time of delivery
b. Commence afterload reduction with an ACEI given her new onset symptoms
c. Refer to an experienced surgeon for consideration for mitral valve repair as there is a high likelihood of successful durable repair
d. Commence afterload reduction with diuretics and hydralazine
e. No therapy at present but follow carefully with serial clinical and echo evaluation

Case 19

A 67-year-old woman is referred to your office for evaluation of a heart murmur. She describes symptoms of significant and limiting exertional dyspnea. On examination, she is normotensive. Pulse rate is 67 bpm and regular. Cardiac examination reveals a sustained but nondisplaced PMI. S_1 and S_2 are normal. An S_4 is present. A loud III/VI systolic ejection murmur is heard throughout the precordium. Carotid upstrokes are delayed and diminished. An echocardiogram is performed (Fig. 2.7); continuous-wave Doppler evaluation reveals a 4.5-m/s jet across the LVOT.

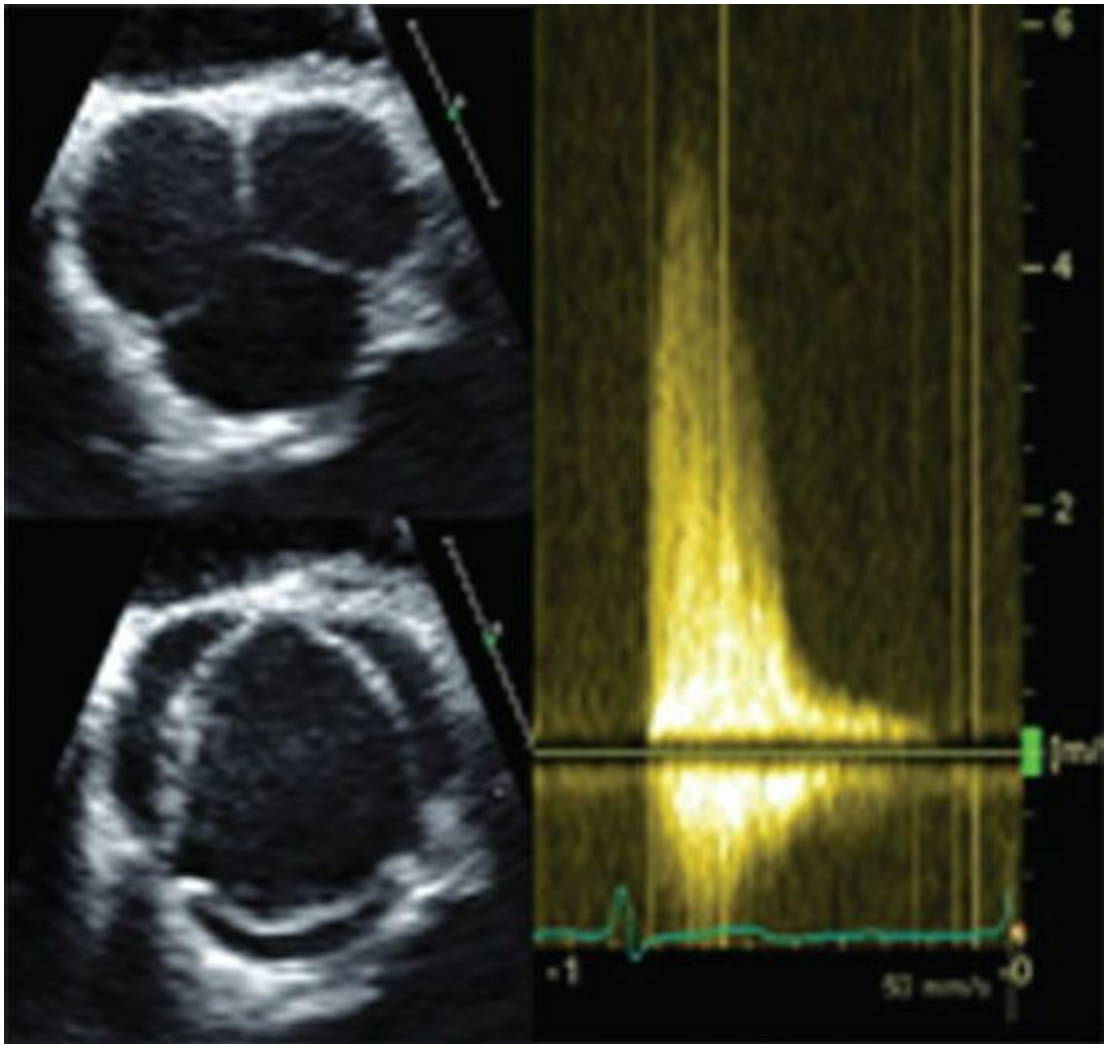

Figure 2.7

30. Which of the following would you do next to arrive at a diagnosis?

a. TEE
b. Repeat echocardiogram with amyl nitrate
c. Stress echocardiogram
d. Dobutamine echocardiogram
e. The Pedoff probe has picked up an MR signal, the MR appears mild on all other views, no need for further investigation

Case 20

A 30-year-old woman presents to your office for a routine physical examination. She is asymptomatic. BP is 95/65 mmHg, with a resting heart rate of 65 bpm. Physical examination is remarkable for a mild pectus deformity. On cardiac auscultation, a mid-systolic click is heard. The click is heard earlier in systole with standing, and later in systole with squatting. No murmur is heard at rest, but a soft systolic murmur becomes audible with dynamic maneuvers.

31. Echocardiography demonstrates no high-risk features. What is the role of aspirin therapy in such patients who have had no evidence of embolic events?

a. Should be prescribed to all patients
b. May play a role, if a murmur is heard
c. There is no clear role for aspirin therapy in such patients

Case 21

A 50-year-old man with severe AI is referred to you for a second opinion. He is asymptomatic. An echocardiogram reveals a mildly dilated LV (end-diastolic dimension of 6.2 cm and end-systolic dimension of 3.5 cm) with a normal ejection fraction. He has already undergone a stress echocardiogram. He exercised for 14 METs. No symptoms or electrocardiographic changes were noted. Resting ejection fraction was calculated at 65%. Post stress, the ejection fraction is 60%. No segmental wall motion abnormalities were seen.

32. What do you recommend?

a. Surgical intervention
b. Continue with vasodilator therapy and reassess in 6 months
c. Cardiac catheterization
d. Stress nuclear ventriculogram

Case 22

A 70-year-old man presents to your office with complaints of exertional dyspnea. He is mildly hypertensive on examination. Carotid upstrokes are brisk, with a secondary upstroke. A loud III/VI systolic murmur is heard along the sternal border radiating to the neck. S_1 and S_2 are normal. An S_4 is heard. The murmur increases in intensity with Valsalva and decreases with handgrip.

33. An echocardiogram reveals a <2-m/s jet across the LVOT. What is your next step?

a. Repeat the echocardiogram, but have Doppler interrogation performed in other views and with a nonimaging transducer. The degree of AS has been underestimated
b. Repeat the echocardiogram with amyl nitrate
c. Transesophageal echocardiogram to better assess the valves
d. Coronary angiography

Case 23

A 26-year-old woman with a history of hypertrophic obstructive cardiomyopathy is referred for consideration for septal myectomy. She has NYHA class III dyspnea on exertion despite maximal medical therapy. On echocardiography, there is severe asymmetric septal hypertrophy with severe systolic anterior motion of the mitral valve.

There is a late-peaking gradient across the LVOT of 60 mmHg, which increased to 105 mmHg with Valsalva. She has a structurally normal mitral valve on cardiac MRI with moderately severe posteriorly directed MR (Fig. 2.8).

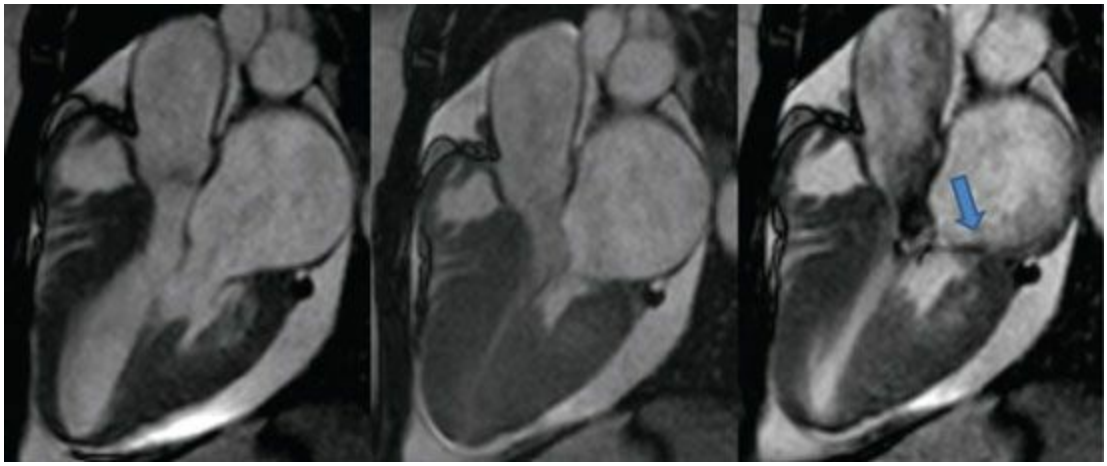

Figure 2.8

34. What would you advise her regarding surgery?

- **a.** She will probably require mitral valve replacement at the time of surgery.
- **b.** She will probably require mitral valve repair during surgery.
- **c.** She will probably not need surgery on her mitral valve.
- **d.** She may need plication of her papillary muscles.

Case 24

A 62-year-old man with a history of rheumatic heart disease presents to your office with complaints of exertional dyspnea. No constitutional complaints are present. He had undergone a mitral valve replacement with a bileaflet tilting disk mechanical valve 11 years prior. He is normotensive with a heart rate of 73 bpm. On examination, you note a grade II/VI holosystolic murmur at the apex. An echocardiogram is performed, which reveals normal LV and RV function. Peak mitral gradient is 30 mmHg. Mean transmitral gradient is 7 mmHg. Pressure half-time is 80 milliseconds.

35. What is your next diagnostic step?

- **a.** Fluoroscopy of the valve
- **b.** Transesophageal echocardiogram
- **c.** Invasive assessment of hemodynamics
- **d.** Draw blood cultures

36. Which of the following would be the expected physical findings in this patient if the valve were functioning normally?

a. Prominent closing click, soft and brief diastolic rumble
b. Prominent opening and closing clicks, soft and brief diastolic rumble
c. Prominent opening click, long diastolic rumble
d. Prominent closing click, systolic murmur

37. If the patient had a ball-and-cage valve instead, what would you expect to hear?

a. Prominent closing click, soft and brief diastolic rumble
b. Prominent opening and closing clicks, soft and brief diastolic rumble
c. Prominent opening click, long diastolic rumble
d. Prominent closing click, systolic murmur

38. Recommended antithrombotic therapy for a patient with a mechanical mitral valve replacement without a prior thromboembolic event or other high-risk features is

a. Warfarin therapy with a target international normalized ratio (INR) of 3.0 to 4.0
b. Warfarin therapy with a target INR of 2.5 to 3.5
c. Warfarin therapy with a target INR of 2.0 to 3.0 plus aspirin 75 to 100 mg
d. Warfarin therapy with a target INR of 2.5 to 3.5 plus aspirin 300 mg
e. Warfarin therapy with a target INR of 2.5 to 3.5 plus aspirin 75 to 100 mg

Case 25

A 65-year-old man presents to your office for evaluation of valvular heart disease. He is asymptomatic. He walks 5 miles a day without difficulty. An echocardiogram reveals severe AS, with a maximum aortic jet velocity of 4.7 m/s by Doppler echocardiography. LV systolic function is preserved. There is mild LV hypertrophy (wall thickness 1.4 cm). He walks on a treadmill for 9 minutes, with a normal hemodynamic response.

39. Continued observation is recommended. What do you tell him is his yearly risk of sudden death, provided he remains asymptomatic?

a. <2%
b. 5%
c. 5% to 10%
d. >10%

40. What is the likelihood that he will become symptomatic, or come to surgery, within the next 3 years?

a. 10%
b. 10% to 25%
c. 25% to 50%
d. >50%

Case 26

A 52-year-old man who previously underwent AVR with a tilting disk valve presents to you several months following a documented transient ischemic attack (TIA). He has no symptoms at present. Workup at the time of his TIA included carotid Dopplers, and transthoracic and transesophageal echocardiogram. These were unremarkable. The valve was well seated and was functioning normally. No thrombus was seen. Only minimal aortic atheroma was seen. No intracardiac shunt was identified. He has been on warfarin throughout and has maintained an INR between 2 and 3. INR was 2.2 at the time of his TIA. On examination, he is in no acute distress. BP is 120/80 mmHg; pulse is 68 and regular. Carotid upstrokes are full and not delayed. Crisp valve closure sound is heard along with a short, early-peaking systolic ejection murmur at the base. No S_3 is heard. P_2 is normal. No peripheral edema is noted.

41. Which of the following would you recommend?

- **a.** Start ASA (acetylsalicylic acid), 325 mg/day.
- **b.** Increase warfarin, to achieve an INR of 3.5 to 4.5.
- **c.** Increase warfarin, to achieve an INR of 4.0 to 5.0.
- **d.** Start ASA, 81 mg/day, and increase warfarin, to achieve an INR of 2.5 to 3.5.

42. If his transesophageal study had revealed a small (1 to 2 mm) echodensity on the valve strut—suggestive of thrombus—but no obstruction to valve function, what should have been done?

- **a.** Intravenous heparin
- **b.** Bolus thrombolytic therapy
- **c.** Reoperation
- **d.** Intravenous IIb/IIIa inhibitors

Case 27

You are following a 50-year-old man with moderate mitral stenosis, who had been asymptomatic. He presents to the emergency room with complaints of mild exertional dyspnea and palpitations, present for the past 3 to 4 days. On arrival, he appears comfortable, with an O_2 saturation of 99% on room air. His pulse rate is 140 bpm and irregular. BP is 130/75 mmHg. Electrocardiogram reveals atrial fibrillation.

43. The above patient spontaneously converts to sinus rhythm. Which of the following are you most likely to recommend?

- **a.** Therapy with warfarin
- **b.** Percutaneous valvuloplasty
- **c.** Mitral valve replacement

d. No change in therapy

Case 28

A 34-year-old woman presents to your office for evaluation because she had been on treatment with anorectic agents 5 years ago. She is asymptomatic at this time. She is now at her ideal body weight. On examination, she is in no acute distress. BP is 107/68 mmHg. Jugular venous pulsations appear normal. Chest is clear. Cardiac examination reveals a nondisplaced PMI. S_1 and S_2 are normal, with an appropriate physiologic split of S_2. P_2 is not loud. No S_3 or S_4 is heard. Auscultation is performed with the patient sitting, supine, and in the left lateral decubitus position. No murmur is heard.

44. What do you most likely recommend for this patient?

a. Reassurance, with a repeat physical examination in 6 months
b. Echocardiogram
c. Stress test
d. TEE

Case 29

A 50-year-old man presents for his first physical examination in several years. He notes that a murmur had been documented a number of years ago. He is entirely asymptomatic. On examination, he has a BP of 120/70 mmHg with a pulse rate of 58 bpm. Neck veins are not distended. Carotid upstrokes are brisk. Lungs are clear. Cardiac examination reveals a nondisplaced PMI. S_1 is soft; S_2 is normal (with a preserved A_2). An S_3 is heard. A III/VI holosystolic murmur is heard at the apex radiating to the base and carotids, which increases with handgrip.

Echocardiogram reveals myxomatous mitral valve disease with posterior leaflet prolapse and severe MR. The prolapse involves the P_2 (middle) segment and is severe. There is no calcification of the valve. End-systolic dimension is 3.0 cm; end-diastolic dimension is 5.6 cm. Ejection fraction is 65%. TR velocity is 2.9 m/s.

45. Which of the following would be most appropriate at this time?

a. Referral for mitral valve replacement
b. Consider elective mitral valve repair at a hospital where repair is performed with a high degree of success or if he wishes to defer surgery, follow up at 6 monthly intervals with echo
c. The addition of an ACEI and follow-up in 2 years
d. The addition of amiodarone to prevent atrial fibrillation
e. Follow-up in 2 years without an echocardiogram

46. The above patient agrees to close medical follow-up. However, he does not present back to your office until 2 years later, now with complaints of dyspnea. A repeat echocardiogram reveals an ejection fraction of 45% with an end-systolic dimension of 4.7 cm. What do you recommend?

a. Referral for mitral valve repair
b. Start an ACEI and reassess in 3 months
c. Mitral valve replacement
d. Start a β-blocker and reassess in 3 months

Case 30

An 80-year-old man with severe AS is turned down for surgical AVR due to significant comorbidities. He is referred to you for consideration for transcatheter AVR.

47. Which of the following findings is considered a contraindication for this procedure?

a. Calcified and tortuous femoral arteries
b. The apex is not accessible
c. Life expectancy <1 year
d. A history of treated endocarditis
e. Annulus size of 20 mm

Case 31

A 35-year-old man presents to your office for evaluation of valvular heart disease. He complains of shortness of breath with only modest amounts of exertion, as well as two-pillow orthopnea. He also complains of easy fatigability, as well as lower extremity edema and abdominal fullness. On examination, he is in no acute distress. He is normotensive. Jugular venous pressure is elevated, with a prominent a wave. The v wave is not easily discerned. S_1 is loud. S_2 is normal. A sound is heard in diastole, 0.07 milliseconds after S_2. A diastolic rumble is heard at the apex. A diastolic murmur is also heard along the left sternal border, which increases with inspiration. Mild hepatomegaly is present. There is 2+ peripheral edema.

48. What is your diagnosis?

a. Mitral stenosis
b. Mitral stenosis with tricuspid insufficiency
c. Mitral and tricuspid stenosis
d. Mitral stenosis and AS
e. Tricuspid stenosis

Case 32

An 80-year-old man presents to your office with complaints of chest tightness when

climbing up a flight of stairs. His past medical history is unremarkable. On physical examination, he is in no acute distress. BP is 140/80 mmHg; pulse is 78 bpm and regular. Chest is clear. Carotid upstrokes are diminished. The PMI is sustained, but not displaced. A fourth heart sound is present. The second heart sound is diminished and single. A loud late-peaking systolic murmur is heard, loudest at the second intercostal space, radiating to the neck.

49. Which of the following would be a reasonable next step in this patient's management?

- **a.** Stress sestamibi
- **b.** Stress electrocardiogram
- **c.** Cardiac catheterization
- **d.** Prescribe prn SL (sublingual) NTG (nitroglycerin) and review back in one week

50. The above patient is found to have an aortic valve area of 0.7 cm^2 with a mean gradient of 60 mmHg. Following catheterization, he develops massive upper gastrointestinal bleeding. Endoscopy reveals a gastric ulcer with a bleeding vessel at its base. Cauterization is performed, which temporarily stops the bleeding. However, the bleeding recurs and urgent partial gastrectomy is recommended. He complains of chest pain during these bleeding episodes. What is the best course of action?

- **a.** Proceed to AVR first.
- **b.** Refer for percutaneous balloon valvuloplasty, followed by gastrectomy.
- **c.** Start nitroprusside and proceed with gastric surgery.
- **d.** Proceed with gastric surgery directly.

51. What valve would you recommend to an 80-year-old patient with severe symptomatic AS?

- **a.** Bovine pericardial valve
- **b.** Ball-and-cage mechanical valve
- **c.** Bileaflet mechanical valve
- **d.** Aortic homograft

Case 33

A 28-year-old man presents for evaluation of difficult to control hypertension. He initially denies any symptoms but on further questioning admits to some leg fatigue and weakness and cold feet. On examination his BP is 180/90 mmHg, heart rate is 77 bpm and regular. His radial pulses are easily palpable but his femoral pulses are weak and there is radiofemoral delay. An ejection systolic murmur is heard at the left upper sternal border that radiates to the intrascapular region. In addition, there is a soft

continuous murmur heard throughout the precordium.

52. Based on your suspicion you order a CT aorta (Fig. 2.9). What is the most common associated lesion?

a. ~5% of cases have a bicuspid aortic valve.
b. ~50% of cases have mitral valve prolapse.
c. ~50% of cases have a bicuspid aortic valve.
d. ~5% of cases have an associated cleft mitral valve.
e. This lesion is rarely associated with concomitant cardiac abnormalities.

Figure 2.9

Case 34

A 65-year-old man with a history of rheumatoid arthritis (well controlled) presents for evaluation of a heart murmur. He notes some increase in fatigue and decrease in activity level over the past 2 years, but denies any specific complaints of dyspnea. He leads a

rather sedentary lifestyle. On examination, he is 6-ft, 1-in. tall. BP is 150/50 mmHg. Heart rate is 80 bpm and regular. Carotid upstrokes are brisk with a rapid upstroke and decline. Apical impulse is displaced and hyperdynamic. S_1 and S_2 are normal. A decrescendo, nearly holodiastolic murmur is heard along the left sternal border, loudest with the patient sitting up. An echocardiogram is performed, which reveals a dilated LV (end-diastolic dimension of 6.8 cm and end-systolic dimension of 3.5 cm). Ejection fraction is 55%. There is significant aortic regurgitation.

53. What do you most likely recommend?

- **a.** Stress test
- **b.** Reassess with repeat echocardiogram in 6 months
- **c.** Start vasodilator therapy and reassess in 2 years
- **d.** Refer to surgery

54. He is started on a vasodilator and is seen back in 6 months. He reports no change in symptoms. A repeat echocardiogram demonstrates an end-diastolic dimension of 7.6 cm. Ejection fraction remains normal. What do you recommend now?

- **a.** Stress test
- **b.** Surgical intervention
- **c.** Increase vasodilators and reassess in 6 months
- **d.** MRI to assess LV volumes

Case 35

A 42-year-old woman, who underwent mitral valve replacement with a bileaflet tilting disk valve for rheumatic disease, presents to the emergency room with complaints of severe dyspnea. On examination, she has a BP of 120/60 mmHg. Heart rate is 83 bpm. Chest reveals bilateral crackles, one-third up. Cardiac examination reveals a nondisplaced PMI. Prosthetic clicks are muffled. A long diastolic rumble is heard at the apex. Her past medical history is otherwise unremarkable.

55. An echocardiogram is ordered on the above patient. Which of the following would you expect to see?

- **a.** Severe MR
- **b.** Mean gradient across the mitral prosthesis of 17 mmHg
- **c.** Pressure half-time of 80 milliseconds
- **d.** Ejection fraction of 20%

Case 36

A 26-year-old woman presents to your office for evaluation. She was told she had a murmur many years ago. She has a history of palpitations, but is otherwise

asymptomatic. On examination, she is in no acute distress. Prominent v waves are noted in the JVP. Carotid upstrokes are normal. Chest is clear to auscultation. Cardiac examination reveals a nondisplaced PMI. Auscultation reveals a widely split first heart sound, with a loud second component that sounds like a click. A holosystolic murmur is heard at the right sternal border, which increases with inspiration. Hepatomegaly is present. An echocardiogram is performed (Fig. 2.10).

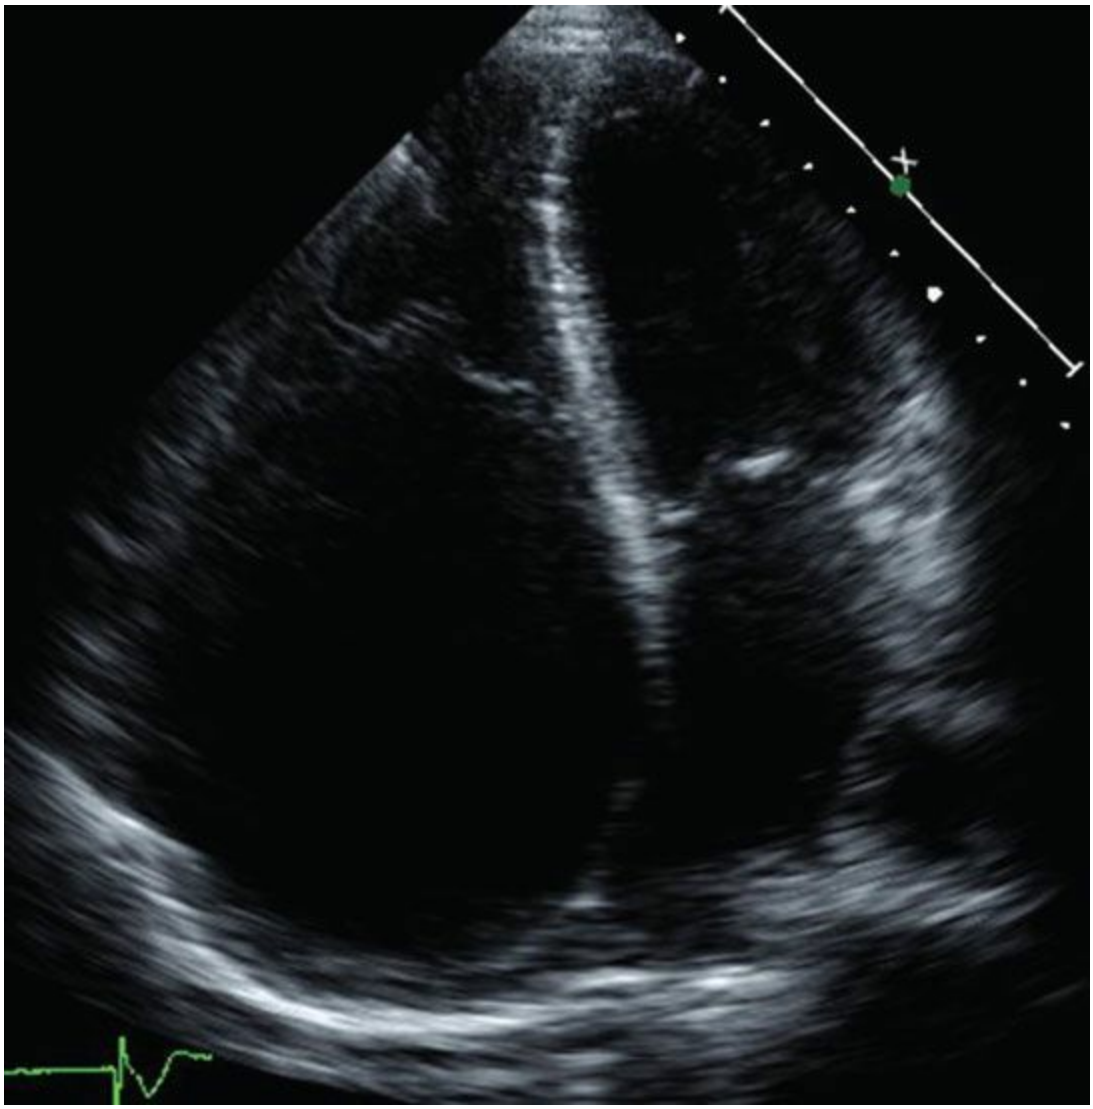

Figure 2.10

56. What is the most likely cause for her palpitations?

a. Arrhythmias secondary to an accessory pathway
b. AV nodal reentrant tachycardia
c. Ventricular tachycardia
d. Atrial fibrillation
e. Anxiety

57. No intervention is performed for the above patient. She returns to your clinic 3 months later. She describes an episode of transient word-finding difficulty, which lasted for a number of seconds. This occurred while she was recovering from a fractured tibia. A CT scan was performed, which was negative. She is concerned that she may have a recurrence. What is the most appropriate next test for her?

a. Echocardiography with saline contrast study
b. Carotid Dopplers
c. 24-hour ambulatory electrocardiographic monitoring
d. Right heart catheterization with oxygen saturation run

Case 37

A 21-year-old man presents to your office for evaluation. He tells you that a murmur was noted a few days after birth. He is presently asymptomatic. On examination, he is normotensive. Pulse is 65 bpm and regular. Carotid upstrokes are normal. Chest is clear. Cardiac examination reveals a nondisplaced PMI. An RV lift is present. A systolic thrill is present in the suprasternal notch. A high-pitched sound is heard after S_1. A crescendo–decrescendo systolic murmur is heard at the left second intercostal space. A_2 is normal.

58. Which of the following would you expect to find on echocardiography?

a. V_{max} across the aortic valve of 4 m/s
b. V_{max} across the pulmonic valve of 4 m/s
c. A wide jet of mitral insufficiency
d. Flow reversal in the hepatic veins

59. The above patient returns 1 year later for follow-up. Which of the following is a definite indication for intervention?

a. He tells you of an episode of syncope
b. No symptoms, but RV to PA peak gradient of 30 to 39 mmHg
c. No symptoms, but RV to PA peak gradient of 20 to 29 mmHg
d. He has occasional feelings that his heart has extra beats

60. If intervention is recommended, what is the preferred treatment approach?

a. Percutaneous valvuloplasty
b. Ross procedure
c. Mechanical valve
d. Bioprosthetic valve

61. In the setting of AS with moderate insufficiency, which of the following methods

would provide the most accurate estimate of aortic valve narrowing?

a. Invasive hemodynamics, using the Gorlin formula
b. Doppler echocardiography, using the continuity equation
c. Pressure half-time
d. Bernoulli equation

62. Which of the following valves has the lowest incidence of endocarditis?

a. Mechanical valve
b. Bioprosthetic valve
c. Aortic homograft
d. Stentless mitral valve

63. What is the most common cause of TR in an adult population?

a. Rheumatic tricuspid disease
b. Carcinoid
c. Congenital abnormalities
d. Pulmonary hypertension resulting from primary left-sided disease
e. Myxomatous disease of the tricuspid valve

64. The most common organism seen in native valve endocarditis is what?

a. Streptococcus viridans
b. Enterobacter faecalis
c. Staphylococcus aureus
d. Chlamydia pneumoniae
e. HACEK organisms

65. A patient presents with systemic embolic events 1 month after uncomplicated mitral valve replacement. He has been febrile for the past week. TEE demonstrates multiple echodensities on the valve ring. Blood cultures that are drawn are most likely to grow which of the following?

a. Streptococcus viridans
b. Staphylococcus aureus
c. Staphylococcus epidermidis
d. E. faecalis
e. Candida albicans

ANSWERS

1. **b.** Transesophageal echocardiography (TEE). The clinical history is of a patient who had an inferior wall myocardial infarction approximately 1 week ago. He now presents in shock with acute congestive heart failure. Mechanical complication of myocardial infarction is first on the differential. The presence of a ventricular gallop and an apical murmur without a thrill makes papillary muscle rupture the leading diagnosis (as opposed to ventricular septal defect). Transthoracic echocardiography may miss eccentric jets in this setting. TEE should be performed to make the diagnosis. He will certainly need a cardiac catheterization (at which time a saturation run may be performed), but a TEE should be done quickly at the bedside to confirm the diagnosis so that the surgical team can be mobilized.

2. **b.** Posterior papillary muscle rupture as it has a single blood supply. The 3D reconstruction of the mitral valve shown here is orientated in the "surgeons view," looking down on the mitral valve from the left atrium with the aortic valve situated on top, the anterior mitral valve leaflet adjacent to it, and the posterior mitral valve leaflet inferiorly. We see a bulky mass (the posterior papillary muscle) protruding into the left atrium in systole. The middle panel (early diastole) clearly shows that the mass is attached to the posterior leaflet. The posterior papillary muscle has a single blood supply (usually the right coronary artery), while the anterior papillary muscle often has dual blood supply. For this reason, post infarction rupture of the posterior papillary muscle is more common.

3. **b.** She likely has more severe MR than is evident on the echocardiogram. Her examination is suggestive of severe MR. The echo confirms LV dilation and mitral leaflet pathology, which could be consistent. The eccentric nature of the jet suggests that it may have been underestimated by transthoracic imaging. A more definitive imaging procedure such as TEE will be helpful here.

4. **b.** Mitral valve surgery. The presence of mild LV dysfunction with LV dilation is a class I indication for surgery. TEE would be the next test of choice prior to surgery to confirm the severity and mechanism of MR and assess suitability for surgical repair. While exercise echo is reasonable in asymptomatic patients with severe MR to assess functional capacity the patient already has indications for surgery.

5. **c.** Stress echocardiogram, to assess for mitral pressures post stress. She has moderate mitral stenosis. The fact that she has stopped exercising may be a clue to the onset of symptoms. An assessment of functional capacity and post-stress mitral pressures would be useful in management There are insufficient data for immediate referral for intervention. Follow-up in a short period of time may not be unreasonable; however, 2 years is too long a period.

6. **a.** Consideration for percutaneous valvuloplasty. Her functional capacity is below average for her age. Her valve is favorable for percutaneous valvuloplasty (splittability score of 6) and she had a significant rise in PA pressures post stress. Ideally, the splittability index should be 8 or less for optimal results post balloon valvuloplasty. A increase in mean valve gradient of 15 mmHg with exercise is a class I indication by the American College of Cardiology (ACC)/American Heart Association (AHA) guidelines. A β-blocker would not be an unreasonable addition, but she should be followed more frequently than every 2 years. In addition, she does have class I indication for intervention. She has normal LV function and is in sinus rhythm—there is no role for digoxin in this setting. Valve replacement is considered only if the valve is deemed unsuitable for percutaneous valvuloplasty or surgical repair.

7. **b.** Carcinoid. The history and examination are consistent with tricuspid stenosis and regurgitation. (She has symptoms of fatigability from decreased cardiac output, signs, and symptoms of systemic venous congestion—hepatic distension and right upper quadrant pain, peripheral edema, and ascites. There is a diastolic murmur along the sternal border, which increases with inspiration, along with a prominent a wave in the JVP. In addition, she has a pansystolic murmur and a prominent v wave.) However, no evidence for mitral stenosis is noted on examination. Isolated rheumatic tricuspid stenosis is very rare. Thus, other causes for tricuspid stenosis should be considered. The second most common cause of tricuspid stenosis is the carcinoid syndrome. She also has bronchospasm and diarrhea, which go along with this diagnosis. She has a normal P_2, making primary pulmonary hypertension unlikely. Liver disease in and of itself would not produce elevation in the JVP.

8. **c.** Check lower extremity BP. He has a bicuspid aortic valve (an ejection sound is heard, along with a short systolic ejection murmur). There is an association between bicuspid aortic valves and coarctation of the aorta. Therefore, looking for discrepancy between the upper and lower extremity BP would be paramount.

9. **c.** Dobutamine echocardiogram. This is a patient presenting with low-gradient AS in the setting of LV dysfunction. It may be that the patient has severe AS, but the gradients are now low secondary to decreased stroke volume. However, the degree of AS may not be that significant, but because of decreased cardiac output, the continuity equation overestimates AS severity. In this setting, low-dose dobutamine echocardiography may be useful. With inotropic stimulation, an improvement in stroke volume and cardiac output may help to differentiate true severe AS from what has been labeled pseudo-AS. If true severe AS is not present, then valve area will increase. It would not be prudent to send such a patient to aortic valve surgery

without performing such an evaluation. It would be necessary to exclude severe stenosis before proceeding with transplant evaluation. ACEI may be beneficial, but it would be important to proceed with the workup as above first. Afterload reduction would need to be introduced with very careful hemodynamic monitoring if true severe AS were in fact present. The use of dobutamine echocardiographic testing to evaluate low-gradient AS in the setting of LV dysfunction is a class IIa indication by ACC/AHA guidelines.

10. **a.** AVR. The patient has true, severe AS and although may have a higher potential complication rate with surgery is likely to benefit prognostically and symptomatically from surgery. Balloon aortic valvuloplasty has not been shown to improve survival without the addition of a more definitive procedure such as aortic valve surgery. It is only indicated for palliation or as a bridge to a more definitive procedure such as transcatheter aortic valve replacement (TAVR) or surgery.

11. **d.** Patient has a lack of contractile reserve but should still be considered for AVR. There are three possible outcomes to a low-dose dobutamine test in this situation: true AS, pseudo-AS, and absence of contractile reserve. As was the case in Question 10, there may be an increase in stroke volume (defined as ≤20% increase from baseline) associated with an increase in transvalvular gradients (mean gradient >40 mmHg) without a significant increase in aortic valve area (AVA) (AVA increase <0.2 cm^2) indicative of true AS. Conversely, in pseudo-AS the increase in stroke volume is associated with an increase in AVA without a significant change in gradients. Finally, absence of contractile reserve is defined as failure to increase the stroke volume by ≤20% from baseline. In this case, dobutamine does not help to differentiate between the former two scenarios. While there is a significantly higher mortality during the perioperative period in those with the absence of contractile reserve compared with true AS, for those that survive surgery their 5-year survival is significantly better than those treated with medical therapy alone. Therefore, surgery should be considered on an individual basis.

12. **b.** Addition of vasodilator therapy. The patient is asymptomatic with good functional capacity. He has a normal ejection fraction with a mildly dilated LV. Surgery is a class III indication (harmful) in this setting. Vasodilator therapy may have some benefit in this asymptomatic population with preserved ejection fraction and LV dilation, although this is not definite. This is a class IIb indication. However, he has systolic hypertension which is likely at least in part related to his aortic regurgitation, and vasodilator therapy is an optimal therapy for this. Observation alone would be reasonable, but such a patient should be followed at 6-month

intervals initially and not every 3 years. There is no role for cardiac catheterization at this juncture.

13. **a.** <1%. From the available published literature, as summarized in the ACC/AHA consensus guidelines, the risk is about 0.2% per year in those asymptomatic patients with preserved LV function.

14. **d.** Referral for surgical intervention to repair or replace his aortic valve and to replace his ascending aorta. An aortic dimension >5.0 cm (or growth >0.5 cm per year) in a patient with a bicuspid aortic valve is a class I indication for surgery. The valve is often repairable in bicuspid valve associated with predominant aortic regurgitation assuming the mechanism is due to prolapse of the conjoint cusp, and there is no significant stenosis or calcification of the valve.

15. **d.** AVR with tricuspid valve repair if feasible. The mitral valve appears morphologically normal. After relief of the outflow tract obstruction, the MR will likely improve; therefore, mitral valve repair is not indicated. Tricuspid valve repair for moderate TR at the time of left-sided valve surgery is reasonable in the context of annular dilation and elevated PA pressures. This is a class IIb indication from the ACC/AHA guidelines but receives a class IIa recommendation from the European Society of Cardiology (2012). Tricuspid valve repair is favored over replacement.

16. **a.** 0.4 cm^2. The EROA based on the assumptions above is 0.4 cm^2 consistent with severe MR. The EROA is calculated using the abbreviated proximal isovelocity surface area (PISA) method as $r^2/2$ (r = radius of the PFCR). In this case, the radius is 0.9 cm; therefore, the EROA can be estimated as 0.4 cm^2.

17. **b.** 2+, moderate. Using the complete PISA method and calculating the regurgitant volume, the MR is determined to be only moderate in severity which is consistent with the brief duration of MR heard on physical examination. The complete method for calculating the EROA is $(2\pi r^2 \times AV)/ V_{max}$ (AV: aliasing velocity; V_{max}: maximum velocity across the mitral valve); therefore, in this case the EROA = $(2\pi(0.9)^2 \times 38.5)/600 = 0.33$ cm^2. However, as we see from the continuous-wave Doppler signal, the MR only occurs in late systole consistent with mitral valve prolapse. The regurgitant volume is equal to EROA × VTI_{MR} (VTI_{MR} = velocity time integral of the mitral regurgitation), which in this case is = 0.33 × 100 = 33 mL consistent with 2+ MR. If we used the EROA from the abbreviated PISA method (0.4 cm^2), the regurgitant volume is 40 mL, which is still consistent with moderate

MR.

18. **a.** Transesophageal echocardiogram. Left atrial and appendage thrombus should be excluded prior to proceeding with percutaneous valvuloplasty and is recommended by ACC/AHA guidelines to be performed prior to the procedure. Transthoracic echocardiography does not have sufficient sensitivity for this purpose. Documentation of atrial fibrillation by ambulatory monitoring may make the likelihood of finding a thrombus higher, but the transesophageal echocardiogram should be performed regardless. Routine surveillance for aortic calcification has no role in this setting. A nuclear perfusion study would not be necessary here (angiography can be performed if needed at the time of the procedure).

19. **a.** It is absolutely indicated. Given LV dysfunction (EF < 50%), this is a class I indication for surgery. There is no question as to the severity of the AS given the gradients and the aortic valve area; thus dobutamine echocardiography is not of value here.

20. **d.** The rate of mortality, for a patient with these findings, is higher compared with patients with severe AS and high gradients across the aortic valve but aortic valve surgery has resulted in better outcomes in these patients. This woman has paradoxical low-gradient, severe AS with preserved ejection fraction. Her clinical history, examination, and 2D imaging of the aortic valve are consistent with severe AS. She has a low indexed stroke volume (<35 mL/m^2), resulting in low gradients across the AV but the dimensionless index and AVA both are consistent with severe AS. When there is discordant echocardiographic data the accuracy of measurements should always be looked at again; however, in this case, the low gradients are consistent with low-stroke volume. There are currently no guidelines from the ACC or AHA on how to manage these patients; however, the recent 2012 European Society of Cardiology guidelines for valvular heart disease provide a class IIa recommendation for AVR in symptomatic patients with paradoxical low-gradient, severe AS with preserved ejection fraction. A number of studies have confirmed that the rate of mortality is higher in this cohort when compared with patients with severe AS and high gradients but surgery on the aortic valve is associated with significantly better outcomes.

21. **c.** Aortic root dimension. The patient clinically has severe AI. The murmur is loudest at the right sternal border, suggesting aortic root dilation as a potential cause of his AI. The presence of root dilation (≤5.5 cm) may lead to earlier surgery, hence is vital to know. The diastolic rumble is most likely an Austin Flint murmur and not concomitant mitral stenosis (no opening snap, S_1 not loud).

22. **a.** Cardiac catheterization with aortography. Clinically, the patient has severe aortic regurgitation. He is symptomatic. Consistent with this, the echocardiogram reveals a dilated LV with low normal systolic function. The degree of aortic regurgitation must be underestimated by this study. When there is such discrepancy, proceed with aortography to confirm aortic regurgitation severity and to assess coronaries prior to surgical referral. As he is symptomatic, continued observation and/or medical therapy is not the preferred treatment approach. β-Blockers, by prolonging the diastolic filling period, could actually increase regurgitant volume.

23. **a.** Transesophageal echocardiogram, emergent cardiac surgical consultation. The patient has a clinical presentation of severe acute AI (short diastolic murmur, soft S_1 from premature mitral valve closure, low output state, and pulmonary edema). In the context of chest pain, this scenario suggests aortic dissection until proven otherwise. The dissection flap likely involves the ostium of the right coronary artery, producing the inferior ST-segment elevation. Thrombolytics should not be used until dissection is ruled out. Even if there is no dissection, an intra-aortic balloon pump should not be used with severe AI. The augmented diastolic pressure worsens the severity of the insufficiency. MRI would also provide the diagnosis, but given the hemodynamic instability of the patient, a bedside TEE would be a safer and quicker option to arrive at the diagnosis.

24. **b.** No evidence for dysfunction. The physical examination does not suggest either stenosis or insufficiency. He appears to be in a high-output state, secondary to his febrile illness. As a result, the gradients are increased. The LVOT VTI is also increased, secondary to the increased cardiac output. The LVOT/aortic valve VTI ratio is the same in the two echocardiograms, which would speak against any significant obstruction.

25. **a.** TEE with surgical consultation. The clinical scenario, with a new first-degree AV block and acute aortic regurgitation, is highly suspicious for prosthetic valve abscess and possibly even partial dehiscence. A transesophageal echocardiogram should be performed, but prompt surgical consultation should also be requested given the high suspicion for aortic root abscess and the onset of heart failure symptoms.

26. **c.** Repeat echocardiogram with planimetry of mitral valve area. With acute changes in atrial and ventricular compliance (as with valvuloplasty), the half-time is unreliable. Usually 72 hours or more is required after the procedure before the half-time can be used with reasonable reliability. Planimetry, if performed correctly, would provide a more reliable estimate of stenosis severity. Clinically, the patient

seems to have had a good result (longer S_2–OS interval, shorter murmur). TEE rarely provides incremental data on mitral stenosis if the transthoracic images are reasonable.

27. **a.** Observation. The shunt is secondary to the valvuloplasty procedure where the interventionalist must perform an interatrial septal puncture in order to access the mitral valve. Most of these small shunts will close over the next 6 months without any intervention. The shunt is left to right by color. He has good O_2 saturation on room air, making any significant right-to-left shunting unlikely. Anticoagulation with an atrial septal defect/patent foramen ovale may be recommended in certain settings, however not indefinitely, given the good chance that the defect will close.

28. **b.** Antibiotic prophylaxis, with yearly office visits. He requires antibiotic prophylaxis with a prosthetic valve (by 2007 guidelines, prosthetic cardiac valves are an indication for subacute bacterial endocarditis prophylaxis prior to dental procedures). These patients still require close follow-up with complete evaluation on a yearly basis. Some advocate a 3-month period of warfarin therapy after bioprosthetic valve placement. He is now 4 months out, and has no other indications or a high-risk profile (LV dysfunction, prior embolic event, and atrial fibrillation); thus warfarin is no longer needed at this time. Similarly, there is no specific indication in this man for clopidogrel therapy.

29. **e.** No therapy at present but follow carefully with serial clinical and echo evaluation. Antibiotics are not recommended routinely for prophylaxis at the time of delivery for patients with valvular heart disease unless infection is suspected. If there is evidence of pulmonary congestion treatment with diuretics and afterload reduction with hydralazine is recommended but ACEIs are teratogenic and are absolutely contraindicated in pregnancy. Your patient is clinically euvolemic and therefore medical therapy need not be initiated. Surgery should only be performed if the mother's life is threatened due to the associated high fetal mortality rate (20% to 30%). Management will involve close follow-up and monitoring by her cardiologist and obstetrician and treatment only if her clinical situation deteriorates.

30. **a.** TEE. The echocardiogram reveals a normal-appearing aortic valve. Yet, the profile of the continuous-wave Doppler jet is more consistent with a fixed obstruction, as opposed to the dagger shape of dynamic obstruction. These findings are suggestive of the presence of a subvalvular membrane. TEE would be useful to better delineate this area and identify the membrane. The patient already has a 5-m jet in the absence of systolic anterior motion; therefore, it would not be prudent to

use provocation with amyl nitrate. A stress echocardiogram would have no diagnostic value and may have some risk in the setting of symptomatic LVOT obstruction. One should always consider contamination with an MR signal; however, the physical examination is consistent with outflow tract obstruction and the continuous-wave Doppler signal begins after the QRS (after isovolumetric relaxation) consistent with outflow tract obstruction. The MR signal will begin earlier relative to the QRS (through isovolumetric contraction).

31. **c.** There is no clear role for aspirin therapy in such patients. If there is echocardiographic evidence for high-risk mitral valve prolapse (leaflet thickening, elongated chordae, left atrial enlargement, and LV dilation), aspirin therapy is considered a class IIb indication. Therapy is clearly recommended if there have been documented stroke or transient ischemic events.

32. **b.** Continue with vasodilator therapy and reassess in 6 months. By ACC/AHA guidelines, decline in ejection fraction following stress echocardiography by itself is not an accepted indication for referral to surgical intervention. Owing to the high afterload and the increase in afterload on exercise, a small-to-modest decline in ejection fraction (<10%) may still be consistent with well-compensated AI. This patient has normal resting ejection fraction and mildly dilated LV with excellent functional capacity.

33. **b.** Repeat the echocardiogram with amyl nitrate (Fig. 2.11). The physical examination is highly suggestive of hypertrophic cardiomyopathy (brisk, bisferiens carotid pulse, normal S_2, and murmur increasing with Valsalva and decreasing with handgrip). The patient may not have a significant resting gradient, but may have a significant provocable gradient. Generally, a transesophageal echocardiogram is not needed to make the diagnosis. Invasive hemodynamics with provocation would be useful, but angiography alone would not be sufficient.

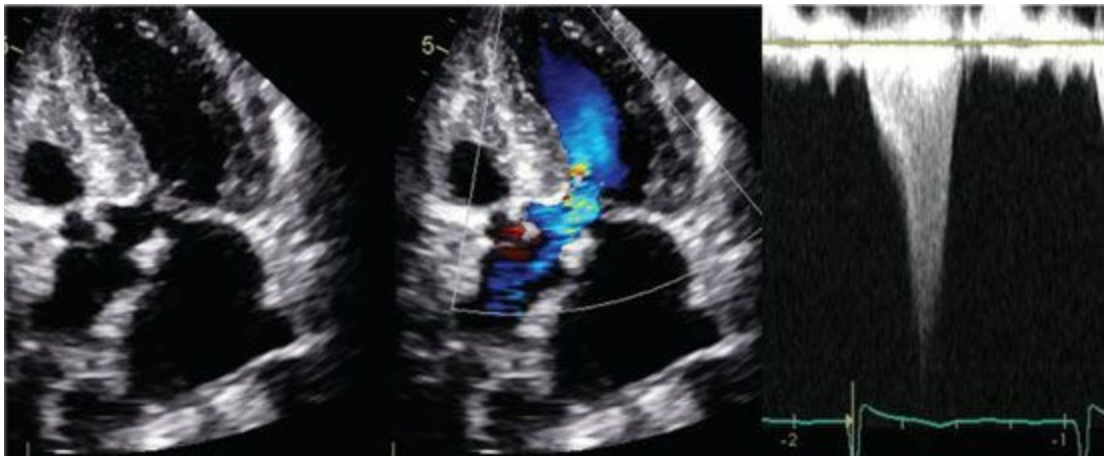

Figure 2.11

34. **c.** She will probably not need surgery on her mitral valve. MR secondary to systolic anterior motion of the mitral valve is related to hydrodynamic drag and Venturi effects on the anterior mitral valve. Often there are intrinsic mitral valve abnormalities that, in combination with septal hypertrophy, predispose to systolic anterior motion. Abnormal chordal attachments or hypermobile papillary muscles seen best on cardiac MRI may mandate chordae remodeling or papillary muscle reorientation; however, in this case the mitral valve apparatus is noted to be structurally normal. Relief of the hydrodynamic effects of a narrowed LVOT after myectomy will usually result in significant improvement in MR without further surgery. Before chest closure, careful assessment of MR should be done after the myectomy, usually with isoproterenol infusion, to ensure resolution.

35. **b.** Transesophageal echocardiogram. By examination, the patient has mitral insufficiency. The echocardiogram is consistent with this, with an elevated peak transmitral gradient. Pressure half-time is not prolonged; thus there does not appear to be any significant stenosis (gradients elevated owing to increased flow from regurgitant volume). A TEE would be the most useful to confirm the diagnosis. Fluoroscopy may identify partial dehiscence, but would not be helpful if there were a leak in the setting of a well-seated valve. There is no evidence for stenosis, where fluoroscopic evaluation of leaflet motion could be diagnostic. There is no clinical evidence for endocarditis.

36. **a.** Prominent closing click, soft and brief diastolic rumble. The bileaflet mechanical valves do not typically produce a loud opening sound, but do have prominent closing sounds. A brief diastolic rumble may be heard in a normally functioning prosthetic valve in the mitral position.

37. **b.** Prominent opening and closing clicks, soft and brief diastolic rumble. With the ball-and-cage valves, one would expect to hear the opening click as well.

38. **e.** Warfarin therapy with a target INR of 2.5 to 3.5 plus aspirin 75 to 100 mg. All patients with a mechanical valve require warfarin. The risk of thromboembolic events is higher for prosthetic valves in the mitral position; therefore, the recommended therapeutic range is higher than that for mechanical valves in the aortic position. The addition of low-dose aspirin (75 to 100 mg) further reduces the risk of thromboembolic event and reduces mortality from cardiovascular disease. Therefore, aspirin is recommended for all patients with valvular prostheses. Higher doses of aspirin have not been shown to be beneficial and increase the bleeding

risk.

39. **a.** <2%. In the absence of symptoms, natural history studies would suggest a relatively low risk of sudden death.

40. **d.** >50%. He has a velocity across the aortic valve of >4 m/s. Observational studies would suggest a high likelihood of symptom development in the next 3 years.

41. **d.** Start ASA, 81 mg/day, and increase warfarin to achieve an INR of 2.5 to 3.5. ACC/AHA guidelines recommended an INR of 2.5 to 3.5 for patients with bileaflet tilting disk mechanical valves in the aortic position who have had a thromboembolic event, and who have atrial fibrillation, LV dysfunction, or a hypercoagulable state. Addition of low-dose ASA (75 to 100 mg) is a class I indication for all patients with mechanical heart valves, and those with the above risk factors and bioprosthetic valves.

42. **a.** Intravenous heparin. Since a small clot was present (without any obstruction to valve function) the patient would benefit from increased anticoagulant therapy. If he were to fail this, then the other alternatives could be considered, such as continuous infusion thrombolytic therapy. Such continuous therapy (although not bolus) could also be used as primary treatment. No established indications exist at this time for glycoprotein IIb/IIIa inhibitors in this clinical setting. It would not be advisable to proceed to reoperation just yet, in the absence of a large clot burden or obstruction to inflow. If treatment with heparin leads to clot resolution, then subsequent warfarin dosing should be increased to maintain INR in the 3.0 to 4.0 range.

43. **a.** Therapy with warfarin. He should be on warfarin. Valvuloplasty in this setting (onset of atrial fibrillation, in an otherwise asymptomatic patient) is a class IIb indication by current guidelines.

44. **a.** Reassurance, with a repeat physical examination in 6 months. If a thorough physical examination reveals no signs of cardiopulmonary disease and the patient has no symptoms, then reassurance and follow-up are all that are required. Echocardiography should be performed if obesity limits the physical examination or if signs or symptoms are present.

45. **b.** Consider elective mitral valve repair at a hospital where repair is performed with a high degree of success or if he wishes to defer surgery, follow up at 6 monthly intervals with echo. Referral for surgery is reasonable (class IIa indication) if chance of repair is >95%. There are no data to suggest a beneficial

role for the addition of afterload-reducing agents in the absence of systemic hypertension (again by ACC/AHA guidelines). There is absolutely no role for the prophylactic use of amiodarone. Close clinical follow-up is reasonable, but repeat evaluation should not be deferred for 2 years. Guidelines use LV dimensions and ejection fraction to guide surgical intervention, even in the absence of symptoms. As such, these patients should have clinical reevaluation and echo every 6 months.

46. a. Referral for mitral valve repair. He is now symptomatic with depressed ejection fraction and a dilated LV. This is a class I indication for surgery. Valve repair as opposed to replacement is the preferred surgical treatment. Medical therapy may be needed as an adjunct, but is insufficient as the sole treatment.

47. c. Life expectancy <1 year. Life expectancy of <1 year, despite treatment of AS, is an absolute contraindication for TAVR. Severe peripheral artery disease precludes a transfemoral approach; however, the procedure may be done via a transapical approach, a transsubclavian approach, and even a transaortic approach. Severe pulmonary disease and an inaccessible apex preclude a transapical approach but the other approaches remain available. Active endocarditis is a contraindication to the procedure. The available valves are suitable for annular sizes between 19 and 29 mm.

48. c. Mitral and tricuspid stenoses. The loud S_1, opening snap, and apical diastolic rumble are features of mitral stenosis. The presence of the diastolic rumble along the sternal border, which increases with inspiration, along with the prominent a wave in the JVP and evidence of systemic venous congestion (hepatomegaly and peripheral edema) suggests that concomitant tricuspid stenosis is present as well.

49. c. Cardiac catheterization. By physical examination, the patient has severe AS (no A_2 of second heart sound, late-peaking murmur, and diminished carotid upstrokes). A stress test would not be appropriate in a patient with symptomatic AS. An echocardiogram would usually be the first step, but proceeding directly to catheterization to measure transvalvular gradients and assess coronary anatomy would be reasonable. SL NTG could have disastrous consequences in this setting. By reducing preload, it may precipitate syncope.

50. b. Refer for percutaneous balloon valvuloplasty, followed by gastrectomy. He has symptomatic critical AS. AVR, with concomitant need for anticoagulation while on cardiopulmonary bypass, is not an attractive first option. Proceeding directly to gastric surgery would carry high risk, given the ongoing symptoms. Valvuloplasty would be a reasonable bridge to lower risk from the noncardiac surgery.

51. **a.** Bovine pericardial valve. He is at an age where there is substantial durability of the bioprosthetic valve. He is at increased risk for anticoagulation; thus, mechanical valves would not be the valve of first choice. By history, he would not appear to need anticoagulation for any other indication. Homograft is not unreasonable, but there would not appear to be any hemodynamic or durability benefits for an 80-year-old patient, and its insertion requires a more difficult operation.

52. **c.** ~50% of cases have a bicuspid aortic valve. Coarctation of the aorta is suspected clinically and confirmed on a gated CT angiogram of the thoracic aorta. This lesion is frequently associated with concomitant congenital cardiac anomalies, the most frequent of which is a bicuspid aortic valve (occurs in ~50% to 85% of cases).

53. **a.** Stress test. The patient has significant aortic regurgitation with a dilated LV although not yet at the dimension that would be an indication for surgery in the absence of symptoms (his end-systolic dimension is <5.0 cm and end-diastolic dimension is <7.0 cm). He leads a sedentary lifestyle, and although he has no dyspnea, he does relate some equivocal symptom. A stress test would be useful to assess functional capacity and to objectively assess symptoms. If he were to develop symptoms at a low level of exercise, this may be an indication for surgical intervention. A vasodilator may be useful (class IIb indication with dilated LV), but he would need more frequent follow-up, given the LV dilation.

54. **b.** Surgical intervention. (Refer for surgery.) His ventricle has dilated even further. An end-diastolic dimension of >7.5 cm is a class IIa indication for surgery and is associated with an increased risk of sudden death, even in the absence of symptoms.

55. **b.** Mean gradient across the mitral prosthesis of 17 mmHg. The clinical presentation and examination are suggestive of prosthetic mitral stenosis (long diastolic rumble, muffled closing click, and clinical heart failure). The PMI is not displaced, so it is unlikely that she has significant LV dysfunction. There are no clinical signs of severe MR. Given the acute onset of symptoms, acute valvular thrombosis leading to valvular obstruction is high on the differential. If this were the case by ACC/AHA guidelines, reoperation would be the preferred treatment approach. If other comorbidities were prohibitive, thrombolytic therapy could be considered.

56. **a.** Arrhythmias secondary to an accessory pathway. The examination is highly suggestive of Ebstein anomaly (presence of TR, widely split first heart sound). The echocardiogram confirms this. Accessory pathways are frequently associated with this condition.

57. **a.** Echocardiography with saline contrast study. Ebstein anomaly is frequently associated with cardiac shunts (either patent foramen ovale, or atrial or ventricular septal defect). The setting of a TIA in someone who has been immobilized (such as with a fracture) raises the concern of paradoxical embolism of a venous thrombus to the systemic circulation.

58. **b.** V_{max} across the pulmonic valve of 4 m/s. The physical examination is consistent with pulmonic stenosis (presence of thrill, RV heave, ejection click, and crescendo-decrescendo murmur loudest over the pulmonic area). Normal carotid upstrokes and preserved A_2 make significant AS unlikely. The murmur is not consistent with a regurgitant murmur.

59. **a.** He tells you of an episode of syncope. The presence of exertional dyspnea, angina, syncope, or near-syncope are class I indications for intervention. For gradients between 30 and 39 mmHg, there is some divergence of opinion about the role of intervention (class IIb for gradients 30 to 39). There is no role for intervention in those with gradients <30 mmHg who have no symptoms. A peak-to-peak gradient >40 mmHg by catheterization is a class I indication for intervention, even in an asymptomatic patient.

60. **a.** Percutaneous valvuloplasty. This is the preferred treatment for young adults with pulmonic stenosis.

61. **b.** Doppler echocardiography, using the continuity equation. With significant insufficiency, the Gorlin formula becomes less reliable. Pressure half-time is not used to calculate aortic valve area, but does give a clue to the severity of the AI.

62. **c.** Aortic homograft. Mechanical and bioprosthetic valves have a similar incidence of endocarditis, which is higher than that seen for homografts. In the setting of acute bacterial endocarditis of a prosthetic aortic valve, homografts are the valve of first choice when surgery is indicated.

63. **d.** Pulmonary hypertension resulting from primary left-sided disease. The most common cause of tricuspid insufficiency is pulmonary hypertension that results from primary pathology on the left side of the heart. This includes aortic and mitral valvular diseases, as well as LV dysfunction from coronary artery disease or other cardiomyopathies.

64. **a.** Streptococcus viridans accounts for up to 50% of cases. Staphylococcus aureus is the next most common pathogen.

65. C. Staphylococcus epidermidis. This patient presents with early prosthetic valve endocarditis (within 2 months of surgery). This is usually acquired during the operation, and the skin species Staphylococcus epidermidis is the most frequent pathogen encountered. Late prosthetic valve endocarditis is similar to native valve endocarditis in terms of the spectrum of pathogens involved.

Acute Myocardial Infarction

Venu Menon • Bhuvnesh Aggarwal

QUESTIONS

1. Which one of the following statements is true regarding trends in incidence of acute coronary syndrome (ACS) in the United States?

   a. Percentage of ACS with ST-segment elevation myocardial infarction (STEMI) is declining.
   b. Percentage of ACS with non–ST-segment elevation myocardial infarction (NSTEMI) is declining.
   c. Percentage of ACS with unstable angina (UA) is increasing.
   d. Overall incidence of ACS is decreasing.
   e. All of the above.

2. Which of the following processes represents the dominant initiating event in the pathogenesis of an ACS?

   a. Plaque rupture
   b. Plaque erosion
   c. Platelet activation
   d. Venous stasis
   e. None of the above

3. What is the most important clinical predictor of 30-day mortality in a patient presenting with acute STEMI?

   a. Age
   b. Systolic blood pressure (BP)
   c. Heart rate
   d. Killip classification stage

e. Location of myocardial infarction (MI)

4. Which of the following is a prodrug and requires bioactivation?

a. Aspirin
b. Clopidogrel
c. Prasugrel
d. Ticagrelor
e. Both b and c

5. Which of the following statements regarding prasugrel is true?

a. Prasugrel has faster onset of action when compared with clopidogrel.
b. Unlike clopidogrel, prasugrel is not influenced by polymorphisms in cytochrome P450 enzyme pathway.
c. Prasugrel provided no net mortality benefit when compared with clopidogrel in patients with ACS in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction (TRITON-TIMI)-38 trial.
d. Prasugrel is contraindicated in patients with a prior history of transient ischemic attack (TIA)/stroke.
e. All of the above.

6. A 72-year-old presents with sudden-onset chest pain at a local emergency department. He has a past medical history significant for hypertension, hyperlipidemia, and gastroesophageal reflux disease. On examination his BP is 95/60 mmHg and heart rate is 90 beats per minute and he is breathing at 90% on ambient air. He reports this is the first time he has had any episode of chest pain. His electrocardiogram (ECG) reveals ST elevation in V_1 to V_4. The nearest hospital with percutaneous coronary intervention (PCI) capability is 3 hours away. What is the next step in management?

a. Perform fibrinolysis; administer unfractionated heparin, aspirin, and clopidogrel; and admit to hospital.
b. Administer unfractionated heparin, aspirin, and clopidogrel and admit to hospital.
c. Administer unfractionated heparin, aspirin, and clopidogrel followed by transfer to PCI-capable hospital.
d. Computed tomography (CT) of the chest with intravenous contrast.
e. Perform fibrinolysis; low-molecular-weight heparin (LMWH), aspirin, and clopidogrel; and transfer to the hospital for possible PCI.

7. The above patient is given intravenous tenecteplase and started on aspirin, clopidogrel, and unfractionated heparin. Thirty minutes into treatment his chest pain has now completely resolved. A repeat ECG shows complete resolution of the earlier noted ST elevation. What is the next step in management?

   a. Continue unfractionated heparin, aspirin, and clopidogrel and transfer to the nearest hospital with PCI capabilities.
   b. Admit to local hospital for observation.
   c. Discharge home with outpatient follow-up following a submaximal stress test.
   d. Discharge home with plan for possible angiography after 4 to 6 weeks.
   e. None of the above.

8. Which of the following is true for management of acute STEMI?

   a. The administration of aspirin has a much larger treatment effect than streptokinase.
   b. The administration of streptokinase has a much larger effect than aspirin.
   c. Streptokinase and aspirin each have a similar effect on outcome.
   d. When streptokinase and aspirin are used together, their effects are blunted.
   e. None of the above.

9. Which of the following is the mechanism of action of ticagrelor?

   a. Thromboxane inhibition
   b. Glycoprotein (GP) IIb/IIIa receptor blockade
   c. Adenosine diphosphate blockade
   d. Increase in cyclic adenosine monophosphate production
   e. Free radical scavenger

10. Which of the following is true regarding use of GP IIb/IIIa inhibitors in STEMI?

   a. Routine upstream use of GP IIb/IIIa inhibitors has been shown to reduce target vessel revascularization (TVR).
   b. Routine GP IIb/IIIa inhibitor use is associated with reduced incidence of recurrent MI.
   c. Routine GP IIb/IIIa inhibitor use is associated with increased risk of bleeding.
   d. Small-molecule GP IIb/IIIa inhibitor use has been shown to reduce 30-day mortality.
   e. Upstream use of GP IIb/IIIa inhibitors is given a class I indication in current American College of Cardiology (ACC)/American Heart Association (AHA) guidelines.

11. In the setting of primary angioplasty for acute MI, which of the following have stents

been convincingly shown to do compared with balloon angioplasty alone?

a. Decrease subsequent repeat TVR.
b. Decrease long-term mortality.
c. Decrease long-term MI risk.
d. Decrease the incidence of heart failure.

12. Which of the following is true about reteplase in Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO-III)?

a. It had a significantly higher rate of stroke than alteplase.
b. It significantly reduced mortality compared with alteplase.
c. It significantly reduced mortality, but increased stroke compared with alteplase.
d. It had similar rates of mortality compared with alteplase.

13. Which of the following statements is true regarding non–ST-segment elevation (NSTE)-ACS?

a. NSTEMI has poorer prognosis than UA.
b. Elevated troponin is associated with worse prognosis in NSTE-ACS.
c. ST-segment deviation is associated with increased risk of long-term ischemic events.
d. One in five patients with NSTEMI has normal ECG.
e. All of the above.

14. A 46-year-old man presents to the emergency with complaints of sudden, severe chest pain radiating to his right arm. He admits to snorting crack cocaine 2 hours prior to the development of chest pain. His BP is 180/100 mmHg and heart rate is 96 per minute. An ECG done reveals downsloping ST depression and T-wave inversion in V_2 to V_4. What is the next best step in management?

a. Administer aspirin, sublingual nitroglycerin, and intravenous metoprolol.
b. Administer aspirin and sublingual nitroglycerin.
c. Administer aspirin, sublingual nitroglycerin, and heparin.
d. Administer activated charcoal.

15. The patient is started on aspirin, nitroglycerin, and intravenous heparin. He continues to have severe substernal chest pain. Repeat ECG is unchanged. Troponin T is borderline elevated to 0.04 ng/mL. What is the next best step in management?

a. Activate the catheterization laboratory for emergent left heart catheterization.
b. Administer diazepam and let the patient rest.
c. Administer tissue plasminogen activator.

d. Cycle cardiac biomarkers and monitor the patient.
e. None of the above.

16. A 64-year-old man is brought to the emergency room for complaints of chest pressure, difficulty breathing, and palpitations. He has a past medical history of hypertension and type 2 diabetes and ischemic stroke and his home medications include metformin, glyburide, lisinopril, and aspirin. ECG on arrival reveals ST-segment elevation in leads I, avL and V_5 to V_6. Catheterization laboratory is activated and the patient is given 325 mg of aspirin and started on nitroglycerin drip. Which of the following additional therapies is currently indicated?

a. Clopidogrel 300 mg, fondaparinux, and atorvastatin 80 mg
b. Prasugrel 60 mg, unfractionated heparin, and atorvastatin 80 mg
c. Ticagrelor 90 mg, unfractionated heparin, and atorvastatin 80 mg
d. Clopidogrel 600 mg, bivalirudin drip, and atorvastatin 80 mg
e. Both a and d are correct

17. Which of the following is true regarding adjunctive medical therapy in patients with acute MI receiving primary PCI?

a. Routine intravenous β-blocker within 24 hours improves mortality.
b. Intravenous angiotensin-converting enzyme inhibitor (ACEI) within 24 hours improves mortality.
c. Mortality benefit with routine intravenous nitroglycerin is not established.
d. Intravenous magnesium improves mortality when used as an adjunct to reperfusion.

18. Which of the following statements is incorrect with regard to acute MI?

a. Primary PCI is associated with reduced rate of intracerebral hemorrhage as compared with fibrinolysis.
b. If rapidly available, primary PCI provides a mortality benefit as compared with fibrinolysis.
c. Primary PCI may be considered 12 hours after symptom onset in patients with signs of ongoing ischemia.
d. Routine PCI of the totally occluded infarct-related artery should be avoided after 24 hours of presentation in hemodynamically stable patients without signs of ischemia.
e. Fibrinolysis should be considered 12 hours after symptom onset in hemodynamically stable patients with signs of ongoing ischemia.

19. Which of the following is an absolute contraindication for use of fibrinolytics for

acute MI?

a. History of ischemic stroke
b. Pregnancy
c. Concomitant use of warfarin for another indication
d. Suspected aortic dissection
e. History of seizure disorder
f. All of the above

20. Which of the statements is true regarding ventricular septal rupture (VSR) after acute MI?

a. VSR is more common in men when compared with women.
b. VSR is more likely after recurrent MI.
c. Presence of collateral circulation in the infarct zone reduces risk of VSR.
d. Fibrinolysis is associated with increased risk of VSR.
e. VSR is more likely after anterior wall MI as compared with nonanterior wall MI.

21. An 82-year-old woman calls 911 after developing sudden-onset chest pain, nausea, and lightheadedness. An ECG done by emergency medical service (EMS) reveals 3-mm ST elevation in leads II, III, and aVF. The nearest catheterization laboratory is activated and the patient undergoes PCI to the right coronary artery (RCA) with drug-eluting stent. She is transferred to the intensive care unit (ICU) in stable condition after the procedure. Two days later, the patient develops sudden-onset lightheadedness and left-sided chest pain. Her vitals reveal BP of 115/60 mmHg, heart rate of 90 per minute and SaO_2 of 92% on ambient air. Physical examination reveals new systolic murmur at the left sternal border that radiates to the apex. An ECG done immediately reveals Q waves in leads II, III, and aVF. No new ST-T changes are noted. A stat bedside echocardiogram reveals basal septal VSR with left-to-right shunt and moderate mitral regurgitation. A pulmonary artery (PA) catheter is placed and shunt fraction (Q_p/Q_s) is calculated at 1.3. What is the next best step in management?

a. Left heart catheterization with ventriculography for better assessment of septum
b. Cardiac magnetic resonance imaging (MRI) to better assess the size of septal rupture
c. Intravenous nitroprusside for afterload reduction
d. Intra-aortic balloon pulsation (IABP) placement
e. Urgent surgical repair

22. Which of the following statements is true regarding ventricular free wall rupture

complicating acute MI?

a. Incidence of ventricular free wall rupture is higher after fibrinolysis when compared with that after primary angioplasty.
b. Ventricular free wall rupture usually presents with acute-onset signs and symptoms of cardiac tamponade, or sudden death.
c. Type I rupture usually occurs within 24 hours of MI.
d. All of the above.

23. Which of the following is true?

a. Ventricular aneurysm is more common than ventricular pseudoaneurysm after MI.
b. Most ventricular pseudoaneurysms resolve over time and require no specific therapy.
c. Ventricular aneurysm is more common with inferior wall MI when compared with anterior MI.
d. Ventricular pseudoaneurysm is more common with anterior wall MI as compared with inferior wall MI.
e. All of the above.

24. A 63-year-old woman presents to the clinic after an episode of sudden transient left-sided vision loss. Symptoms lasted about 15 minutes with spontaneous resolution. Her past medical history is significant for an anterior MI 3 weeks ago treated with PCI with bare metal stent (BMS) to the left anterior descending artery (LAD). Other medical conditions include hypertension, type 2 diabetes mellitus, and hyperlipidemia. Current medications are aspirin, prasugrel, atorvastatin, metformin, and metoprolol. Physical examination is normal. There are no carotid bruits. Ophthalmologic examination is within normal limits. An ECG reveals sinus rhythm with persistent ST elevations in V_2 to V_4. What is the next step in management?

a. Exercise stress test with nuclear imaging
b. MRI of the brain with contrast
c. Carotid ultrasound
d. Left heart catheterization
e. Transthoracic echocardiogram

25. A previously healthy and independently functional 77-year-old man is brought to the catheterization laboratory after developing sudden-onset chest pain radiating to the jaw and shortness of breath. ECG by EMS during transfer revealed ST elevation in V_2 to V_4 and leads I and aVL. The patient was in respiratory distress during transfer requiring emergent endotracheal intubation. His BP is 70/30 mmHg and heart rate is 110 per minute. Angiogram reveals fresh mural thrombus in proximal LAD, which

is stented with BMS with resultant TIMI-2 flow. No significant disease is noted in the RCA and circumflex vessels. An echo reveals a left ventricular ejection fraction (LVEF) of 30% with no significant valvular pathology. He is subsequently transferred to the critical care unit (CCU) in critical condition. His current vital signs are as follows: BP 80/40 mmHg, HR 120 beats per minute, and SaO of 92% on 60% FiO_2. A PA catheter is placed. Which of the following readings is associated with worst prognosis in this patient?

a. Pulmonary capillary wedge pressure (PCWP) 30, Cardiac Index (CI) 1.6
b. PCWP 24, CI 3.2
c. PCWP 10, CI 1.8
d. PCWP 16, CI 2.4

26. What is the next step to be considered in the management of this patient?

a. Consideration for advanced mechanical support
b. IV nitroprusside
c. Refer for urgent coronary artery bypass grafting (CABG)
d. Repeat left heart catheterization

27. A 72-year-old woman is admitted to the hospital with acute STEMI. She has no other past medical history. She underwent BMS to the left circumflex artery with good subsequent flow. She is now free of chest pain and feels well. Echocardiogram revealed an estimated ejection fraction of 30%. In addition to aspirin and clopidogrel what other medications must be considered in the patient's discharge medication regimen?

a. Atorvastatin, lisinopril, and carvedilol
b. Atorvastatin, lisinopril, carvedilol, and warfarin
c. Atorvastatin, lisinopril, carvedilol, and eplerenone
d. Lisinopril, metoprolol, eplerenone, and niacin

28. The above patient had a brief (10 seconds) episode of nonsustained ventricular tachycardia (VT) at a rate of 180 beats per minute on the day of admission in the catheterization laboratory that spontaneously converted to sinus rhythm. What additional therapy is warranted for this patient?

a. Amiodarone at the time of discharge
b. Intravenous lidocaine in the hospital and amiodarone at discharge
c. Only intravenous lidocaine in the hospital
d. Implantable cardioverter–defibrillator (ICD) placement prior to discharge
e. Cardiac Resynchronization Therapy with Defibrillator (CRT-D) device placement prior to discharge

f. None of the above

29. A 45-year-old man presents to an emergency room with 30 minutes of crushing chest pain. The nearest catheterization laboratory is 45 minutes away and a decision to transfer for primary PCI is made. What is the optimal door in door out that has been associated with decreased mortality?

a. 60 minutes
b. 45 minutes
c. Within 120 minutes
d. Within 30 minutes
e. Within 24 hours

30. A 46-year-old man develops sudden chest pain and collapses to the ground. Bystander Cardio-Pulmonary Resuscitation (CPR) is immediately initiated. On EMS arrival 8 minutes later, he is noted to be in ventricular fibrillation and is promptly defibrillated. His ECG shows ST elevation in the inferior leads. The patient is comatose and is intubated for airway protection. Apart from performance of primary PCI which of the following actions is associated with mortality benefit?

a. Bolus of 2 L of normal saline
b. Intravenous lidocaine initiation to prevent recurrent arrest
c. Initiation of transvenous pacing to prevent polymorphic VT
d. Initiation of hypothermia protocol
e. Placement on Extracorporeal Membrane Oxygenation (ECMO)

31. An 85-year-old man presents with increasing intensity of his typical angina pain associated with shortness of breath. His ECG is unchanged from prior tracings. He has a history of established coronary artery disease and has previously refused revascularization. A decision is made to manage him conservatively. Which of the following interventions would be considered inappropriate?

a. Initiation of anticoagulation with fondaparinux
b. Treatment with clopidogrel 300 mg followed by 75 mg daily
c. Initiate treatment with prasugrel bolus 60 mg followed by 5 mg once daily
d. Increase the dosage of prior β-blocker therapy
e. Continue treatment with aspirin

32. Which of the following is not a direct thrombin inhibitor?

a. Bivalirudin
b. Argatroban
c. Hirudin

d. Dabigatran
e. Apixaban

33. Which of the following is true regarding pericarditis in acute MI?

a. Fibrinolysis has no effect on the incidence of pericarditis in MI.
b. Fibrinolysis reduces the incidence of pericarditis in MI.
c. Fibrinolysis increases the incidence of pericarditis in MI.
d. No data have examined this issue.

34. Which of the following are potential indications for IABP in the setting of acute MI?

a. Refractory ischemia despite intensive medical therapy
b. STEMI and secondary acute mitral regurgitation
c. STEMI and refractory polymorphic VT
d. STEMI and refractory cardiogenic shock
e. All of the above

35. A 66-year-old man presents to the emergency with complaints of on–off episodes of chest discomfort for the last 24 hours. Each episode lasts from 15 to 45 minutes and occurs at rest. He denies any history of similar pain in the past. He has a past medical history of hypertension, diabetes mellitus, and peripheral vascular disease. He is an active smoker with 40 pack-year history. An ECG done reveals nonspecific ST-T wave changes. Troponin T is elevated at 0.62. He is taken to the catheterization laboratory and a 90% lesion is noted in first diagonal via a transfemoral approach. He is treated with overlapping BMSs with subsequent TIMI-3 flow. He is transferred to CCU in stable condition. About 4 hours later, the patient develops hypotension with BP of 80/40 mmHg and heart rate of 110 per minute. There is no jugular venous distension. He is pale, diaphoretic, and dizzy. Cardiac auscultation is unchanged. A repeat ECG done is similar to admission ECG. No pericardial effusion is noted on a bedside echocardiogram. Which of the following is most likely to identify the cause of his current condition?

a. Repeat left heart catheterization
b. CT chest with contrast
c. CT abdomen without contrast
d. Chest X-ray
e. Bedside transesophageal echocardiography

36. A 48-year-old man presents to the emergency room agitated after abusing cocaine. His heart rate is 110 per minute, his BP is 200/120 mmHg, and an ECG shows ST elevation in the inferior leads. On examination he is diaphoretic with clear lung

sounds. Auscultation is pertinent for a diastolic murmur at the base of the heart that accentuates with expiration. What is the appropriate next step for definitive diagnostic evaluation?

a. Performance of a CT pulmonary embolus protocol
b. Performance of a gated CT of the aorta
c. Activation of the catheterization laboratory for primary PCI
d. Initiation of intravenous heparin and load with ticagrelor
e. Performance of a two-dimensional echocardiogram at the bedside

37. A 78-year-old man calls 911 because he has sudden-onset chest pain. On EMS arrival he has a BP of 120/80 mmHg and a heart rate of 80 beats per minute. His lungs are clear to auscultation and he has a left ventricular (LV) S_4 noted. ECG done on the field confirms an anterior MI with ST elevation from V_1 to V_4. He is given an aspirin and a sublingual nitroglycerin and transfer is initiated. Within 5 minutes while en route his BP is noted to be 60 mmHg and a saline bolus is initiated. Cardiovascular examination is unchanged and no murmurs are noted. Which of the following scenarios may likely explain his observed hemodynamic deterioration?

a. Hypotension resulting from bleeding due to administration of aspirin
b. Right ventricular (RV) infarction
c. Anaphylaxis reaction from aspirin
d. Recent exposure to a phosphodiesterase 5 inhibitor
e. Massive pulmonary embolism

38. A 42-year-old mother is visiting her child who is undergoing chemotherapy in the Children's Hospital. She suddenly develops chest pain and is noted to be nauseous and diaphoretic. An ECG is performed (Fig. 3-1). On angiography, the coronaries are free of significant epicardial stenosis. A ventriculogram shows apical ballooning with an LVEF of 25%. The patient is admitted to the CCU. Which of the following statements will most likely define her clinical course?

a. She will likely require an ICD as LV function is unlikely to recover.
b. Her prognosis will likely be excellent with full recovery of LV function.
c. She is at risk for recurrent atherosclerotic ischemic events.
d. Indefinite anticoagulation with warfarin will be indicated.
e. She is at higher risk for a malignancy in the ensuing year.

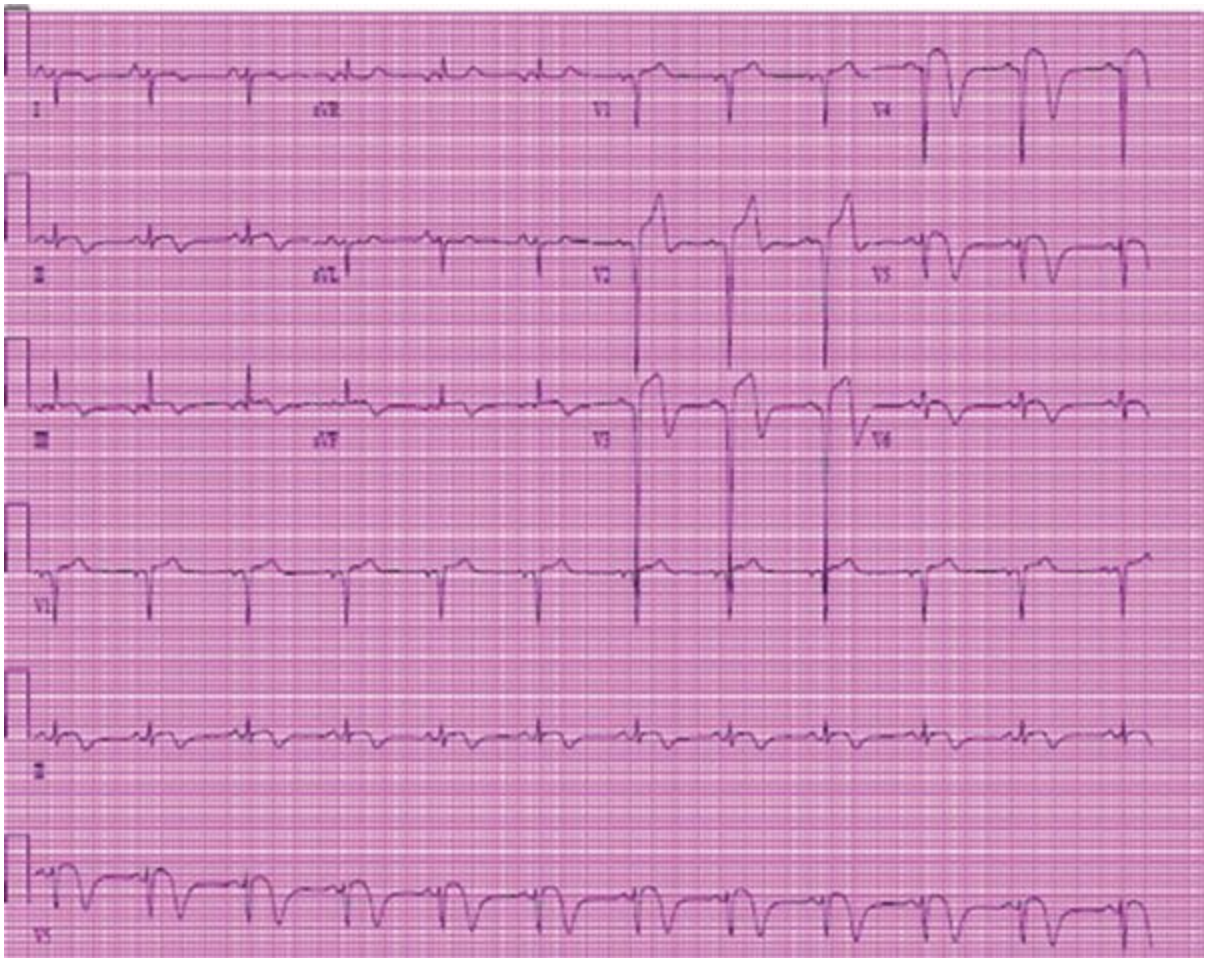

Figure 3.1

39. A 91-year-old man with a history of prior CABGx2 is brought from the nursing home with shortness of breath and hypotension. He is debilitated and has required 24/7 nursing care for activities of daily living. His ECG shows diffuse ST-segment depression, and he is noted to be in pulmonary edema. His heart rate is 110 per minute and his BP is 70/40 mmHg. He has a recent stroke 3 months prior and has stage 4 chronic kidney disease. History is also relevant for a diagnosis of prostate cancer with extensive metastasis to his spine. Which of the following is indicated?

a. Discussion with the family explaining his poor prognosis and the near futility of escalating care
b. Emergent catheterization and revascularization as indicated by anatomy
c. Placement of an IABP for medical stabilization
d. Plan for emergent dialysis
e. Urgent oncology consultation to estimate his prognosis from his prostate cancer

40. A 64-year-old man presents with ST elevation and is taken for primary angioplasty (see Fig. 3-2). Identify the infarct-related artery?

a. LAD
b. Diagonal
c. RCA
d. Left Circumflex
e. Obtuse marginal

41. A 45-year-old man is status post hip replacement. He develops sudden-onset shortness of breath. On examination, he is hypotensive with a BP of 80/40 mmHg. An ECG shows sinus tachycardia at 100 beats per minute with ST elevation in V_1 to V_2. A bedside echo is performed (Fig. 3-3). What is the most appropriate intervention?

a. Activate catheterization laboratory to perform a primary PCI.
b. Perform a CT angiogram to rule out a dissection.
c. Initiate intravenous heparin and assess risks and benefits of fibrinolysis.
d. Perform a saline contrast study to assess right-to-left shunt.
e. Initiate antibiotics and perform blood cultures.

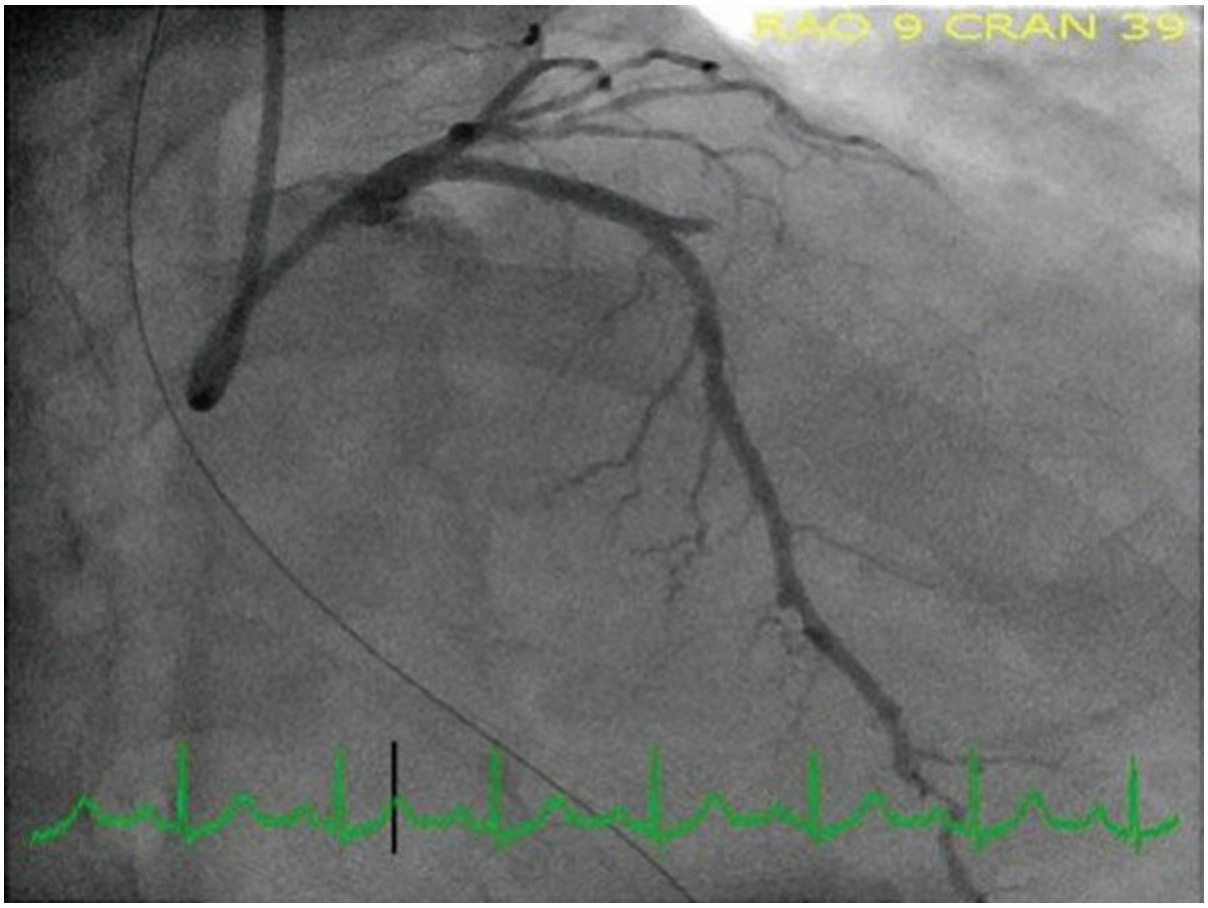

Figure 3.2

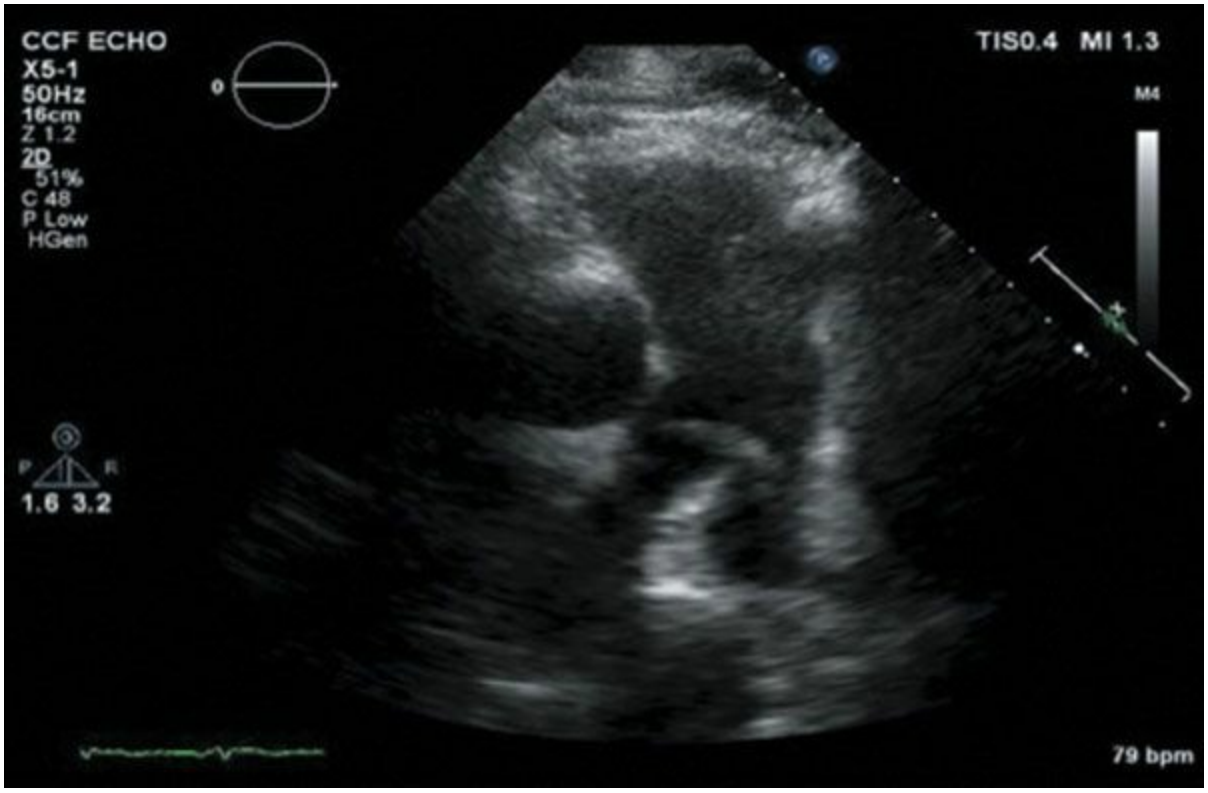

Figure 3.3

42. A 75-year-old woman presented with shortness of breath and generalized malaise of 1-week duration. Her heart rate was 90 per minute and BP was 90/50 mmHg. Examination revealed rales in bilateral lung bases, an elevated jugular venous pulse, and a loud systolic murmur in the left parasternal area. An echo (Fig. 3-4) was performed. What is the likely infarct-related artery?

a. Proximal LAD
b. Distal LAD
c. Obtuse marginal in a dominant circumflex
d. Mid-RCA in dominant RCA
e. Proximal nondominant RCA

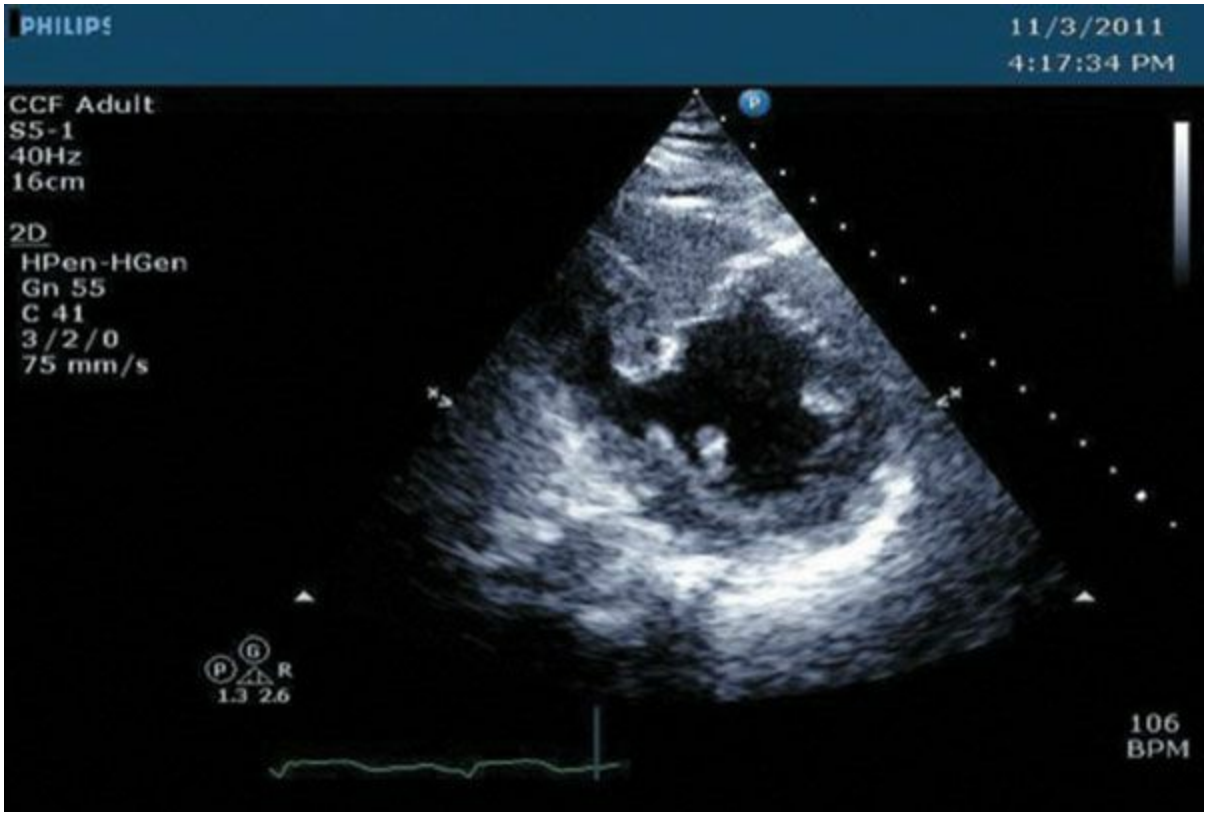

Figure 3.4

43. A 42-year-old male nurse in a rural emergency room develops crushing chest pain 30 minutes after he smoked a cigarette during a break in his shift. An ECG (Fig. 3-5) is performed. What is the most appropriate intervention?

a. Load with clopidogrel 600 mg and initiate heparin for a diagnosis of NSTEMI ACS.
b. Load with prasugrel 60 mg once daily and transfer for primary PCI to a laboratory 4 hours away.
c. Treat with intravenous verapamil for vasospasm.
d. Initiate fibrinolytic therapy with reteplase with adjunctive treatment with aspirin and intravenous heparin.
e. Treat with intravenous metoprolol 5 mg three times.

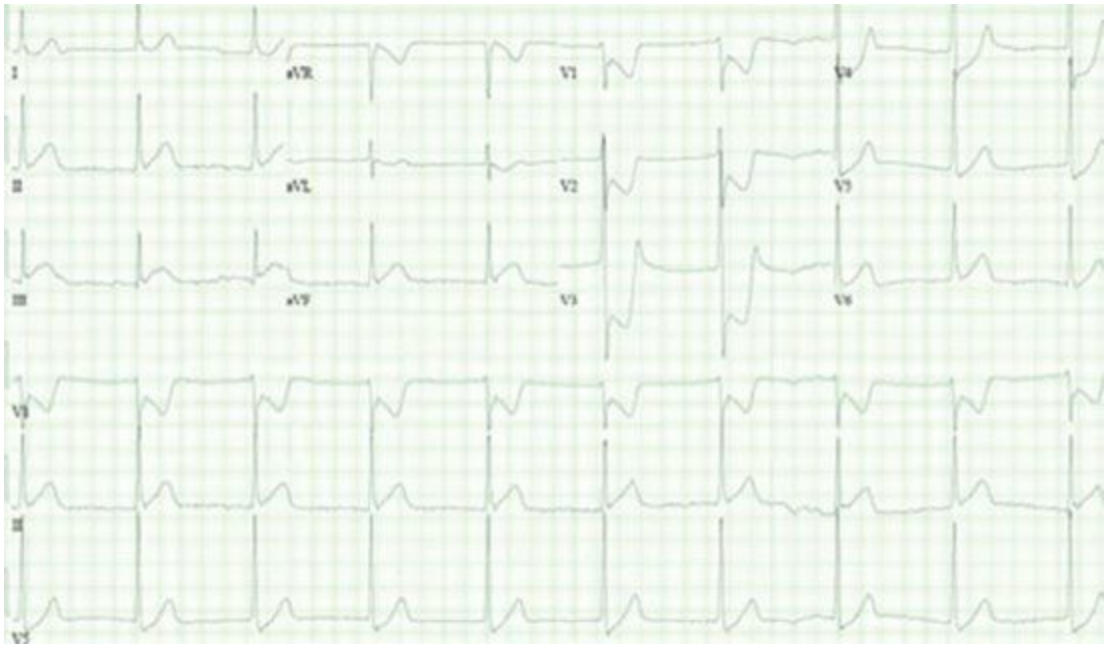

Figure 3.5

ANSWERS

1. **e.** All of the above. Based on data from national heart disease stroke statistics, while the incidence of overall ACS, STEMI, and NSTEMI has declined with time, the incidence of UA has been increasing in the last decade. The observed decline in the rate of UA is largely attributable to the availability of sensitive troponin assays that detect myocardial necrosis.

2. **a.** Plaque rupture. Plaque rupture is the dominating initiating event of acute MI. Rupture of the fibrous cap of the coronary atheroma exposes the underlying subendothelial matrix eventually leading to activation of platelets, thrombin generation, and final thrombus formation. While erosion of the plaque without rupture can lead to thrombus formation, it is not as frequent an event as plaque rupture and accounts for a third of MIs.

3. **a.** Age. Based on results of the large GUSTO-I trial the strongest predictor of mortality following STEMI is advanced age. In addition to age, other major predictors of poor prognosis on presentation include systolic BP <100 mmHg, heart rate >100 per minute, higher Killip classification stage, and anterior infarction.

4. **e.** Both b and c. Aspirin, clopidogrel, prasugrel, and ticagrelor are all antiplatelet agents. Aspirin irreversibly blocks the formation of thromboxane A_2 in platelets, producing an inhibitory effect on platelet aggregation. While clopidogrel and

prasugrel are prodrugs that require hepatic bioactivation to their pharmacologically active metabolite, ticagrelor is phenotypically active and is not affected by hepatic metabolism.

5. **e.** All of the above are correct. Prasugrel has faster onset of action and potency of platelet inhibition when compared with clopidogrel. Unlike clopidogrel, prasugrel is not influenced by P-450 genetic polymorphisms. In the large, randomized TRITON-TIMI-38 trial, investigators compared prasugrel with clopidogrel in patients with ACS initiated following coronary angiography. While there was no difference in mortality, there was a reduction in composite of major adverse cardiovascular events primarily driven by reduction in nonfatal MI. A higher incidence of bleeding with prasugrel when compared with clopidogrel was noted. Post hoc analysis showed net harm in patients with prior history of TIA/stroke and prasugrel should be avoided in these patients.

6. **e.** Fibrinolysis; low-molecular-weight heparin (LMWH), aspirin, and clopidogrel; and transfer to hospital for possible PCI. This patient has acute STEMI. Current ACC/AHA guidelines recommend (class I) administration of fibrinolytic therapy (within 30 minutes) when there is an anticipated delay to performing primary PCI within 120 minutes of first medical contact. In addition to fibrinolysis, adjunctive antiplatelet therapy (aspirin 162 to 325 mg loading dose and clopidogrel 300 mg loading dose in patients aged <75 years) and antithrombotic therapy (weight-adjusted unfractionated heparin or LMWH) should be promptly initiated. Adjunctive LMWH in the setting of fibrinolysis was compared with heparin in the randomized ENTIRE-TIMI-23 trial. The study showed reduced ischemic events (death/recurrent MI) with LMWH when compared with unfractionated heparin at 30 days (4.4% versus 15.9%). The benefit of early routine angiography regardless of symptom status and hemodynamic stability has been confirmed in a number of clinical trials. As a result, transfer to a PCI hospital following lytic administration is encouraged.

7. **a.** Continue unfractionated heparin, aspirin, and clopidogrel and transfer to the nearest hospital with PCI capabilities. Repeat ECG reveals resolution of ST-segment elevation that likely indicates reperfusion. As previously stated, a significant proportion of patients receiving fibrinolysis may undergo reocclusion of the infarct artery. Therefore, it is reasonable to transfer patients to the nearest PCI-capable hospital (ACC/AHA class IIa recommendation). Angiography 3 to 24 hours after fibrinolysis is now recommended in these subjects regardless of hemodynamic status. Discharge home after stress test and referral for delayed angiography are not preferred options for patients with acute STEMI treated with

fibrinolysis.

8. **c.** Streptokinase and aspirin each have a similar effect on outcome. Based on results of International Studies of Infarct Survival (ISIS-2) trial from the fibrinolytic era, aspirin provides as much mortality benefit as streptokinase and the combination provides additive benefit in acute MI.

9. **c.** Adenosine diphosphate blockade. Ticagrelor reversibly blocks adenosine diphosphate receptors of subtype $P2Y_{12}$ on platelet cell membranes eventually leading to inhibition of platelet activation. Aspirin acts by a thromboxane inhibition and abciximab is a chimeric human monoclonal antibody that works by blockade of the activated GP II/IIIa receptor on the platelet surface.

10. **c.** Routine GP IIb/IIIa inhibitor use is associated with increased risk of bleeding. While prior studies documented benefits of routine intravenous GP IIb/IIIa in STEMI, the emergence of potent platelet adenosine diphosphate $P2Y_{12}$ receptor inhibitors sparked controversy regarding their additive benefit. Most subsequent trials demonstrated no clinical benefit with possible increased risk of bleeding with routine use of these agents in addition to dual oral antiplatelet therapy. A benefit for upstream GP IIb/IIIa inhibition was also not evident in the Early Glycoprotein IIb/IIIa Inhibition in Non–ST-Segment Elevation Acute Coronary Syndrome (EARLY ACS) and Acute Catheterization and Urgent Intervention Triage strategY (ACUITY) trials. Use of these agents is now reserved in the catheterization laboratory for patients undergoing high-risk PCI with high thrombus burden and for bailout.

11. **a.** Decrease subsequent repeat TVR. Stents decrease the rate of subsequent TVR compared with balloon angioplasty alone, but there is no favorable impact on TIMI-3 flow or mortality.

12. **d.** It had similar rates of mortality compared with alteplase. It had similar rates of mortality to alteplase. This noninferiority trial randomized over 15,000 patients with STEMI to intravenous alteplase or reteplase. The rates of mortality (11.20% and 11.06% at 1 year, respectively) and stroke were similar for reteplase and alteplase. The major advantage of reteplase was that it could be given as two boluses rather than as an infusion.

13. **e.** All of the above. Results from large TIMI registry indicate that biomarker elevation (NSTEMI) and ST-segment deviation on admission ECG carries poorer prognosis in patients with NSTE-ACS. In addition, one in five patients with NSTE-

ACS may have normal or nonspecific changes on ECG.

14. **c.** Administer aspirin, sublingual nitroglycerin, and heparin. The patient has signs and symptoms suggestive of cocaine-induced ACS. The dominant underlying pathophysiologic factor in cocaine-induced ACS can be coronary spasm or thrombus formation caused by α-adrenergic stimulation. Atherosclerosis is also accelerated by cocaine use. This patient should be started on aspirin, sublingual nitroglycerin, and intravenous heparin. β-Blockers are contraindicated as they may allow unopposed β-adrenergic stimulation and have been associated with increased mortality.

15. **a.** Activate the catheterization laboratory for emergent left heart catheterization. The patient has persistent ischemia after initiation of antianginal therapy. He needs to be sent for emergent left heart catheterization. Intravenous benzodiazepine can temporarily relieve cocaine-induced chest pain but this patient has ischemic symptoms with ECG changes suggestive of ACS. Fibrinolytics have not been shown to be useful in cocaine-induced chest pain without evident thrombosis.

16. **d.** Clopidogrel 600 mg, bivalirudin drip, and atorvastatin 80 mg. This patient has acute MI. Current ACC/AHA guidelines mandate adjunctive medical therapy in addition to aspirin, including loading dose of $P2Y_{12}$ receptor inhibitor (clopidogrel 600 mg, prasugrel 60 mg, or ticagrelor 180 mg) and anticoagulant therapy (unfractionated heparin or bivalirudin). Fondaparinux (a) should not be used as a sole anticoagulant to support primary PCI as it has been shown to increase catheter thrombosis. Prasugrel is contraindicated in patients with history of stroke.

17. **c.** Mortality benefit with routine intravenous nitroglycerin is not established. Although widely used, no randomized trial has established a mortality benefit with intravenous nitroglycerin. Intravenous ACE-I formulations have no proven benefit and were associated with increased mortality in Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS 2). Routine intravenous β-blocker use within 24 hours also did not have any impact on mortality and led to higher rates of cardiogenic shock in the Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study (COMMIT/CCS-2) megatrial. No benefit with intravenous magnesium was noted in the National Heart, Lung and Blood Institute (NHLBI)-supported Myoblast Autologous Grafting in Ischemic Cardiomyopathy (MAGIC) trial.

18. **e.** Fibrinolysis should be considered 12 hours after symptom onset in hemodynamically stable patients with signs of ongoing ischemia. Fibrinolysis has

not been shown to be useful and may even lead to harm after 12 hours of symptom onset in patients with STEMI. Two large, randomized trials (Late Assessment of Thrombolytic Efficacy (LATE) and Enhanced Myocardial Efficacy and Removal by Aspiration of Liberated Debris (EMERAS)) investigated the utility of late fibrinolysis in patients with STEMI and found no mortality benefit beyond 12 hours of symptom onset. Primary PCI is associated with reduced rate of intracerebral hemorrhage when compared with fibrinolysis. If rapidly available, primary PCI has been convincingly shown to reduce mortality when compared with fibrinolysis. Primary PCI may be considered 12 hours after symptom onset in patients with signs of ongoing ischemia. While primary PCI should be considered in patients with signs of ongoing ischemia 12 to 24 hours after symptom onset, routine PCI of the totally occluded infarct-related artery >24 hours after presentation in hemodynamically stable patients without signs of ischemia provides no additional benefit and may even be harmful. Delayed PCI (3 to 28 days after MI) of the occluded asymptomatic Infarct Related Artery (IRA) was evaluated in the randomized Occluded Artery Trial (OAT). While PCI did not reduce the occurrence of death, reinfarction, or heart failure, there was a trend toward excess reinfarction during long-term follow-up in stable patients.

19. **d.** Suspected aortic dissection. Suspected aortic dissection is an absolute contraindication for use of fibrinolysis. History of stroke, pregnancy, use of warfarin, and history of seizure disorders are all relative contraindications for fibrinolysis.

20. **c.** Presence of collateral circulation in the infarct zone reduces risk of VSR. VSR is more likely in women and after first MI. Fibrinolytic therapy is not associated with increased risk of VSR but may accelerate rupture in vulnerable subjects. VSR is equally likely after anterior or nonanterior wall MI.

21. **e.** Urgent surgical repair. This patient has VSR after acute MI. Although the shunt fraction is small, the rupture may rapidly progress in an unpredictable manner and lead to hemodynamic collapse and death. Although controversial, urgent surgical closure remains the treatment of choice. Vasodilators (nitroprusside) and IABP placements can reduce shunt fraction and increase forward flow and can be utilized in hemodynamically unstable patients as bridge to surgery. This patient is hemodynamically stable with a small shunt fraction.

22. **d.** All of the above. Acute ventricular free wall rupture usually presents with acute onset cardiac tamponade, pulsus paradoxus, and sudden death. It accounts for approximately 10% of mortality after MI. Fibrinolysis may increase risk and this

potentially accounts for the "early hazard" with thrombolytic therapy as noted in the randomized clinical trials. Type I rupture is a slit-like full-thickness rupture that is usually seen within the first 24 hours. It usually occurs in the border zone between the akinetic infarct-related segment and the adjacent hyperkinetic noninfarct zone.

23. **a.** Ventricular aneurysm is more common than ventricular pseudoaneurysm after MI. True ventricular aneurysm is more likely than pseudoaneurysm (contained rupture of LV free wall). While ventricular aneurysm is more likely with anterior MI, pseudoaneurysms occur more often after inferior wall MI. In contrast to patients with true aneurysms that are initially managed with medical therapy, pseudoaneurysms have a high risk of rupture and surgical therapy is recommended irrespective of size or presence/absence of symptoms.

24. **e.** Transthoracic echocardiogram. This patient presents with symptoms suggestive of TIA. He had a recent anterior wall MI. Persistent ST elevation in V_2 to V_4 suggests apical aneurysm that increases the risk of mural thrombus formation. Current symptoms suggest an embolic event secondary to LV mural thrombus. Echocardiogram must be done to confirm the diagnosis. Although the patient has persistent ST elevation on ECG, there are no clinical signs of recurrent ischemia and repeat left heart catheterization is not indicated.

25. **a.** Pulmonary capillary wedge pressure (PCWP) 30, confidence interval (CI) 1.6. This patient has acute STEMI complicated by cardiogenic shock. Cardiogenic shock is defined as evidence of ineffective tissue perfusion arising from cardiac dysfunction supported by the presence of a systolic BP <90 mmHg, PCWP >15 mmHg, and cardiac index <2.2 L/min/kg/m^2. Classic study performed in the pre-reperfusion era by Forrester risk stratified patients with cardiogenic shock based on PCWP and CI. Patients with both elevated PCWP and low CI have worst prognosis. In the GUSTO-I trial low cardiac output (and cardiac index) remained the strongest hemodynamic predictors of death in patients with cardiogenic shock.

26. **a.** Consideration for advanced mechanical support. Advanced mechanical support with IABP, ECMO, or TANDEM heart is indicated at this time. IABP reduces afterload, increases cardiac output, and reduces myocardial oxygen requirement by means of reduction in wall stress. The recently conducted Intra-aortic balloon counterpulsation in acute myocardial infarction complicated by cardiogenic shock (IABP SHOCK-II) trial failed to show a mortality benefit in this setting with IABP counterpulsation, as a result IABP support in the setting of shock is now downgraded to a IIa indication in the most recent ACC/AHA guidelines. Other supportive devices such as the TANDEM and Impella have been shown to provide

superior hemodynamic support to IABP alone, although no clear benefits with regard to mortality have been noted. The patient described achieved satisfactory mechanical reperfusion and urgent CABG or repeat angiography is not indicated and nitroprusside would not be considered in this setting.

27. **c.** Atorvastatin, lisinopril, carvedilol, and eplerenone. Current guidelines in post reperfusion care include medical management for optimal risk factor control and treatment of myocardial dysfunction. High-potency statins (atorvastatin or rosuvastatin) and β-blockers are indicated in the absence of contraindications in all patients with STEMI. ACEIs are indicated in all patients after MI with ejection fraction <40% or anterior wall MI and aldosterone antagonists are indicated in patients with MI and ejection fraction <40% with clinical signs of heart failure.

28. **f.** None of the above. This patient had a brief episode of nonsustained VT in the setting of MI. Routine antiarrhythmic therapy with amiodarone or lidocaine is not indicated in patients with MI and brief, self-limited, and hemodynamically insignificant arrhythmias within 48 hours of symptoms. This patient has low ejection fraction and warrants consideration for a primary prophylaxis ICD based largely on the Multicenter Automatic Defibrillator Implantation Trial (MADIT II) trial if ventricular function does not recover. Early use of ICD post MI was not associated with benefit in the Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) and Immediate Risk Stratification Improves Survival (IRIS) trials. Patients with MI and low ejection fraction need to be reevaluated after 40 days on optimal medical therapy to determine candidacy for device therapy.

29. **d.** Within 30 minutes. Door in door out time in the setting of STEMI is the time from patient presentation to discharge from a non-PCI hospital to a PCI-capable hospital. A door in door out time of less than 30 minutes is associated with decrease in mortality.

30. **d.** Initiation of hypothermia protocol. Initiation of therapeutic hypothermia in post cardiac arrest patient has been shown to be associated with a significant mortality benefit. The patient is not in shock and administration of normal saline may lead to pulmonary edema. Prophylactic intravenous lidocaine in this setting has not been shown to have any clinical benefit and may lead to harm. The patient does not have polymorphic VT and there is no role for transvenous pacing in ischemically triggered polymorphic VT. While ECMO has been shown to be useful in patients with refractory cardiogenic shock, it is not indicated in a hemodynamically stable patient post cardiac arrest.

31. **b.** Treatment with clopidogrel 300 mg followed by 75 mg daily. This patient has UA and will likely rule in for an NSTEMI. Initiation of antiplatelet therapy with a bolus dose of clopidogrel 300 mg followed by 75 mg once daily is indicated based on the results of the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial. The use of prasugrel in the elderly is associated with increased risk of bleeding. In this patient who is not undergoing revascularization, the use of bolus dose prasugrel cannot be supported. In addition to antiplatelet therapy with aspirin, the patient also needs to be started on antithrombotic therapy (with unfractionated heparin, LMWH, or fondaparinux). Lastly, since he has refused revascularization, medical antianginal therapy should be maximized. Increasing β-blocker as tolerated is indicated.

32. **e.** Apixaban. Bivalirudin, argatroban, and hirudin are intravenous direct thrombin inhibitors and dabigatran is an oral direct thrombin inhibitor. Apixaban is an oral factor Xa inhibitor.

33. **b.** Fibrinolysis reduces the incidence of pericarditis in MI. Several studies, including Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (Italian) (GISSI 1), have examined this issue and found that fibrinolysis reduces the incidence of pericarditis in the setting of acute MI. Indeed, in the era of reperfusion therapy, the rate of both early and late pericarditis has decreased. Probably, by reducing infarct size, reperfusion decreases the incidence of pericarditis, which is more common with large MIs.

34. **e.** All of the above are acceptable indications for IABP use.

35. **c.** CT abdomen without contrast. The patient has signs and symptoms suggestive of massive retroperitoneal bleeding after left heart catheterization. Retroperitoneal bleeding is a common complication after left heart catheterization through femoral access. Patients present with anemia that may be hard to detect on clinical examination. CT abdomen without contrast is the test of choice to confirm bleeding. He has no signs of recurrent ischemia on ECG and as such repeat catheterization to look for stent thrombosis (a) is not indicated. Lack of elevated jugular venous pulse makes pulmonary embolism (b) or cardiac tamponade/acute mitral regurgitation (e) unlikely.

36. **b.** Performance of a gated CT of the aorta. This patient has acute aortic regurgitation and performance of gated CT aorta is urgently indicated. Development of a new diastolic murmur at the base of the heart that accentuates with expiration should raise suspicion of acute aortic regurgitation. Acute aortic regurgitation is usually

secondary to endocarditis or acute ascending aortic dissection. Ascending aortic dissection can involve the coronary cusps leading to acute coronary dissection that can present with chest pain and ST elevations on ECG. Cocaine use is a major risk factor for acute aortic dissection. While nongated CT with pulmonary embolus protocol can often detect acute aortic detection, it is often associated with motion artifacts in the aortic root and is not the ideal test. The patient has a suspected acute aortic dissection, and activation of catheterization laboratory for revascularization or antiplatelet therapy is not indicated. Confirmation by the performance of a CT aorta followed by immediate surgical consultation appears warranted. While two-dimensional echo can often detect an aortic dissection flap, absence of the same does not rule out aortic dissection.

37. **d.** Recent exposure to a phosphodiesterase 5 inhibitor. This patient developed immediate hypotension after administration of nitroglycerin. Administration of nitrates in patients who have recently taken phosphodiesterase 5 inhibitors such as sildenafil acetate can lead to severe hypotension, circulatory collapse, and death. The patient is unlikely to develop massive hemorrhage within 5 minutes of aspirin load, and anaphylaxis in this setting is extremely uncommon. Administration of nitrates can cause profound hypotension in RV infarction but this patient has ST elevations in V_1 to V_4, suggesting anterior-apical wall MI.

38. **b.** Her prognosis will likely be excellent with full recovery of LV function. This patient has Takotsubo cardiomyopathy, also known as transient apical ballooning syndrome. This transient weakening of LV apex is often triggered by emotional stress, such as the death of a loved one, a breakup, or constant anxiety, and is most often seen in middle-aged women. Most patients achieve complete recovery within few months. There is no indication for ICD and there is no increased risk of atherosclerosis or malignancy. Routine anticoagulation with warfarin is not indicated in the absence of apical thrombus.

39. **a.** Discussion with the family explaining his poor prognosis and the near futility of escalating care is the ideal next step in this scenario. The patient presents with acute STEMI complicated by cardiogenic shock. The large randomized SHOCK trial did not show any benefit for a revascularization strategy in patients >75 years with cardiogenic shock. Data from multiple registries suggest that aggressive measures (IABP, heart catheterization, and revascularization) should be considered in patients with good baseline functional status, and such efforts are likely to be futile in this patient with poor functional status, extensive history of coronary artery disease, and multiple medical comorbidities.

40. **b.** Diagonal. The culprit infarct-related artery is the diagonal branch of LAD.

41. **c.** Initiate intravenous heparin and assess the risks and benefits of fibrinolysis. The echo shows a linear density in the main PA extending into the left PA. Findings are most consistent with a hemodynamically significant pulmonary embolism. Starting intravenous heparin and assessment for fibrinolysis are urgently indicated.

42. **d.** Mid RCA in dominant RCA. The echo shows a VSR in the basal inferoseptum. This area is usually supplied by the PDA. As a result, a dominant RCA infarction likely accounts for these changes.

43. **d.** Initiate fibrinolytic therapy with reteplase with adjunctive treatment with aspirin and intravenous heparin. The ECG shows significant anterior ST depression with upright T waves consistent with a true posterior current of injury. Although no benefit is noted with fibrinolytic therapy over placebo in randomized clinical trial, a benefit was noted in patients with true posterior injury defined as ST depression >2 mm in the anterior precordial leads. This patient is in the golden hour. Transfer to a remote location for PCI 4 hours later would be inappropriate.

Coronary Artery Disease

Baris Gencer • Debabrata Mukherjee • Marco Roffi

QUESTIONS

1. A 67-year-old man presents to the emergency room with increasing frequency of chest pain on exertion and one episode of rest pain lasting 15 minutes the day of admission. Other than for hypertension and hyperlipidemia his medical history is unremarkable. He quit smoking (1 pack a year for 20 years) 11 years ago. On physical examination he is afebrile, his pulse is 78 bpm, and his blood pressure is 138/76 mmHg. Cardiac and pulmonary auscultations are unremarkable. His current medications include aspirin, metoprolol, ramipril, and atorvastatin. The electrocardiogram (ECG) at admission reveals deep T-wave inversion in the precordial leads and no pathologic Q waves. You admit the patient to the hospital and start intravenous (IV) unfractionated heparin (UFH) and nitroglycerine. The first available serum troponin I level is 1.4 μg/L (upper limit of normal, 0.09 μg/L). Cardiac echocardiography shows an anterior and apical hypokinesia with mildly depressed left ventricular function. The next step in his management would be

   a. low-level exercise stress ECG next morning.
   b. to continue IV heparin and nitroglycerin, increase β-blocker, and add a calcium antagonist until completely free of chest pain for 24 hours, then discharge home.
   c. coronary angiography within 48 hours followed by percutaneous intervention/surgical revascularization if indicated.
   d. dobutamine echocardiogram or myocardial perfusion scan within 48 hours.
   e. continue IV heparin and nitroglycerin, increase β-blocker, and add a calcium antagonist until completely free of chest pain for 24 hours, then transfer to a cardiac rehabilitation program.

2. A 57-year-old man presenting with unstable angina (UA) was successfully treated with percutaneous coronary intervention (PCI) of a significant lesion of the right

coronary artery (RCA) in the presence of a normal left ventricular ejection fraction (LVEF). He is referred for cardiac rehabilitation program. What is the expected benefit?

a. Reduced risk of stent restenosis
b. Lower rate of hospital readmission
c. Reduction in maximal $\dot{V}O_2$
d. Higher event rate related to exercise
e. Reduced risk of stent thrombosis

3. A 66-year-old man with stable angina at low exertion level was investigated with coronary angiography that showed an isolated significant lesion (70%) of the ostium and mid-portion of the left main coronary artery in the presence of a normal left ventricular function. What is the correct statement regarding the recommended approach?

a. Heart team discussion between the interventional cardiologist and the cardiac surgeon to select the best treatment option is the recommended approach.
b. Coronary artery bypass grafting (CABG) is the recommended approach for all patients with left main disease.
c. PCI is the recommended approach for all patients with left main disease.
d. A calculation of the Society of Thoracic Surgeons (STS) and SYNTAX (Synergy between PCI with TAXUS and Cardiac Surgery) scores is not recommended at this stage.
e. The choice of treatment is independent of the clinical presentations (stable angina or acute coronary syndromes [ACSs]).

4. A 58-year-old man with coronary artery disease (CAD) and severe chronic obstructive pulmonary disease (COPD) with forced expiratory volume in the first second of expiration (FEV_1)/forced vital capacity <0.74 with FEV_1 <40% predicted had stenting of the mid-left anterior descending artery (LAD) 10 months prior to admission with a 3.0 mm × 24 mm bare metal stent (BMS). He presents now with recurrent angina despite intensified medical treatment, and coronary angiography reveals a severe and diffuse in-stent restenosis (ISR). A reasonable next therapeutic option would be

a. plain balloon angioplasty.
b. coronary artery bypass surgery.
c. drug-eluting stent (DES) implantation (stent-in-stent).
d. medical therapy.
e. brachytherapy.

5. A 66-year-old man had in the last few months sporadic episodes of chest pain on exertion. His cardiovascular (CV) risk factors included diabetes, hypertension, and hypercholesterolemia. He had no other comorbidity. Coronary angiography revealed a lesion of 60% of the RCA in addition to multiple nonsignificant plaques affecting the three coronary arteries. The fractional flow reserve (FFR) of the RCA (0.0.85) and LVEF were normal. What is the recommended treatment for this patient?

   a. CABG is the first recommended approach as the risk of surgical procedure is low.
   b. PCI is the first recommended approach as the SYNTAX score is low.
   c. Perform an additional imaging (myocardial perfusion scan or magnetic resonance [MR] perfusion scan) in addition to optimal medical management.
   d. Guideline-directed medical therapy is the first recommended approach.
   e. Repeat coronary angiography after 6 months to exclude disease progression in addition to optimal medical management.

6. A 58-year-old male smoker treated for hypertension complained about chest pain on exertion in the preceding 4 weeks. To investigate the clinical symptoms, you performed a stress perfusion cardiac magnetic resonance showing hypoperfusion during IV administration of adenosine. Which area of the myocardium is more vulnerable to hypoperfusion?

   a. Subepicardium
   b. Mid-myocardium
   c. Subendocardium
   d. Pericardium
   e. All of the above

7. A 73-year-old man presents to the emergency room with severe mid-sternal chest discomfort. He appears anxious and in distress. His heart rate is 66 bpm, blood pressure is 92/68 mmHg, and respiratory rate is 14. There is marked jugular venous distention. Cardiac auscultation is unremarkable and the lungs are clear. ECG reveals 2-mm ST-segment elevation in leads II, III, and aVF. The most likely diagnosis is

   a. acute pericarditis.
   b. acute aortic dissection.
   c. pneumothorax.
   d. inferior wall myocardial infarction (MI) with right ventricular infarction.
   e. pneumonia.

8. A 65-year-old hypertensive man was hospitalized for non-ST-segment-elevation myocardial infarction (NSTEMI). The clinical examination shows a fourth heart sound (S_4). What is expected to be found at the echocardiography?

   a. Reduction in left ventricular compliance
   b. Rapid deceleration of transmitral flow during protodiastolic filling of the left ventricle
   c. Increased inflow into the left ventricle
   d. Reduced left ventricular systolic function
   e. Aortic sclerosis

9. A 66-year-old man known for diabetes mellitus treated with oral glucose lowering medications presents with UA. Coronary angiography reveals a three-vessel disease: 70% mid-LAD lesion, complex, long, and calcified; 70% focal proximal left circumflex artery (LCX) stenosis; and 70% focal mid-RCA lesion. A hybrid coronary revascularization was proposed. All the following statements are correct regarding hybrid coronary revascularization, with the exception of one.

   a. Hybrid revascularization is defined as the planned combination of surgical and percutaneous revascularization (typically left internal mammary artery [LIMA]-to-LAD and PCI of ≥1 additional vessel).
   b. Hybrid revascularization is reasonable in patients with limitations to traditional CABG, such as heavily calcified proximal aorta.
   c. Hybrid revascularization is reasonable in patients with lack of suitable graft conduit.
   d. Hybrid revascularization is reasonable in patients with unfavorable LAD artery for PCI.
   e. Hybrid revascularization mandates surgical and percutaneous revascularization during the same procedure.

10. A 57-year-old female smoker presents to the emergency department for an ongoing new typical chest pain lasting 30 minutes. The physical examination is unremarkable and she is hemodynamically stable. The ECG reveals T inversion in II, III, and aVF leads. Which of the following biomarker elevation has been associated with an improved benefit of ticagrelor therapy over clopidogrel in patients hospitalized with ACS?

    a. Ultrasensible C-reactive protein
    b. Interleukin-6
    c. High-sensitive troponin T (Hs-TnT)
    d. D-dimers
    e. Lactate dehydrogenase

11. A 58-year-old man known for a metabolic syndrome shows increasing frequency of chest pain on exertion in the preceding 2 weeks. Resting ECG did not show significant abnormalities. Which of the exercise parameters are associated with adverse prognosis?

a. Duration of symptom-limiting exercise <5 METs (metabolic equivalents)
b. Failure to increase systolic blood pressure ≥120 mmHg, or a sustained decrease ≥10 mmHg, or below rest levels, during progressive exercise
c. ST-segment depressions ≥2 mm
d. Angina pectoris at low exercise workloads
e. All of the above

12. A 58-year-old man presented stable chest pain on moderate effort exertion in the preceding 12 months. The medical history is relevant for hypertension and hyperlipidemia. His current treatment includes lisinopril, atorvastatin, metoprolol, and aspirin. He is addressed for coronary angiography that showed a 70% to 90% lesion of the LCX successfully treated with PCI with a placement of a DES. The LVEF was normal. What was the expected benefit of a PCI over a medical therapy?

a. Decrease of total mortality
b. Decrease of CV mortality
c. Decrease of MI
d. Decrease of heart failure events
e. No improvement of any of the mentioned endpoints

13. The same patient was investigated with stress imaging before and after PCI to assess the extension of myocardial ischemia. Which of the following statements is correct regarding the benefit of PCI over medical therapy in this setting?

a. A greater reduction in the extension of residual myocardial ischemia
b. A greater resolution of angina episodes
c. An increased benefit of ischemia reduction in patients with extensive ischemic areas at baseline
d. A greater improvement in symptoms
e. All of the above

14. A 63-year-old man has been successfully treated with percutaneous coronary revascularization for a stable angina pectoris. His low-density lipoprotein cholesterol (LDL-C) value was 143 mg/dL. Which of the following statement is incorrect regarding the impact of prescribing intensive lipid-lowering therapy (e.g., 80 mg atorvastatin daily) compared with less intensive therapy (e.g., 10 mg atorvastatin daily)?

a. Higher LDL-C level reduction
b. Significant absolute risk reduction of major adverse cardiovascular events (MACE) of ~2% over 5 years
c. Significant relative risk reduction of MACE of ~20% over 5 years
d. Increased incidence of persistent liver aminotransferase levels of 1%
e. Significant reduction of overall mortality

15. A 67-year-old man is treated with PCI. Which of the following statement is not correct regarding periprocedural anticoagulation?

a. An anticoagulant should be administered to all patients undergoing PCI.
b. Administration of IV UFH is useful in patients undergoing PCI.
c. An additional dosage of IV enoxaparin should be administered at the time of PCI to patients who received the last subcutaneous dose of enoxaparin 12 hours or more prior to PCI.
d. The appropriate diagnostic test to check for the level of anticoagulation with UFH during PCI is the activated clotting time.
e. Fondaparinux might be used as the sole anticoagulant to support PCI.

16. A 65-year-old male hypertensive smoker benefited from primary PCI of the RCA for inferior STEMI. Which of the following statements is not correct regarding secondary prevention in this patient?

a. Medically supervised cardiac rehabilitation programs are recommended.
b. Blood pressure should be controlled with a goal of <140/90 mmHg.
c. Statin therapy should be uptitrated to achieve an LDL-C <70 mg/dL
d. Smoking cessation program should be proposed.
e. Even in the absence of symptoms, routine periodic stress testing is indicated.

17. A 60-year-old male patient was treated 2 years earlier with PCI and the implantation of BMS in the LAD for NSTEMI. He complains about recurrent worsening exertional chest pain in the last week. Coronary angiography reveals ISR. What are the predisposing factors for BMS restenosis?

a. Diabetes
b. Increasing stent length
c. Increasing stent number
d. Decreasing stent diameter
e. All of the above

18. A 60-year-old healthy colleague on no medication with an LDL-C level of 123 mg/dL and High-sensitivity C-reactive protein (hs-CRP) level >2.0 mg/L asked to

you whether he should take rosuvastatin 20 mg a day. Which of the following statements is incorrect regarding JUPITER trial?

a. Rosuvastatin 20 mg/day reduced LDL-C levels by 50%.
b. Rosuvastatin 20 mg/day significantly decreased the incidence of MI.
c. Rosuvastatin 20 mg/day reduced hs-CRP by 37%.
d. Rosuvastatin 20 mg/day did not significantly decrease the incidence of stroke.
e. Rosuvastatin 20 mg/day significantly increased the incidence of physician-reported diabetes.

19. A 65-year-old man with diabetes presented typical chest pain on exertion in the previous 2 months. Coronary angiography revealed significant complex multivessel coronary disease (SYNTAX score, 34). What is the expected benefit of a revascularization with CABG versus PCI?

a. CABG is associated with a reduction of death only.
b. CABG is associated with a reduction of stroke only.
c. CABG is associated with a reduction of death and of MI, but not of stroke.
d. CABG is associated with a reduction of all following individual endpoints: stroke, myocardial infraction, and death.
e. CABG is associated with a reduction of MI only.

20. A 41-year-old male smoker was admitted for STEMI and quitted smoking after hospitalization. Which of the following statements is incorrect regarding smoking cessation?

a. Smoking cessation reduces the relative risk of total mortality by >30% over a mean follow-up of 5 years.
b. Smoking cessation reduces the relative risk of nonfatal MI by >30% over a mean follow-up of 5 years.
c. More than 70% of patients quit smoking after ACS.
d. Smoking cessation counseling program is effective to help smokers to quit smoking.
e. Smoking cessation counseling program should be proposed during hospital stay and continued after discharge.

21. Six hours after the start of chest pain, a 55-year-old diabetic man was admitted to the emergency department for anterior STEMI with hemodynamic instability (cold extremities, heart rate of 110 bpm and blood pressure of 85/50 mmHg) and severe reduced LVEF (25% to 30%) estimated by echocardiography. What is the correct statement regarding the decision to perform an emergent revascularization versus an initial medical stabilization according to the SHOCK trial?

a. Significant reduction of mortality with early revascularization compared with intensive medical therapy at 30 days
b. No significant difference of mortality with early revascularization compared with intensive medical therapy at 30 days
c. Significant reduction with intensive medical therapy compared with early revascularization at 30 days
d. Significant reduction of mortality with early revascularization compared with intensive medical therapy at 6 months
e. Answers b and d are correct

22. A 63-year-old man known for chronic kidney disease (CKD) due to long-term uncontrolled hypertension is hospitalized for elective coronary angiography. Which of the following statements is not correct?

a. Patients with CKD undergoing cardiac catheterization should receive adequate preparatory hydration.
b. In patients with CKD, the volume of contrast should be minimized.
c. Administration of N-acetyl-cysteine is useful for the prevention of contrast-induced acute kidney injury (AKI).
d. Contrast-induced AKI is one of the leading causes of hospital-acquired AKI.
e. In elective cases, patients should be assessed for risk of contrast-induced AKI before coronary angiography.

23. A 45-year-old man benefited from primary PCI for STEMI. The adjunctive antithrombotic therapy consisted of aspirin, heparin, and abciximab. The addition of abciximab is associated with

a. no significant difference in the risk of stroke.
b. a significant increase in the risk of stroke.
c. a significant decrease in the risk of stroke.
d. a significant decrease of nonhemorrhagic stroke only.
e. a significant increase of hemorrhagic stroke only.

24. A 65-year-old diabetic man known for a multivessel coronary disease underwent revascularization with CABG. What is the target LDL-C that should be aimed?

a. 160 mg/dL
b. 130 mg/dL
c. 100 mg/dL
d. 70 mg/dL
e. 50 mg/dL

25. A 62-year-old man was hospitalized for an NSTEMI and underwent invasive strategy with DES-based PCI. Which of the following statements about antiplatelet therapy is wrong?

a. Patients not on aspirin should be given nonenteric aspirin 325 mg before PCI.
b. After PCI, use of aspirin should be continued indefinitely.
c. Additional aspirin (81 to 325 mg) is recommended in all patients on chronic aspirin therapy before PCI.
d. A loading dose of a $P2Y_{12}$ receptor inhibitor should be given to patients undergoing PCI with stenting at the latest after completion of PCI (e.g., clopidogrel 600 mg, prasugrel 60 mg, and ticagrelor 180 mg).
e. In patients receiving a stent (BMS or DES) during PCI for ACS, $P2Y_{12}$ receptor inhibitor should be given for 12 months.

26. A 50-year-old white female nonsmoker without history of cardiovascular disease (CVD) and treated only with ramipril for hypertension was hospitalized for UA. The ECG revealed T inversion in the lateral leads. The medical student who admitted the patient asks you what is the proportion of patients that undergo coronary angiography for ACS who have nonsignificant CAD.

a. <5%
b. 10% to 15%
c. 20% to 30%
d. 25% to 35%
e. 30% to 40%

27. A 59-year-old man was successfully treated with PCI for NSTEMI. During the procedure, the patient received bivalirudin. Due to closure device failure, the patient suffered a major bleeding at the access site difficult to control with manual compression and you are in need of reversing the anticoagulation. Your treatment of choice is

a. fresh frozen plasma.
b. prothrombin complex.
c. epsilon aminocaproic acid.
d. protamine.
e. vitamin K.

28. A 63-year-old man presents typical chest pain at moderate exertion in the preceding month and he is admitted to the hospital for coronary angiography. While considering the best access for the procedure, which of the following statements is not correct regarding a radial vascular access?

a. The radial vascular access may be useful to decrease access site complications.
b. The radial vascular access is preferred in patients with coagulopathy.
c. The radial vascular access is preferred in patients with morbid obesity.
d. The radial vascular access is preferred in patients with an elevated INR.
e. The radial vascular access is more frequently performed in the United States than in Europe.

29. Which of the following conditions does not justify immediate coronary angiography and, if needed, revascularization?

a. A 57-year-old man presenting with typical chest pain lasting 60 minutes up to emergency department arrival. As cardiologist on call you are called in immediately and when you see the patient, his pain has virtually disappeared while ECG shows 2-mm ST-segment elevation in the inferior leads.
b. A 60-year-old diabetic man known for previous coronary disease presenting with not better defined chest discomfort lasting for 10 hours and currently decreasing in intensity, pulmonary edema, and 3-mm ST-segment elevation in the anterior leads on ECG in the absence of Q waves.
c. A 65-year-old man known for CAD complaining of progressive shortness of breath since 1 week. At admission, no ongoing chest pain with stable hemodynamic status but bibasilar rales at lung auscultation. The ECG revealed ST-segment elevation as well as Q waves in the anterior leads.
d. A 70-year-old man presenting to the emerging department with on–off chest pain in the preceding 20 hours. Upon your arrival he has mild chest pain and on ECG 2-mm ST elevation in the lateral leads in the absence of Q waves.
e. A 68-year-old diabetic man presenting to the emerging department with chest pain lasting 4 hours, hypotension, and tachycardia and on ECG 3-mm ST-segment elevation in the anterior and lateral leads.

30. A 76-year-old man with no prior cardiac history presents to the emergency department with acute retrosternal chest pain. He had a single episode of chest pain lasting 4 hours 5 days ago. At that time he did not seek medical attention. Physical examination reveals a slightly confused diaphoretic patient, with heart rate of 95 bpm, blood pressure of 76/42 mmHg, and cold extremities. He is able to lie flat, the lungs are clear, and the jugular veins are distended even if the upper part of the body is raised at 45°. On cardiac auscultation a loud systolic murmur is audible, while on ECG Q waves associated with ST-segment elevation are detected in the inferior leads. The most likely diagnosis is

a. severe left ventricular failure.
b. ventricular septal defect.

c. acute mitral regurgitation.
d. right ventricular infarction.
e. cardiac rupture.

31. Considering the suspected diagnosis for the patient described in the previous question, what is the next diagnostic step?

a. Cardiac enzymes
b. Chest X-ray
c. Transesophageal echocardiography
d. Immediate coronary angiography
e. Transthoracic echocardiography

32. While considering surgery for the patient described in the previous two questions, the most effective cardiac unloading treatment for him is

a. fluid resuscitation.
b. β-blockers.
c. mechanical ventilation with positive end-expiratory pressure.
d. vasopressors.
e. intra-aortic balloon pump.

33. A 66-year-old man with a history of diabetes was referred for coronary angiography. The procedure showed complex multivessel disease. Which of the following statements justify the use of DES over BMS?

a. Patient with diabetes mellitus
b. Long coronary lesions
c. Multifocal coronary lesions
d. Small vessel disease
e. All of the above

34. A 63-year-old male smoker with no history of CVD and a treatment for hypertension complains of typical chest pain on exertion the preceding 2 months without any aggravation. He is scheduled for coronary angiography in 7 days. In the meantime, you should start the following antiplatelet treatment(s):

a. Low-dose aspirin daily
b. Clopidogrel 75 mg daily without loading dose
c. A loading dose of clopidogrel 300 mg followed by 75 mg daily should be given
d. A loading dose of ticagrelor 180 mg followed by 2 × 90 mg/day should be given
e. No antiplatelet therapy needed prior to coronary angiography

35. A 66-year-old man with intermediate probability of ischemic heart disease is scheduled for stress testing. Which of the following strategies is not recommended?

a. Exercise ECG if able to exercise and ECG interpretable
b. Exercise echocardiography if able to exercise but uninterpretable ECG
c. Pharmacologic stress with nuclear myocardial perfusion imaging if able to exercise and ECG interpretable
d. Exercise stress with nuclear myocardial perfusion imaging if able to exercise but uninterpretable ECG
e. Pharmacologic stress with cardiac MR imaging if unable to exercise and interpretable ECG

36. A 65-year-old man with hypercholesterolemia, diabetes, and hypertension presents new, worsening, typical angina symptoms. The angiogram (Fig. 4.1) shows

a. occluded LAD.
b. occluded left circumflex coronary artery.
c. severe ostial and moderate distal left main trunk stenosis.
d. normal coronary arteries.
e. normal RCA.

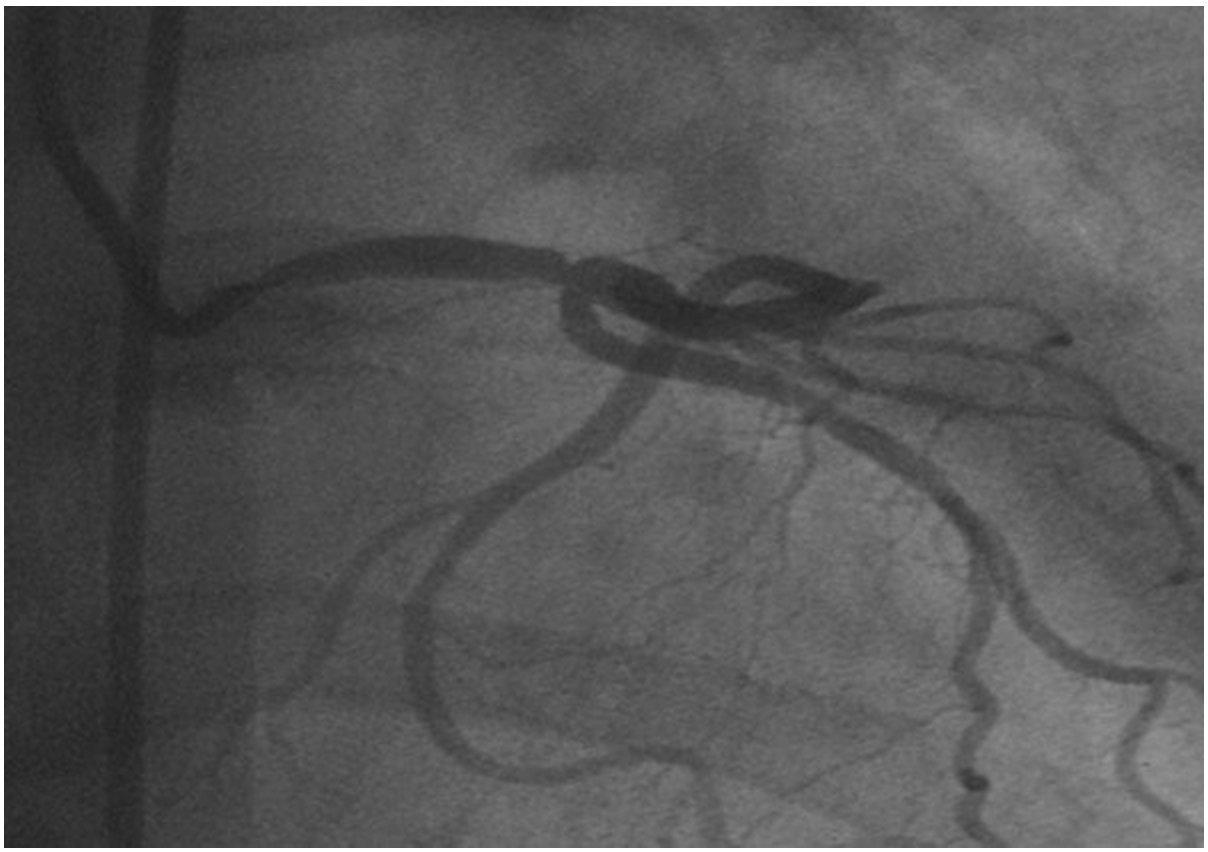

Figure 4.1

37. A 64-year-old man with stable ischemic heart disease (SIHD) wants to know whether he is at high risk for mortality. Which of the following clinical and exercise testing data are useful to predict the risk?

a. Typical angina symptoms
b. Diabetes
c. ST-segment depression during exercise
d. Proportion of predicted METs achieved
e. All of the above

38. A 48-year-old woman presents with congestive heart failure. The etiology of her heart failure based on the coronary angiogram (Fig. 4.2) is

a. severe CAD.
b. arteriovenous fistula.
c. aortic regurgitation.
d. absent RCA.
e. coronary perforation.

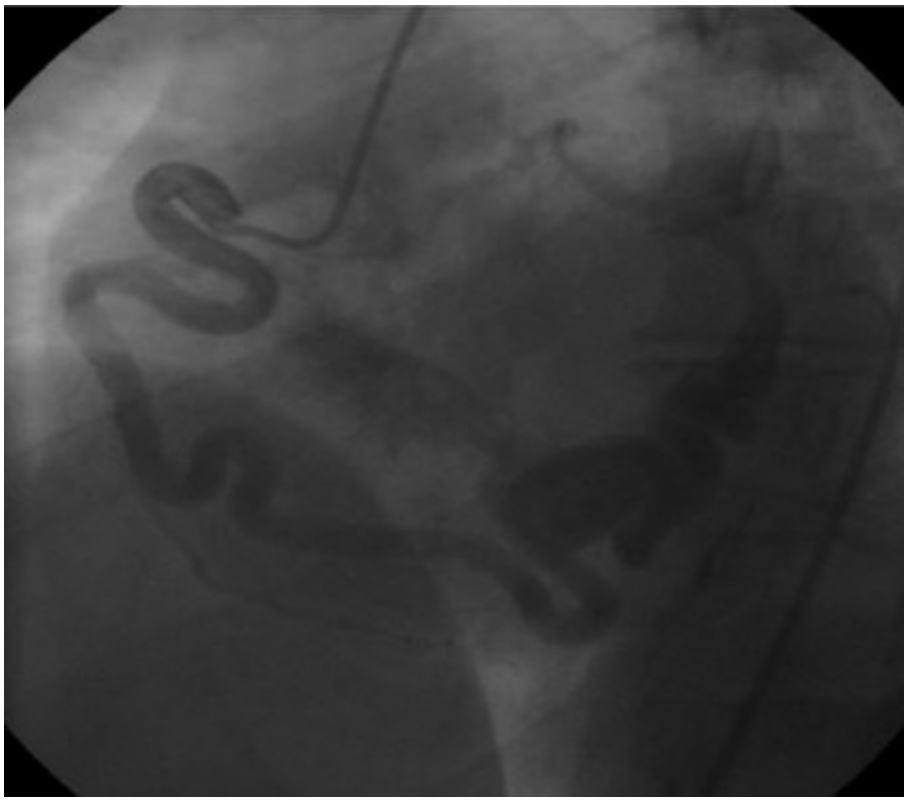

Figure 4.2

39. A 72-year-old man known with a history of coronary heart disease presents typical chest pain. During the transport to the PCI center, the patient had two episodes of ventricular fibrillation requiring electrical reanimation. ECG shows inferolateral

ST depression. What does the angiography show (Fig. 4.3)?

a. Lesions at bifurcation
b. Stenosis of the ostium of the LCX
c. Stenosis of the ostium of the LAD
d. Stenosis of the distal left main trunk
e. All of the above

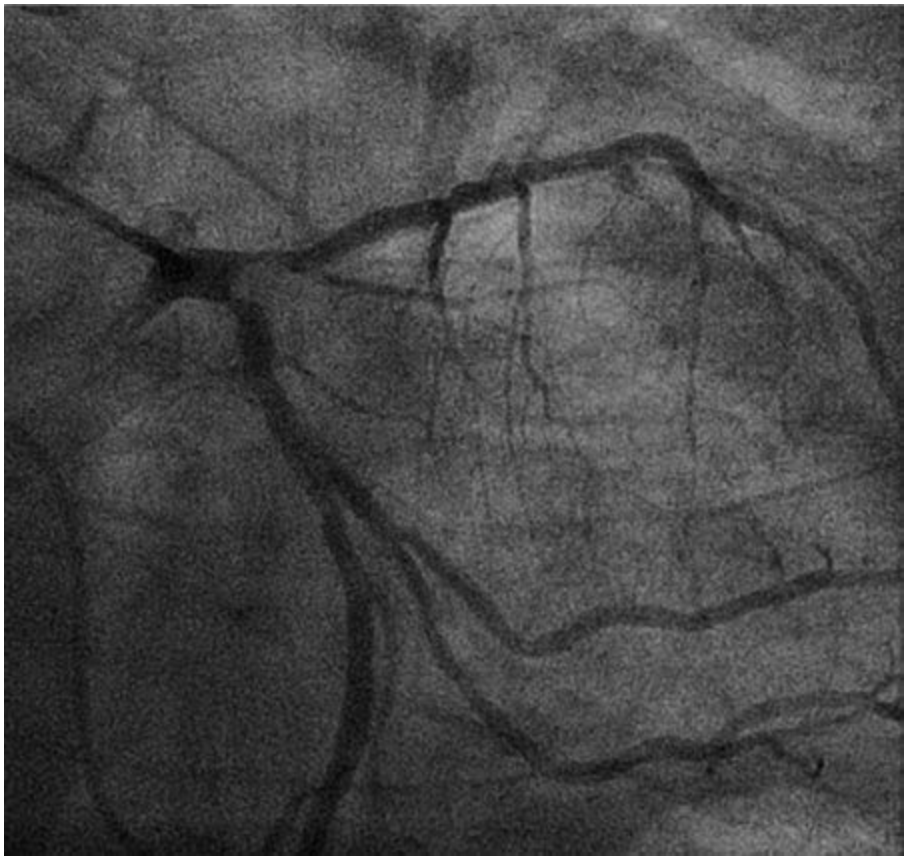

Figure 4.3

40. During coronary angioplasty of the RCA, this 72-year-old patient developed sharp chest pain with rapid development of hypotension and tachycardia. The etiology based on Figure 4.4 is

a. abrupt closure of the RCA.
b. dissection of the RCA.
c. perforation of the RCA.
d. allergic reaction.
e. distal embolization of an atherosclerotic plaque.

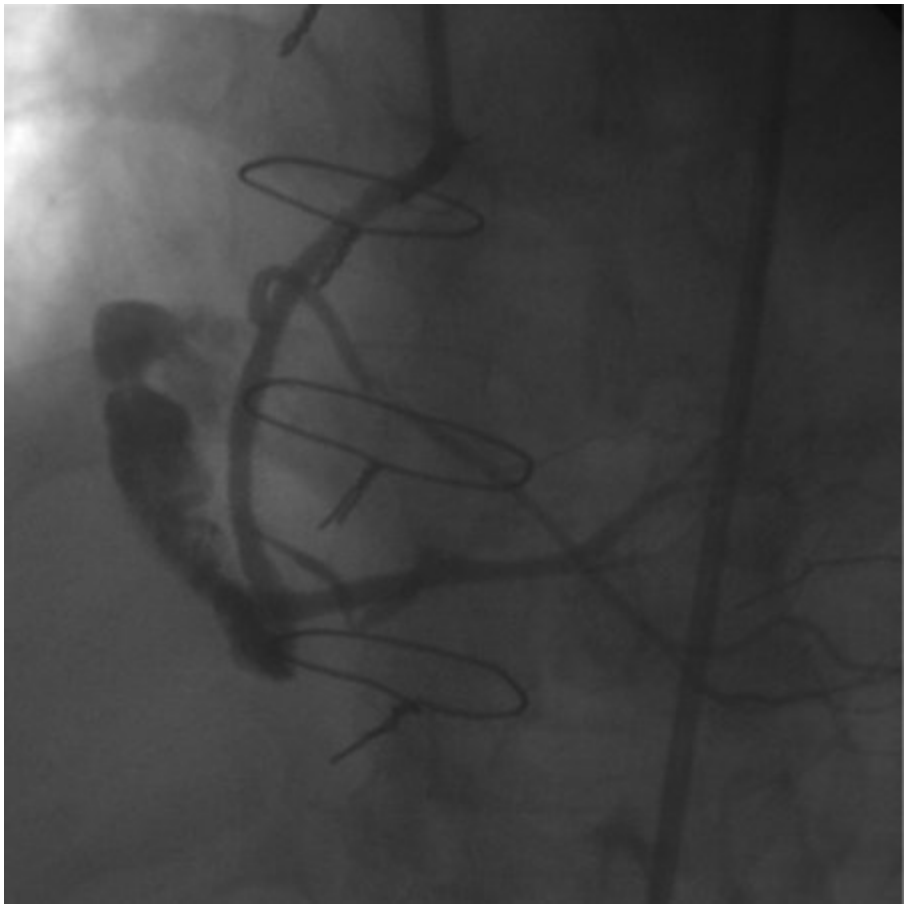

Figure 4.4

41. For which clinical situation is coronary angiography not recommended in patients with SIHD?

- **a.** Risk assessment in patients with SIHD not candidates for revascularization because of comorbidities
- **b.** Risk assessment in patients with SIHD who have preserved LV function and low-risk criteria on noninvasive testing
- **c.** Risk assessment in patients who are at low risk according to clinical criteria and have not undergone noninvasive risk testing
- **d.** Risk assessment in asymptomatic patients with no evidence of ischemia on noninvasive testing
- **e.** All the mentioned clinical situations do not justify coronary angiography in the initial phase of patient management

42. A 66-year-old man with diabetes with no hypertension but end-stage renal failure treated with hemodialysis in the last 15 years presents with worsening dyspnea and suspicion of ischemia at the stress imaging. What are the most characteristic findings relating to the coronary arteries to be found at angiography?

a. Tortuous coronary vessels
b. Calcified coronary arteries
c. Ectatic coronary arteries
d. Coronary arteries with anomalous origins
e. Normal coronary arteries (symptoms caused by small vessel disease)

43. A 65-year-old man with SIHD wants to optimize secondary prevention. Which of the following statements does not apply?

a. Smoking cessation and avoidance of exposure to environmental tobacco smoke at work and home should be encouraged.
b. Patients should be screened for depression and treated when indicated.
c. Treatment with clopidogrel is reasonable when aspirin is contraindicated.
d. Dipyridamole is not recommended as antiplatelet therapy for patients with SIHD.
e. Acupuncture might be used for the purpose of improving symptoms of patients with SIHD.

44. A 74-year-old man was hospitalized for a subacute MI. He presented 1 week prior to admission one episode of chest pain lasting 3 hours but he did not seek medical attention. The ECG at admission revealed deep Q waves and persisting ST-segment elevation in the anterior leads. The angiography showed a total occlusion of the proximal left anterior ascending coronary artery. Which statement about the benefit of revascularization in this particular patient does apply?

a. PCI reduces the occurrence of death.
b. PCI reduces the occurrence of reinfarction.
c. PCI reduces the occurrence of heart failure.
d. CABG should be preferred to PCI.
e. PCI does not reduce the occurrence of death, reinfarction, or heart failure.

45. A 60-year-old man with a history of PCI 3 years previously asks for your advice with respect to his pharmacologic treatment. He is asymptomatic and his CV risk factors include smoking, hypertension, hypercholesterolemia, and impaired glucose tolerance. His medications include aspirin, atorvastatin, metoprolol, metformin, and lisinopril. His friend told him that clopidogrel should be added to his regimen. What is the correct statement about that suggestion in this particular patient?

a. There is no significant benefit associated with clopidogrel plus aspirin as compared with placebo plus aspirin in reducing the incidence of the primary endpoint of MI, stroke, or death from CV causes.
b. There is a significant benefit associated with clopidogrel plus aspirin as

compared with placebo plus aspirin in reducing the incidence of the primary endpoint of MI, stroke, or death from CV causes.

c. The rate of severe or moderate bleeding is not significantly greater with clopidogrel and aspirin compared with aspirin alone.

d. The rate of severe or moderate bleeding is significantly greater with clopidogrel and aspirin compared with aspirin alone.

e. Answers a and d are correct.

46. A 60-year-old woman was discharged after an MI. Pharmacologic secondary prevention with antiplatelet agents, statins, β-blockers, and angiotensin-converting enzyme inhibitors is associated with

a. significant reduction in recurrent angina but no mortality benefit.

b. significant survival advantage.

c. no significant clinical benefit.

d. significant reduction in recurrent hospitalization but no mortality benefit.

e. significant survival advantage only in patients treated with PCI.

47. A 55-year-old man presents since 3 months typical chest pain at moderate exertion. The angiography revealed single-vessel disease. An optimal therapy has been started; what is the benefit of a treatment with PCI of the culprit lesion?

a. PCI would reduce the risk of death, MI, or other major CV events when added to optimal medical therapy (OMT).

b. PCI may reduce the episodes of angina in the presence of moderate-to-severe ischemia at stress single-photon emission computed tomography (SPECT) but not the risk of death, MI, or other major CV events when added to OMT.

c. PCI would not reduce the risk of death, MI, angina episodes, or other CV events when added to OMT.

d. The benefit of revascularization in patients with stable angina and ischemia detected on SPECT is independent of the extent of ischemia.

e. Selective ischemia-driven PCI approach should be avoided, as thus not improved clinical outcomes.

48. A 67-year-old man known for hypertension and hypercholesterolemia presented significant ST elevation in inferoposterior leads during the treadmill test. The angiogram shows (Fig. 4.5)

a. severe LCX stenosis.

b. severe left main trunk stenosis.

c. severe LAD stenosis.

d. severe RCA stenosis.

e. no significant coronary artery stenosis.

Figure 4.5

49. A 66-year-old man hospitalized for an NSTEMI was successfully treated with DES for a subtotal lesion of the proximal LAD. What is the recommended minimal duration of dual antiplatelet therapy according to the 2011 American College of Cardiology (ACC)/American Heart Association (AHA) guidelines on PCI?

a. 1 month
b. 3 months
c. 6 months
d. 12 months
e. 24 months

50. A 54-year-old man known for smoking and hypertension is admitted to the emergency department with an NSTEMI. Echocardiography reveals abnormalities in the acute lateral wall motion. The angiogram (Fig. 4.6) shows

a. severe LCX stenosis.
b. severe left main trunk stenosis.
c. severe LAD stenosis.
d. severe RCA stenosis.

e. no significant coronary artery stenosis.

Figure 4.6

51. A 75-year-old man has been treated 1 month ago with a DES in the proximal LAD for ACS. At that time he did not mention that he was supposed to require surgery for debilitating knee arthritis. Which of the following statements is correct?

a. The recent implantation of a DES is not problematic as long as aspirin can be continued during surgery.
b. The recent implantation of DES is not problematic as long as clopidogrel can be continued during surgery.
c. The recent implantation of DES is not problematic as long as aspirin and clopidogrel can be continued during surgery.
d. Discontinuation of dual antiplatelet therapy followed by noncardiac surgery in the first few weeks following stent implantation is associated with increased ischemic cardiac events with both DES and BMS.
e. Discontinuation of dual antiplatelet therapy followed by surgery in the first few weeks following stent implantation is problematic with DES but not BMS.

52. A 66-year-old woman had a second-generation DES implantation after an acute MI.

What is the correct statement?

a. To prevent DES late thrombosis, dual antiplatelet therapy with aspirin and clopidogrel is recommended for 3 years.
b. Based on the results of the CHARISMA (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization Management, and Avoidance) trial, aspirin and clopidogrel should be administered for at least 2 years in patients with an acute coronary event, independently of the implantation of a DES.
c. At 1 year, clopidogrel may be discontinued but if the patient is on low-dose aspirin, the dose of aspirin has to be increased to 325 mg/day.
d. In patients who have already suffered a stent thrombosis dual antiplatelet therapy may be extended long term, although currently there are no data to support this strategy.
e. Following DES implantation, aspirin should be discontinued at 12 months and clopidogrel administered indefinitely.

53. A 60-year-old man known for current smoking is admitted to the emergency department for prolonged typical chest pain. The 12-lead ECG is shown in Figure 4.7. What is the most likely finding at the coronary angiography?

a. Occlusion of the first marginal branch of the left circumflex coronary artery
b. Occlusion of the proximal left anterior descending coronary artery
c. Occlusion of the dominant RCA
d. Occlusion of the left main trunk
e. Occlusion of the first diagonal branch

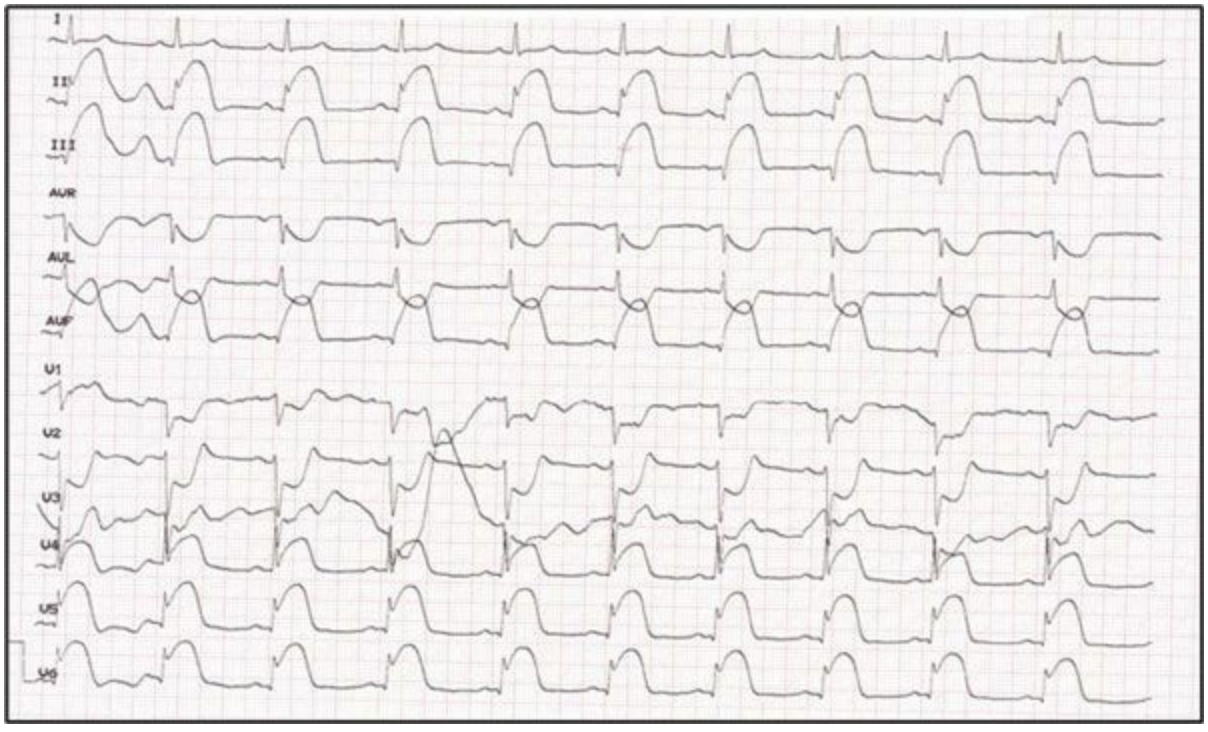

Figure 4.7

54. A 37-year-old man known for obesity felt typical chest pain while playing tennis accompanied by nausea, dyspnea, and sudations. The ECG shows ST-segment elevation. He is immediately admitted to the catheterization laboratory (Fig. 4.8). What is the underlying pathology?

a. Thrombotic occlusion of the left main trunk
b. Anomalous origin of the left main trunk
c. Dissection of the left main trunk
d. Vasospasm of the left main trunk
e. None of the above

55. A 58-year-old man known for hypertension and smoking suffered chest pain and dyspnea in the previous 48 hours. He consulted emergency department for persisting symptoms. The rest 12-lead ECG at admissions is shown in Figure 4.9. What is the diagnosis?

a. Takotsubo cardiomyopathy
b. Pericarditis
c. Anterior subacute MI
d. Cardiomyopathy hypertrophic obstructive
e. Hypertensive heart disease

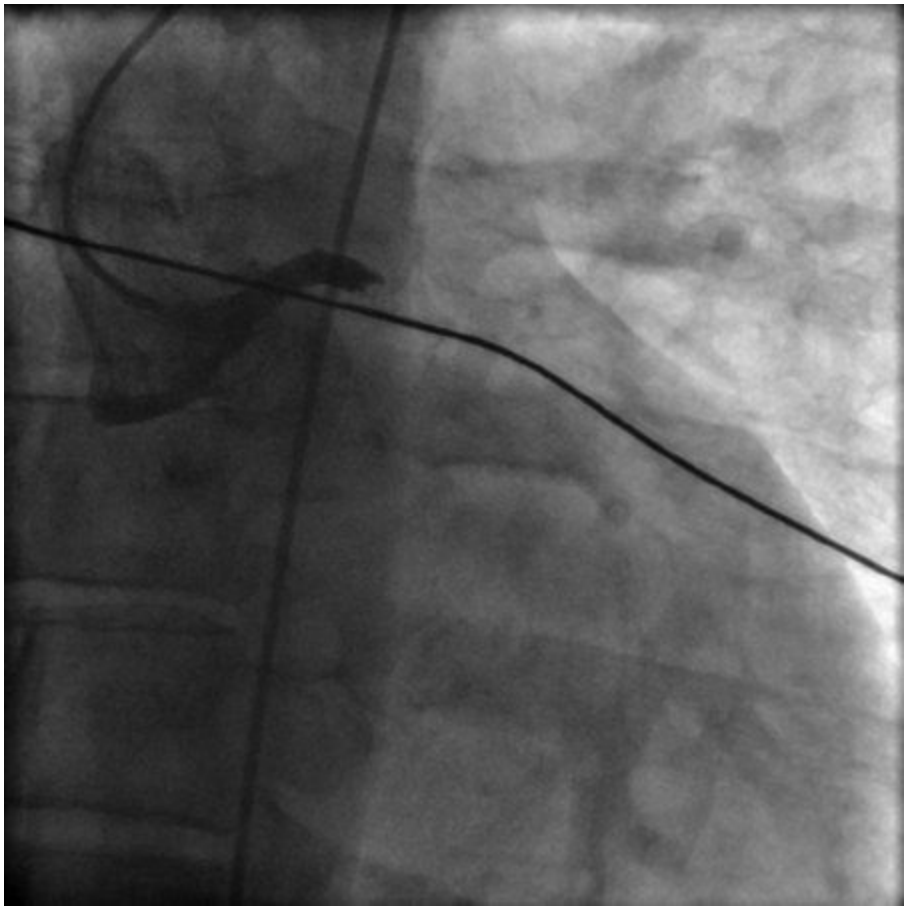

Figure 4.8

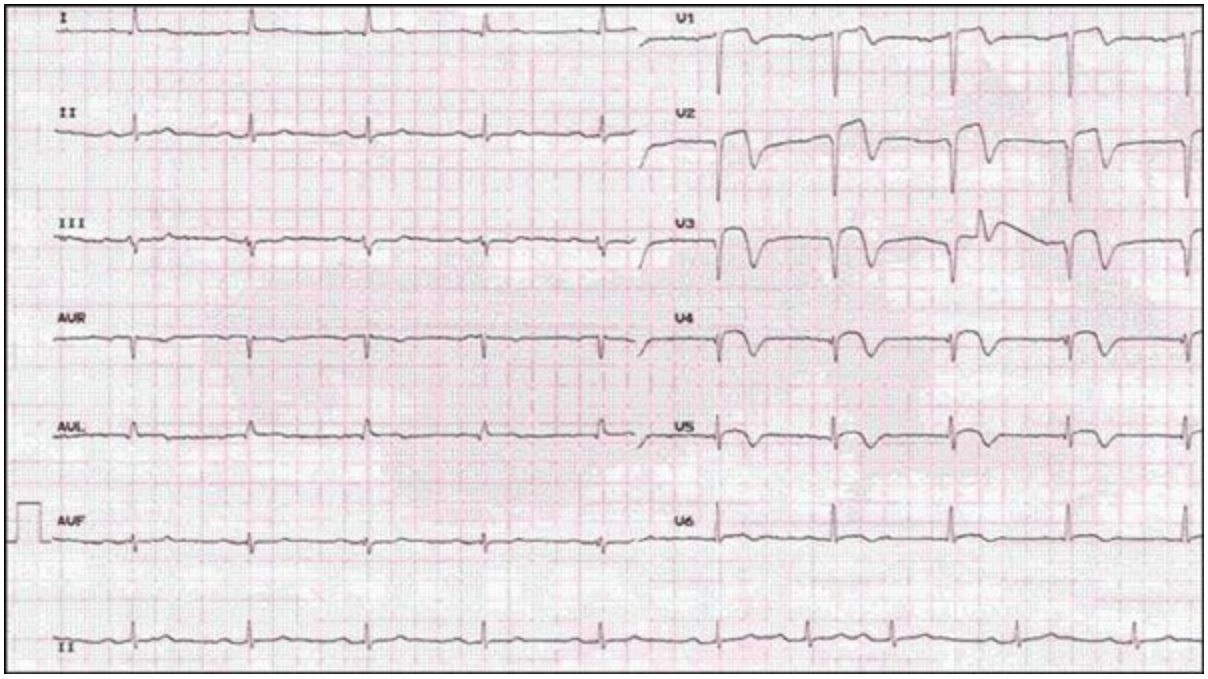

Figure 4.9

56. A 28-year-old male smoker presented after wakeup typical inaugural chest pain. The

12-rest ECG at admission is shown in Figure 4.10. He is transferred immediately to the catheterization laboratory. What is the most likely finding?

a. Occlusion of a large diagonal branch
b. Occlusion of the left anterior descending coronary artery
c. Occlusion of the left circumflex coronary artery
d. Occlusion of the RCA
e. Normal coronary angiogram

57. A 69-year-old man known for hypertension and diabetes consulted emergency department for typical chest pain. The ECG did not show significant changes. Troponins were elevated (1.4 µg/L). Coronary angiography (Fig. 4.11) shows

a. no significant lesion of the RCA.
b. perforation of the mid-portion of the RCA.
c. anomalous origin of the RCA.
d. visible thrombus in the mid-portion of the RCA.
e. dissection of the mid-portion of the RCA.

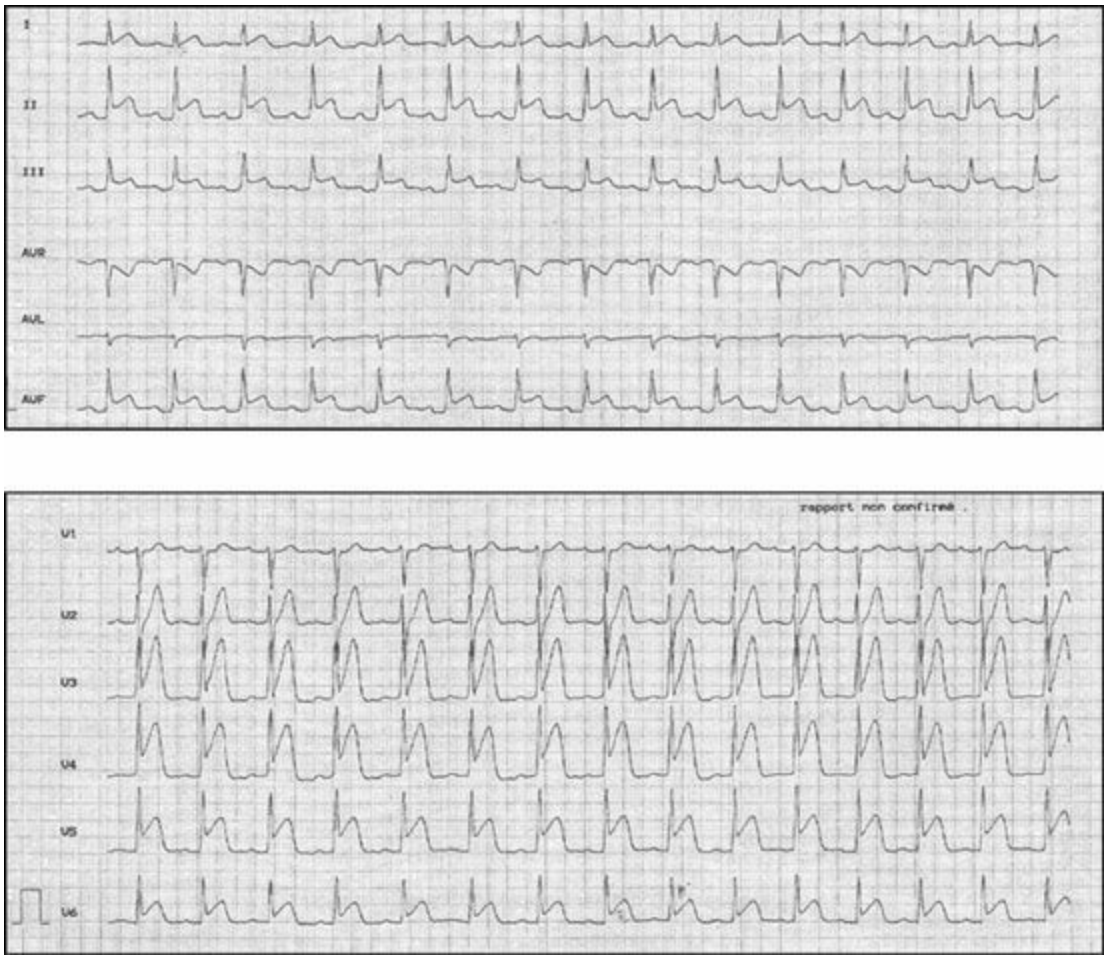

Figure 4.10

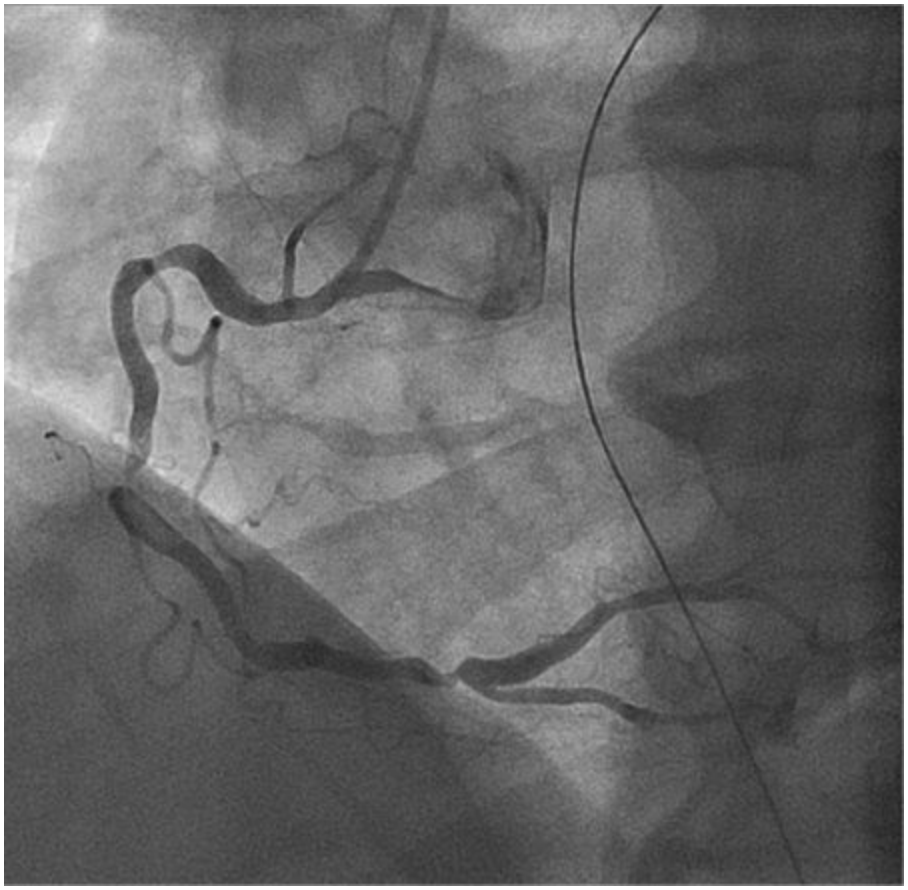

Figure 4.11

58. A 41-year-old overweight heavy-smoker construction worker presented with chest pain while on the job associated with diaphoresis and dyspnea. In the field, no ECG could be obtained due to the extreme diaphoresis. In the ambulance, the patient developed hypotension, bradycardia, and subsequently asystole. Under cardiopulmonary resuscitation he was transferred to the cardiac catheterization laboratory and circulation was reestablished using extracorporeal membrane oxygenation. Subsequently, coronary angiography (Fig. 4.12) shows

- **a.** subtotal occlusion of the left main trunk.
- **b.** aortic dissection.
- **c.** anomalous origin of the left main trunk.
- **d.** left main trunk stenosis equivalent (i.e., severe stenosis of the left anterior descending coronary artery and left circumflex).
- **e.** severe aortic stenosis.

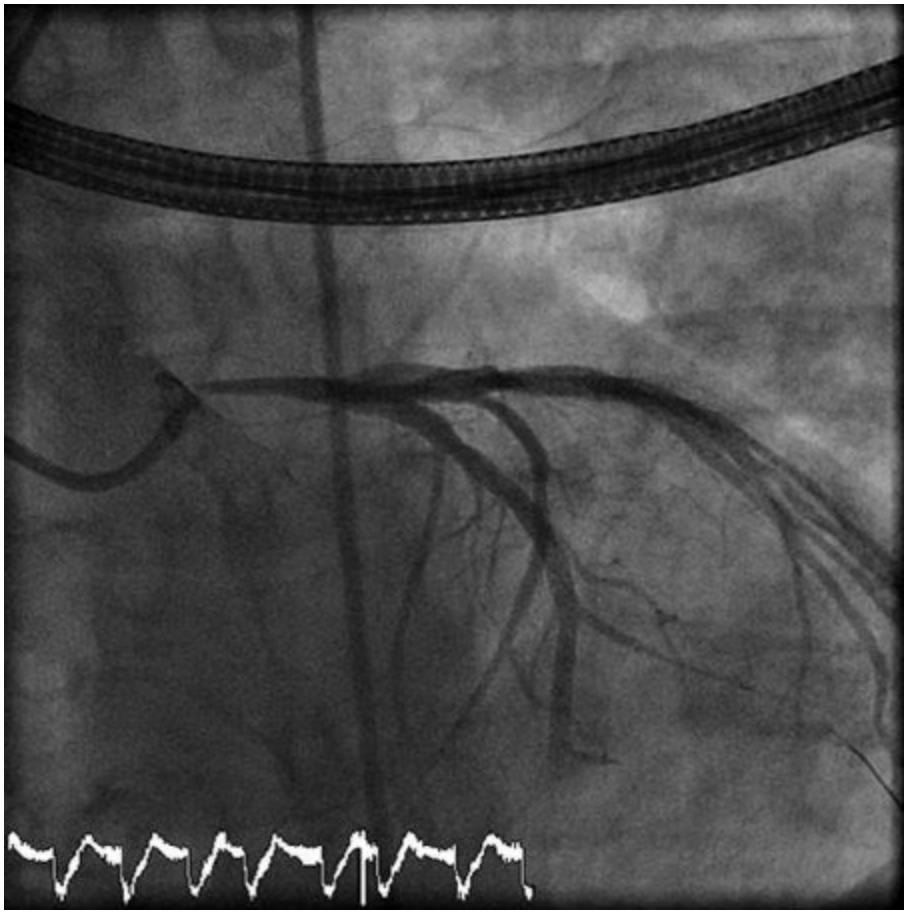

Figure 4.12

59. A 61-year-old man known for diabetes, hypercholesterolemia, hypertension, and a history of PCI with stenting of the mid-left anterior descending coronary artery 10 years earlier presents with worsening typical angina on exertion and a positive stress test. Coronary angiography (Fig. 4.13) shows

- **a.** ISR of the left descending coronary artery.
- **b.** significant stenosis of LCX.
- **c.** stenosis of the ostium of the left main trunk.
- **d.** normal coronary arteries.
- **e.** none of the above.

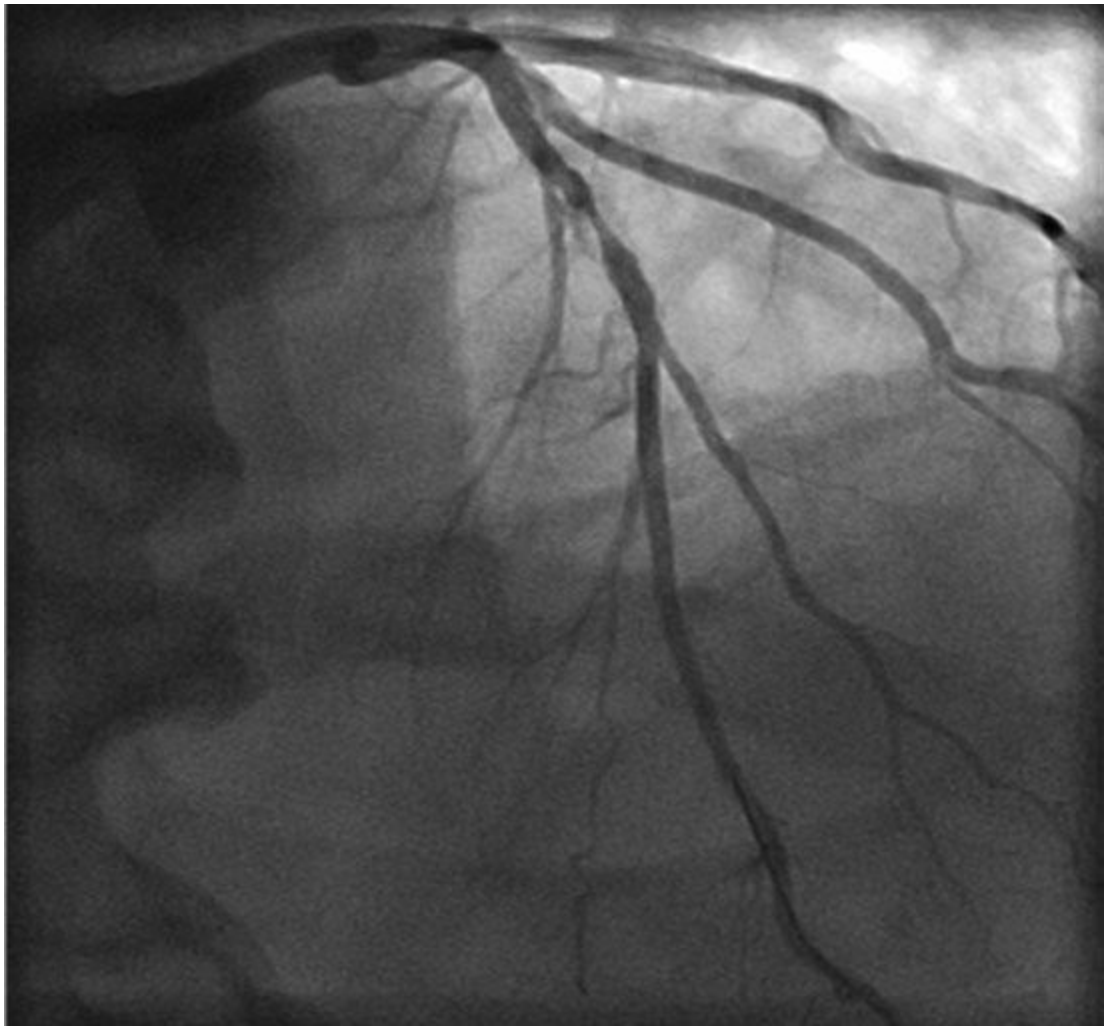

Figure 4.13

ANSWERS

1. **C.** Coronary angiography within 48 hours followed by percutaneous intervention/surgical revascularization if indicated. There is continued debate as to whether a routine, early invasive strategy is superior to a conservative strategy for the management of UA and NSTEMI. A pooled analysis of randomized controlled trials with 5,467 patients compared the impact of routine invasive (RI) strategy with selective invasive (SI) strategy: Over 5 years, 14.7% of patients randomized to an RI strategy experienced CV health or nonfatal MI versus 17.9% in the SI strategy (hazard ratio [HR]: 0.81; 95% confidence interval [CI]: 0.71 to 0.93; P = 0.002). However, the largest absolute effect was mainly observed in higher-risk patients (11.1%).[1] Another meta-analysis using data from eight trials (3,075 women and 7,075 men) compared early invasive versus conservative treatment strategies in women and men with UA and NSTEMI and reported comparable odds ratio (OR)

for reducing MACE (death, MI, and rehospitalization for ACS) of 0.81 (95% CI: 0.65 to 1.01) in women and 0.73 (95% CI: 0.55 to 0.98) in men. In contrast, an invasive strategy was not associated with a significant reduction in low-risk (biomarker-negative) women.[2] The 2012 ACC/AHA guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction recommend an early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) in patients who have refractory angina or hemodynamic or electrical instability, and in those initially stabilized who have an elevated risk of clinical events.[3] Table 4.1 lists patients at elevated risk and in whom invasive strategy is preferred based on the ACC/AHA 2011 guidelines. Our patient has several high-risk criteria (ongoing angina, elevated biomarkers, and echocardiographic abnormalities). TIMI (Thrombolysis in Myocardial Infarction) risk score revealed 5 points (26% risk at 14 days of MACE) and GRACE (Global Registry of Acute Cardiac Events) risk score showed a high risk of mortality.

2. **b.** Lower rate of hospital readmission. Belardinelli et al. addressed the effects of exercise training (ET) on functional capacity and quality of life (QOL) in patients who received percutaneous transluminal coronary angioplasty (PTCA) or coronary stenting (CS). The authors studied 118 consecutive patients with CAD (mean age 57 ± 10 years) who underwent PTCA or CS on one (69%) or two (31%) native epicardial coronary arteries. Patients were randomized into two matched groups. Group T (n = 59) was exercised three times a week for 6 months at 60% of peak VO_2. Group C (n = 59) was the control group. Only patients in the active group had significant improvements in peak VO_2 (26%, P <0.001) and QOL (26.8%, P = 0.001 versus C). The angiographic restenosis rate was unaffected by ET (T: 29%; C: 33%, P = not significant). However, residual diameter stenosis was lower in trained patients (–29.7%, P = 0.045). In patients with angiographic restenosis, thallium uptake improved only in group T (19%, P <0.001). During the follow-up (33 ± 7 months), trained patients had a significantly lower event rate than controls (11.9% versus 32.2%; risk ratio [RR]: 0.71; 95% CI: 0.60 to 0.91; P = 0.008) and a lower rate of hospital readmission (18.6% versus 46%; RR: 0.69; 95% CI: 0.55 to 0.93; P <0.001). Moderate ET improved functional capacity and QOL after PTCA or CS. During the follow-up, trained patients had fewer events and a lower hospital readmission rate than controls, despite an unchanged restenosis rate.[4] The 2011 ACC/AHA guidelines for PCI recommend (class I, evidence A) medically supervised exercise programs to patients after PCI, particularly for moderate- to high-risk patients for whom supervised ET is warranted.[5] Participation in cardiac rehabilitation is associated with significant reductions in all-cause mortality (OR 0.80; 95% CI: 0.68 to 0.93)[6] in several community-based surveys and meta-

analyses.[6-8]

3. **a.** Heart team discussion between the interventional cardiologist and the cardiac surgeon to select the best treatment option is the recommended approach. The 2011 AHA/ACC guidelines for PCI recommend the heart team approach (class I, evidence C) for the revascularization of patients with unprotected left main trunk disease.[5] Several trials used protocols that involve a multidisciplinary approach.[9,10] The heart team is composed of an interventional cardiologist and a cardiac surgeon and aims at (1) reviewing patients' medical history, (2) determining the approach of revascularization (PCI versus CABG), and (3) discussing with the patient the options of revascularization. The guidelines endorse a heart team approach in patients with unprotected left main CAD and/or complex CAD in whom the optional strategy is not straightforward. Because the STS score and the SYNTAX score predict clinical outcomes, their use is often useful in making revascularization decisions.[11,12]

TABLE 4-1 Selection of Initial Treatment Strategy: Invasive Versus Conservative Strategy

Preferred Strategy	Patient Characteristics
Invasive	Recurrent angina or ischemia at rest or with low-level activities despite intensive medical therapy
	Elevated cardiac biomarkers (TnT or TnI)
	New or presumably new ST-segment depression
	Signs or symptoms of HF or new or worsening mitral regurgitation
	High-risk findings from noninvasive testing
	Hemodynamic instability
	Sustained ventricular tachycardia
	PCI within 6 mo
	Prior CABG
	High risk score (e.g., TIMI, GRACE)
	Reduced left ventricular function (LVEF 40%)
Conservative	Low risk score (e.g., TIMI, GRACE)
	Patient or physician preference in the absence of high-risk features

TnT, troponin T; TnI, troponin I; HF, heart failure; PCI, percutaneous coronary intervention; CABG, coronary artery bypass grafting; GRACE, Global Registry of Acute Cardiac Events; TIMI, Thrombolysis in Myocardial Infarction; LVEF, left ventricular ejection fraction.

Adapted from Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 2002 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction) developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *J Am Coll Cardiol* 2007;50:e1–e157.

4. **C.** Drug-eluting stent (DES) implantation (stent-in-stent). In the randomized trial TAXUS V ISR (treatment of De Novo Coronary Disease Using a Single Paclitaxel-Eluting Stent trial), the slow-release, polymer-based, paclitaxel-eluting stent was found to be not only noninferior to β-source vascular brachytherapy but also superior in terms of reducing clinical and angiographic restenosis at 9 months after treatment of bare-metal ISR lesions. Because of both greater acute gain and less late loss, luminal dimensions were significantly larger with paclitaxel-eluting stents compared with brachytherapy in the injury zone, at the distal edge, and over the entire analysis segment. Proximal edge luminal dimensions were also numerically larger with the paclitaxel-eluting stent.[13] Similarly, the Sirolimus-Eluting Stent with Vascular Brachytherapy for the Treatment of In-Stent Restenosis (SISR) trial demonstrated a marked reduction in target vessel failure with the sirolimus-eluting stent, driven predominantly by a reduction in the rate of target vessel

revascularization.[14] Based on available data and the severity of the patient's COPD, DES implantation is the best option for this patient with BMS restenosis. Brachytherapy is no longer available except in a few research centers.[15]

5. **d.** Guideline-directed medical therapy is the first recommended approach. In the COURAGE (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) trial, 2,287 patients with stable CAD were randomized to undergo PCI and medical therapy or to medical therapy alone. The primary outcome was death from any cause and nonfatal MI during a follow-up of 2.5 to 7.0 years. The cumulative event rates were 19.0% in the PCI group and 18.5% in the medical therapy group (P = 0.62). As an initial management strategy, PCI did not reduce the risk of death, MI, or other MACE in the COURAGE trial.[16] About 314 patients were enrolled in the nuclear substudy of the COURAGE study to perform serial stress imaging. The addition of PCI to medical therapy improved ischemia reduction in patients with significant ischemia at baseline.[17] A recent meta-analysis of 10 randomized controlled trials (6,752 patients) comparing PCI with medical therapy in stable CAD did not detect significant differences in PCI versus CABG; the relative risk (RR) for all-cause mortality was 0.97 (95% CI: 0.84 to 1.12), CV mortality RR 0.91 (95% CI: 0.70 to 1.12), MI RR 1.09 (95% CI: 0.92 to 1.29), or angina relief RR 1.10 (95% CI: 0.97 to 1.26).[18] According to the AHA/ACC guidelines CABG or PCI should not be performed to improve symptoms or survival in patients with CAD with one or more coronary stenoses who do not meet anatomic (≥70% non-left main stenosis diameter), physiologic (FFR >0.80, no or mild ischemia on noninvasive testing) criteria for revascularization and involve only LCX or RCA, or subtend only a small area of viable myocardium.[5] The multiple meta-analyses comparing PCI versus medical therapy in patients with SIHD showed that PCI reduced the incidence of angina, but has not been demonstrated to improve survival or lower the long-term risk of MI in stable patients.[17,19] Our patient does not have criteria for coronary revascularization, and the first-line therapy should be an aggressive medical therapy.

6. **c.** Subendocardium. The subendocardium is most susceptible to ischemic damage. Although the mechanisms of subendocardial ischemia remain to be fully defined, they are clearly associated with the transmural distribution of intramyocardial systolic pressures. Even though almost all the myocardium is perfused in diastole, a reduction of diastolic perfusion pressure or duration will result in subendocardial ischemia.[11] The abnormal subendocardial perfusion in patients with cardiac syndrome X (typical angina, abnormal exercise test results, and normal coronary arteries) has been described with CV MR imaging during the IV administration of

adenosine.[20]

7. **d.** Inferior wall myocardial infarction (MI) with right ventricular infarction. The association of inferior wall MI on ECG and elevated jugular venous pressure with clear lungs is suggestive of additional right ventricular infarction. Tall c–v waves of tricuspid regurgitation may be evident in patients with necrosis or ischemia of the right ventricular papillary muscles.

8. **a.** Reduction in left ventricular compliance. An S_4 is frequently present in patients with acute MI and is related to auricular contraction and ventricular compliance reduction during ventricular filling.[21] Rapid deceleration of transmitral flow during protodiastolic filling of the left ventricle and increased inflow into the left ventricle are responsible for the third heart sound (S_3). A systolic ejection murmur is suggesting for aortic sclerosis.

9. **e.** Hybrid revascularization mandates surgical and percutaneous revascularization during the same procedure. According to the ACC/AHA PCI guidelines, hybrid coronary revascularization is defined as the planned combination of LIMA-to-LAD artery grafting and PCI of ≥1 non-LAD coronary arteries and intended to combine the advantages of CABG (i.e., durability of the LIMA graft) and PCI. Hybrid revascularization is particularly suitable in patients with limitations to traditional CABG (e.g., heavily calcified proximal aorta, lack of graft conduits, or a non-LAD coronary artery unsuitable for bypass but amenable to PCI) and situations in which PCI of the LAD artery is not feasible (e.g., excessive tortuosity or calcification, complex bifurcation lesion, and very long lesion). The procedure may be performed in one operative setting or as a staged procedure. CABG before PCI is preferred.[5] Preliminary reports suggest that this approach is feasible and safe,[22] but randomized data are lacking.

10. **c.** High-sensitive troponin T (Hs-TnT). In the PLATO (Platelet Inhibition and Patient Outcomes) trial, 9,946 patients presented with non-ST-elevation ACS: 5,357 were revascularized and 4,589 managed conservatively. High-sensitive elevated Hs-TnT (>14.0 ng/L) have been described to predict substantial benefit (reduction rate of CV death, MI, and stroke) of ticagrelor over clopidogrel in patients who were revascularized or treated conservatively, while no apparent was observed in those who had normal Hs-TnT.[23]

11. **e.** All of the above. Patients with extensive and severe CAD are more likely to present abnormal exercise ECG results.[24] Early onset of angina, ischemic ST

depression ≥2 mm, downsloping ST segment starting at <5 METs, involving ≥5 leads and persisting ≥5 minutes into recovery, and fall in blood pressure at low exercise are all associated with adverse prognosis.

12. **e.** No improvement of any of the mentioned endpoints. The COURAGE trial enrolled 2,287 patients with significant CAD to an initial strategy: (1) PCI and OMT or (2) OMT only. There were no significant differences between the PCI group and the medical therapy group in the composite of death, MI, and stroke (HR: 1.05; 95% CI: 0.87 to 1.27), and hospitalization for ACS (HR: 1.07; 95% CI: 0.84 to 1.37) or MI (HR: 1.13; 95% CI: 0.89 to 1.43). The authors concluded that as initial management strategy in patients with stable CAD, PCI did not reduce the risk of death, MI, or other MACE when added to OMT.[16] According to the 2011 ACC/AHA PCI guidelines, revascularization should not be performed to improve survival in patients with SIHD with one or more coronary artery stenoses that are not anatomically significant, or involve only the LCX or RCA, or subtend only a small area of viable myocardium.[5]

13. **e.** All of the above. In the COURAGE patients, 314 were enrolled in the substudy of myocardial perfusion SPECT performed before treatment and 6 to 18 months after randomization. At follow-up, the reduction in ischemic myocardium was greater with PCI + OMT than with OMT (–2.7% versus –0.5%, P <0.0001). The patients with PCI + OMT exhibited significant ischemia reduction (33% versus 19%, P = 0.0004), especially those patients with moderate-to-severe myocardial ischemia at baseline (78% versus 52%, P = 0.007).[17] The 2012 AHA/ACC guidelines for PCI mentioned in patients with stable ischemic coronary heart disease a benefit of angina reduction and symptom improvement with PCI versus OMT; however, PCI has not been demonstrated to improve survival in stable patients.[5]

14. **b.** Significant absolute risk reduction of major adverse cardiovascular events (MACE) of ~2% over 5 years. The 2012 ACC/AHA guidelines for the management of SIHD recommend the prescription of moderate or high dose of a statin therapy in addition to lifestyle changes (class I, evidence A).[25] The Treating to New Targets (TNT) study randomized 10,001 patients with stable coronary heart disease and LDL >130 mg/dL to receive atorvastatin 10 or 80 mg daily. The mean LDL-C was 2.0 mmol/L during the treatment with 80 mg of atorvastatin, whereas it was 2.6 mmol/L during the treatment with 10 mg of atorvastatin. About 8.7% of patients in the group with intensive lipid-lowering therapy and 10.9% in the group with moderate lipid-lowering therapy presented MACE during a median follow-up of 4.9 years, representing a significant absolute reduction in the rate of MACE of

2.2% and a 22% relative reduction in risk. There was no difference between both treatment groups in the overall mortality.[26]

15. **e.** Fondaparinux might be used as the sole anticoagulant to support PCI. The 2011 ACCF/AHA PCI guidelines made the following recommendations regarding anticoagulant therapy during the procedure. Following recommendations are class I: (1) All patients undergoing PCI should receive an anticoagulant to prevent thrombus formation during the procedure; (2) the administration of IV UFH is a useful standard therapy in patients undergoing PCI; (3) an additional dose of 0.3 mg/kg IV enoxaparin should be administered at the time of PCI to patients who have received fewer than two therapeutic subcutaneous doses (e.g., 1 mg/kg) or received the last subcutaneous enoxaparin dose 8 to 12 hours before PCI; and (4) for patients undergoing PCI, bivaluridin is useful as an anticoagulant with or without prior treatment with UFH. In contrast, fondaparinux should not be used as the sole anticoagulant to support PCI.[5] An additional anticoagulant with anti-IIa activity should be administered because of the risk of catheter thrombosis. Fondaparinux is an indirect factor Xa inhibitor, but no effect on thrombin (IIa). The use of fondaparinux alone was associated with thrombus catheter formation and therefore the anticoagulant with anti-IIa should be used during PCI.[27]

16. **e.** Even in the absence of symptoms, routine periodic stress testing is indicated. According to the 2011 AHA/ACC PCI and 2011 AHA/ACC secondary prevention guidelines, the following interventions and targets are strongly recommended in patients with CHD to reduce morbidity and mortality: (1) to refer to a medically supervised cardiac rehabilitation program post discharge, (2) to manage lipid-lowering treatment for an LDL-C target <70 mg/dL, (3) to control blood pressure with the goal of <140/90 mmHg, and (4) to advise patients for complete smoking cessation. Conversely, there is no proven benefit or indication for routine periodic stress testing in patients after PCI, and thus, it is not indicated.[24]

17. **e.** All of the above. The clinical situations associated with higher risk of BMS restenosis have been defined by the 2011 AHA/ACC PCI guidelines as follows: (1) left main disease, (2) small vessels, (3) ISR, (4) bifurcations, (5) diabetes, (6) long lesions, (7) multiple lesions, and (8) saphenous vein grafts. The ISR of BMS presented by the patient should be treated with DES,[5] as sirolimus- or paclitaxel-eluting stents are superior to balloon angioplasty.[28] The use of DES over BMS had decreased the incidence of ISR by over 70%.[13,28]

18. **b.** Rosuvastatin 20 mg/day significantly decreased the incidence of MI. The

JUPITER trial randomized 17,802 men and women without CVD presenting an LDL-C lower than 130 mg/dL, but high levels of hs-CRP, to rosuvastatin, 20 mg daily, or to placebo. Rosuvastatin reduced LDL-C levels by 50% and hs-CRP levels by 37%. The primary endpoint outcome was a composite of MI, stroke, arterial revascularization, hospitalization for UA, or death from CVD. The study was interrupted after 1.9 years at interim analyses because of a significant decrease for primary outcome (HR: 0.56; 95% CI: 0.46 to 0.69). HR for MI was 0.46, 95% CI (0.30 to 0.70), and HR for stroke was 0.52, 95% CI (0.34 to 0.79). In the adverse events section, the physician-reported diabetes was more frequent in the rosuvastatin group (n = 270) than in the placebo group (n = 216, P = 0.01); the difference in the median glycated hemoglobin value was minimal (5.9% versus 5.8%, respectively, P = 0.001).[29]

19. **c.** CABG is associated with a reduction of death and of MI, but not of stroke. The future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial randomized 1,900 patients with diabetes and multivessel CAD to a revascularization strategy with (1) CABG or (2) PCI. The primary outcome was defined as death from any cause, nonfatal MI, or nonfatal stroke. The primary outcome rate at 5 years was 26.6% in the PCI group and 18.7% in the CABG group. The benefit of CABG was observed in reduction of death (P = 0.049) and MI (P <0.001) rates, but stroke was more frequent in the CABG group than the PCI group (5.2% versus 2.4%, P = 0.03).[30]

20. **c.** More than 70% of patients quit smoking after ACS. About 50% to 70% of smokers continue to smoke after an ACS,[31] despite the fact that smokers who quit smoking have a 36% reduction in the risk of mortality and 32% in the risk of recurrent nonfatal MI in comparison with continuing smokers over a mean follow-up of 5 years.[32] Smoking cessation intervention is a major target of secondary prevention of CVD and should be one of the priorities of clinicians providing care to such patients. Given the large benefits of smoking cessation, promotion of smoking cessation is the most effective intervention to reduce morbidity and mortality in smokers with CHD.[32] Unfortunately smoking receives less attention from cardiologists than other CV risk factors,[33] and many smokers with CHD are unable to quit smoking without assistance. Based on a systemic review, several studies found a beneficial effect on smoking cessation rates through a smoking cessation intervention that started in hospital and continued in the ambulatory setting.[31]

21. **e.** Answers b and d are correct. The leading cause of death in patients hospitalized

for acute MI is cardiogenic shock. The SHOCK investigators conducted a randomized trial to evaluate early revascularization in patients with cardiogenic shock. Patients with shock caused by left ventricular failure complicating MI were randomly assigned to emergency revascularization (152 patients) or initial medical stabilization (150 patients). Revascularization was accomplished by either CABG or angioplasty. Intra-aortic balloon counterpulsation was performed in 86% of the patients in both groups. The primary endpoint was mortality from all causes at 30 days. Six-month survival was a secondary endpoint. The mean age of the patients was 66 ± 10 years; 32% were women and 55% were transferred from other hospitals. The median time to the onset of shock was 5.6 hours after infarction, and most infarcts were anterior in location. Ninety-seven percent of the patients assigned to revascularization underwent early coronary angiography, and 87% underwent revascularization; only 2.7% of the patients assigned to medical therapy crossed over to early revascularization without clinical indication. Overall mortality at 30 days (primary endpoint) did not differ significantly between the revascularization and medical therapy groups (46.7% and 56.0%, respectively; difference, –9.3%; 95% CI for the difference, –20.5% to 1.9%; P = 0.11). However, at 6 months mortality was lower in the revascularization group than in the medical therapy group (50.3% versus 63.1%, P = 0.027).[34]

22. **a.** Patients with CKD undergoing cardiac catheterization should receive adequate preparatory hydration. The 2011 ACC/AHA PCI guidelines made recommendations regarding contrast-induced AKI. Contrast-induced AKI is considered one of the most frequent causes of iatrogenic AKI. Risk factors for developing contrast-induced AKI are hypotension, intra-aortic balloon pump, congestive heart failure, CKD, diabetes, age >75 years, anemia, and volume of contrast.[35] The following recommendations are of class I for the prevention of AKI: (1) Patients should be assessed for risk of contrast-induced AKI before PCI; (2) patients undergoing catheterization with contrast media should receive adequate preparatory hydration; and (3) in patients with CKD (creatinine clearance <60 mL/min), the volume of contrast media should be minimized. However, the administration of N-acetyl-cysteine is not useful for the prevention of contrast-induced AKI and is not recommended based on the results of several randomized controlled trials.[36]

23. **a.** No significant difference in the risk of stroke. Abciximab, a potent inhibitor of the platelet glycoprotein IIb/IIIa receptor, reduces thrombotic complications in high-risk patients undergoing PCI in the setting of ACS compared with a regimen of aspirin and UFH. Akkerhuis et al. combined analysis of data from 8,555 patients undergoing PCI assigned to receive a bolus and infusion of abciximab (n = 5,476) or matching placebo (n = 3,079). No significant difference in stroke rate was

observed between patients assigned abciximab (n = 22 [0.40%]) and those assigned placebo (n = 9 [0.29%]; P = 0.46). The rate of nonhemorrhagic stroke was 0.17% in patients treated with abciximab and 0.20% in patients treated with placebo (difference: –0.03%; 95% CI: –0.23% to 0.17%), and the rates of hemorrhagic stroke were 0.15% and 0.10%, respectively (difference: 0.05%; 95% CI: –0.11% to 0.21%). Abciximab in addition to aspirin and heparin does not increase the risk of stroke in patients undergoing PCI.[39]

24. **d.** 70 mg/dL. For patients with established CAD, LDL-lowering therapies significantly reduce the risk of MACE and yield highly favorable cost-effectiveness ratios. In high-risk persons, the recommended LDL-C goal is <100 mg/dL. An LDL-C goal of <70 mg/dL is a therapeutic option on the basis of available clinical trial evidence, especially for patients at very high risk. Diabetic patients with established advanced CAD, like the mentioned patient, should be considered at very high risk for MACE and qualify for the ambitious target of LDL <70 mg/dL.[42]

25. **c.** Additional aspirin (81 to 325 mg) is recommended in all patients on chronic aspirin therapy before PCI. The 2011 AHA/ACC PCI guidelines recommend the use of antiplatelet therapy before PCI.[5] Aspirin reduced ischemic CV events after PCI[37,38] and should be given at least 2 hours before PCI after which aspirin has to be continued indefinitely.[39] In addition to aspirin, a loading dose of $P2Y_{12}$ receptor inhibitor might be given to patients undergoing PCI with stenting.[40-42] Options include clopidogrel 600 mg, prasugrel 60 mg, or ticagrelor 180 mg. The duration of $P2Y_{12}$ receptor inhibitor after stent implantation (BMS or DES) for ACS should be of at least 12 months.[43,44] Options include clopidogrel 75 mg daily, prasugrel 10 mg daily, and ticagrelor 90 mg twice daily. In patients receiving DES for a non-ACS indication, clopidogrel 75 mg daily should be given for 12 months if patients are not at high risk for bleeding.[45] In patients receiving BMS for a non-ACS indication, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months.[44] A benefit of additional aspirin in patients on chronic aspirin undergoing PCI has never been demonstrated.

26. **c.** 20% to 30%. A proportion of patients who present with suspected ACS are found to have insignificant CAD during coronary angiography. Of the 5,767 patients with non-ST-segment-elevation ACS who were enrolled in the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin (Eptifibatide) Therapy (PURSUIT) trial and who underwent inhospital angiography, 88% had significant CAD (any stenosis >50%), 6% had mild CAD (any stenosis >0% to ≤50%), and 6% had no CAD (no stenosis identified). Overall, 12% of the patients

had nonsignificant CAD.[44] Patients with nonsignificant CAD were more likely to be women, non-white, younger, nondiabetic, nonhypercholesterolemic, without history of CVD, without ST-segment changes, but with more T-wave inversion compared with patients with significant CAD. Based on the profile of the patient admitted, her probability of having nonsignificant CAD is >12%.

27. **b.** Prothrombin complex. Bivaluridin is a naturally occurring anticoagulant secreted by the salivary glands of the leech Hirudo medicinalis. It is a potent and specific anticoagulant and exerts its action by binding directly to the active catalytic site of thrombin. Unlike heparin, it does not require a cofactor (antithrombin) and does not appear to cause immune-mediated thrombocytopenia. It is also a more potent inhibitor of platelet function than heparin, probably because of a direct inhibitory effect on thrombin. Unlike heparin, which is readily neutralized by protamine or platelet factor 4, a specific agent useful in reversing the effects of bivalirudin is unavailable. Irani et al. demonstrated the first clinical experience, suggesting benefit from prothrombin complex concentrate in neutralizing the effect of r-hirudin. Although the specific mechanism of action remains unclear, the generation of additional thrombin probably plays a role. Also, epinephrine-induced platelet aggregation in hirudinized platelet-rich plasma is restored by addition of prothrombin complex concentrate, most probably by additional thrombin generation. Adverse effects of prothrombin complex concentrate include intravascular thrombosis, particularly in patients with liver disease and possible viral hepatitis. As the product contains some activated clotting factors (II, VII, IX, and X) and has thrombogenic potential, it should be used as a last resort, especially in patients with liver disease. Clinical experience suggests that prothrombin complex concentrate in a dose of 25 to 30 UI/kg can be considered for patients with life-threatening hemorrhage caused by bivalirudin.[45]

28. **e.** The radial vascular access is more frequently performed in the United States than in Europe. Radial site access is used more frequently in Europe and Canada than in the United States.[46] The 2011 AHA/ACC PCI guidelines recommend radial artery access to decrease access site complications.[5] In fact, it has been demonstrated that radial access, compared with femoral access, decreases the rate of access-related bleeding and complications.[47] Its utility is more pronounced in patients at higher risk for bleeding or vascular access complications such as in patients with coagulopathy, anticoagulated, or morbid obesity.

29. **c.** A 65-year-old man known for CAD complaining of progressive shortness of breath since 1 week. At admission, no ongoing chest pain with stable hemodynamic

status but bibasilar rales at lung auscultation. The ECG revealed ST-segment elevation as well as Q waves in the anterior leads. The 2011 AHA/ACC PCI guidelines elaborated indication of PCI in patients with STEMI.[5] Primary PCI should be performed in patients within 12 hours of onset of STEMI, within 90 minutes of the first medical contact in patients presenting to a hospital with PCI capabilities and within 120 minutes of the first medical contact in patients presenting to a hospital without PCI capabilities ("systems goal").[48–50] Primary PCI should be performed in patients with STEMI who are candidates for primary PCI, who develop severe heart failure or cardiogenic shock irrespective of time delay,[34,51] and who had clinical and/or ECG evidence for ongoing ischemia between 12 and 24 hours after symptom onset.[52] Delayed PCI in patients with STEMI is reasonable in patients with infarct artery reocclusion or demonstrating ischemia on invasive testing.[53] PCI of hemodynamically significant stenosis in patent infarct artery greater than 24 hours after STEMI might be considered as part of an invasive strategy (class of recommendations IIb).[54,55] PCI of a totally occluded infarct artery greater than 24 hours after STEMI should not be performed in asymptomatic patients with one- or two-vessel disease if patients are hemodynamically stable and do not present evidence of severe ischemia (class III).[56]

30. **d.** Right ventricular infarction. Rupture of the interventricular septum is one of the mechanical complications of MI, less frequent than left free wall rupture.[57] It occurs in general 3 to 5 days after acute MI. An increase in risk is observed in patients with occlusion of LAD wrapping the distal inferior wall and inferior septum (inferior MI with large anterior MI). The ECG findings of the interventricular septum rupture are typical for ST elevation and Q waves in the inferior leads II, III, and aVF.[58] Clinically, the patients present a rapid onset of hemodynamic compromise characterized by hypotension, biventricular failure, and a new harsh, loud, holosystolic murmur best heard at the lower left sternal border.[59]

31. **d.** Immediate coronary angiography. The septal defect and the associated turbulent transseptal flow can be visualized by a transthoracic echocardiography using color flow Doppler imaging.[60] The addition of Doppler to echocardiography improves significantly the sensitivity of the examination demonstrating the transseptal turbulent flow and diastolic–systolic turbulences in the right ventricle.

32. **c.** Mechanical ventilation with positive end-expiratory pressure. The timing of surgical repair with post-MI ventricular septal rupture is controversial. In patients with cardiogenic shock, a fatal prognosis is inevitable in the absence of urgent

surgical treatment. First, stabilization with an intra-aortic balloon pump counterpulsation, inotropic agents, diuretics, and, if tolerated, vasodilators is attempted.[61] This is followed by cardiac catheterization to define the coronary anatomy and then surgical repair.

33. **e.** All of the above. The 2011 ACC/AHA PCI guidelines assessed the risk–benefit profile for the use of BMS versus DES. DES is preferred to BMS when high risk of stent restenosis is present with BMS. The clinical situations associated with higher risk of restenosis are (1) left main disease, (2) small vessels, (3) ISR, (4) bifurcations, (5) diabetes, (6) long lesions, (7) multiple lesions, and (8) saphenous vein grafts. All the criteria mentioned above increased the risk of restenosis, suggesting the use of DES over BMS.[5]

34. **a.** Low-dose aspirin daily. The patient will have coronary angiography for a high suspicion of SIHD. Until the angiogram is performed, he should be treated with optimal medical treatment including aspirin, statins, control of blood pressure (β-blockers/angiotensin converting), and additional medical therapy for the relief of symptoms (β-blockers, calcium channel blockers, long-acting nitrates, or sublingual nitroglycerin).[25] The efficacy of clopidogrel pretreatment compared with the administration in the catheterization laboratory is controversial.[62] There is no evidence to give prasugrel or ticagrelor in patients with SIHD.

35. **c.** Pharmacologic stress with nuclear myocardial perfusion imaging if able to exercise and interpretable ECG. Patients with intermediate pretest probability of CAD are those who most benefit from stress testing to improved diagnostic accuracy. The choice of stress test depends on two questions: Is the patient able to exercise? Is the resting ECG interpretable?[25] The ACC/AHA SIHD guidelines recommend standard exercise ECG testing for interpretable ECG and at least moderate physical functioning or no disabling comorbidity (level of evidence A, class I).[63] Exercise with nuclear myocardial perfusion imaging or echocardiography is recommended for patients with an intermediate to high pretest probability of ischemic heart disease who have an uninterpretable ECG and at least moderate physical activity functioning or no disabling comorbidity.[64,65] Pharmacologic stress with cardiac MR can be useful for patients with an intermediate to high pretest probability who have an uninterpretable ECG and at least moderate physical functioning or no disabling comorbidity.[66] Pharmacologic stress with nuclear myocardial perfusion imaging, echocardiography, or cardiac MR is not recommended for patients who have an interpretable ECG and at least moderate physical functioning or no disabling comorbidities.[67]

36. **c.** Severe ostial and moderate distal left main trunk stenosis. The coronary angiography shows severe ostial and moderate distal left main trunk stenosis.

37. **e.** All of the above. The 2012 AHA/ACC guidelines on SIHD[25] recommend using a nomogram to predict the risk of death in patients with SIHD.[68] This score is based on following clinical and exercise testing variables: age, male gender, typical angina, diabetes, cigarette smoking, hypertension, proportion of predicted METs achieved, ST-segment depression, test-induced angina, abnormal heart rate recovery, and frequent ventricular ectopy during recovery.

38. **b.** Arteriovenous fistula. The coronary angiography reveals large coronary AV fistula involving the RCA. Patient underwent surgical ligation of the fistula with resolution of her symptoms.

39. **e.** All of the above. The coronary angiography shows a bifurcation lesion involving the distal left main trunk as well as the ostium of the left anterior descending and left circumflex coronary arteries.

40. **c.** Perforation of the RCA. The coronary angiography demonstrates extravasation of contrast caused by perforation of the RCA.

41. **e.** All the mentioned clinical situations do not justify coronary angiography in the initial phase of patient management. According to 2012 AHA/ACC SIHD guidelines,[25] coronary angiography is not recommended as an initial testing strategy to assess risk in the following clinical situations (class III, no benefit): (1) patients with SIHD who elect not to undergo revascularization or who are not candidates for revascularization because of comorbidities or individual preferences; (2) patients with SIHD who have preserved left ventricular function and low-risk criteria on noninvasive testing; (3) low risk according to clinical criteria and who have not undergone noninvasive risk testing; and (4) asymptomatic patients with no evidence of ischemia on noninvasive testing.

42. **b.** Calcified coronary arteries. Patients with long-standing terminal nephropathy have frequently severely calcified vessels including the coronary arteries.[69] Qualitative analysis of the coronary arteries showed significantly more calcified plaques of coronary arteries in patients with end-stage renal failure. Plaques of nonuremic patients were mostly fibroatheromatous, while coronary plaques in patients with end-stage renal failure were characterized by increased media thickness and marked calcification. Deposition of calcium within the plaques may contribute to the high event rate in uremic patients.

43. **e.** Acupuncture might be used for the purpose of improving symptoms of patients with SIHD. According to 2012 AHA/ACC SIHD guidelines,[25] acupuncture should not be used for the purpose of improving symptoms or reducing CV risk in patients with SIHD (class III, no benefit). Smoking cessation and avoidance of exposure to environmental tobacco smoke at work and home should be encouraged (class I), dipyridamole is not recommended as antiplatelet therapy for patients with SIHD (class III, no benefit), treatment with clopidogrel is reasonable when aspirin is contraindicated in patients with SIHD (class I), and it is reasonable to consider screening SIHD patients for depression and to refer or treat when indicated (class IIa).

44. **e.** PCI does not reduce the occurrence of death, reinfarction, or heart failure. The Occluded Artery Trial (OAT) study showed high rates of procedural success with PCI and sustained patency but no clinical benefit during an average 3-year follow-up with respect to death, reinfarction, or heart failure.[56] There was, in fact, a trend toward excess nonfatal reinfarction when routine PCI was performed in stable patients who were found to have occlusion of the infarct-related artery 3 to 28 days after MI. A strategy of CABG was not tested in the OAT.

45. **e.** Answers a and d are correct. In the CHARISMA trial of 15,603 patients with established stable atherothrombotic disease or at high risk for such disease, there was no significant benefit associated with clopidogrel plus aspirin as compared with placebo plus aspirin in reducing the incidence of the primary endpoint of MI, stroke, or death from CV causes. Clopidogrel was associated with a significant increase in the rate of moderate bleeding.[70]

46. **b.** Significant survival advantage. A cohort study of approximately 1,400 patients demonstrated that the use of combination evidence-based medical therapies was independently and strongly associated with lower 6-month mortality in patients with ACSs.[71] Furthermore, there was a gradient of benefit across the different TIMI risk groups with higher-risk patients obtaining higher absolute benefit.[72] The 2013 AHA/ACCA STEMI guidelines[73] recommend (1) indefinitely aspirin 81 to 325 mg daily maintenance dose after PCI (class I), (2) β-blockers should be continued after hospitalization for all patients with STEMI and with no contraindications to their use (class I), (3) angiotensin-converting enzyme inhibitors are reasonable for all patients with STEMI and no contraindications to their use (class IIa and class I if presence of reduced LVEF), and (4) high-intensity statin therapy should be initiated or continued in all patients with STEMI and no contraindications to its use.

47. **b.** PCI may reduce the episodes of angina in the presence of moderate-to-severe ischemia at stress single-photon emission computed tomography (SPECT) but not the risk of death, MI, or other major CV events when added to optimal medical therapy. The COURAGE trial compared OMT alone or in combination with PCI as an initial management strategy in patients with stable CAD. Although the addition of PCI to OMT reduced the prevalence of angina, especially in case of moderate-to-severe ischemia detected by SPECT, it did not reduce long-term rates of death, nonfatal MI, and hospitalization for ACSs.[16]

48. **d.** Severe RCA stenosis. Coronary angiography shows severe mid-RCA stenosis explaining the inferior ischemia.

49. **d.** 12 months. The 2011 AHA/ACC PCI guidelines recommend the continuation of aspirin indefinitely (class I) and the duration of $P2Y_{12}$ inhibitor after stent implantation as follows: (1) BMS or DES during PCI for ACS, at least 12 months; (2) DES for a non-ACS indication, at least 12 months if patients are not at high risk for bleeding; and (3) BMS for a non-ACS indication, a minimum of 1 month, and ideally up to 12 months (unless the patient is at increased risk for bleeding).[5]

50. **a.** Severe LCX stenosis. The coronary angiography of the left circulation shows severe mid-left circumflex coronary artery stenosis.

51. **e.** Discontinuation of dual antiplatelet therapy followed by surgery in the first few weeks following stent implantation is problematic with DES but not BMS. In patients scheduled for noncardiac surgery in the year following PCI, the implantation of DESs should be avoided. Accordingly, one of the most frequent predisposing conditions to DES thrombosis is the (partial or complete) discontinuation of dual antiplatelet therapy because of urgent or elective noncardiac surgery.[74] Although preliminary data suggest that continuation of dual antiplatelet therapy during surgery, if feasible, may be protective of DES thrombosis, no recommendation can be made at this time. Conceptually, the potential for stent thrombosis remains because of the intrinsic prothrombotic state related to surgery. Perioperative thrombosis of BMS implanted shortly prior to noncardiac surgery have been described and associated with prohibitive morbidity and mortality. Therefore, whenever possible, noncardiac surgery should be postponed for at least 6 weeks following implantation of a BMS and 6 to 12 months following DES implantation.

52. **d.** In patients who have already suffered a stent thrombosis dual antiplatelet therapy may be extended long term, although currently there are no data to support this

strategy. Currently, there are no data to support an extension of dual antiplatelet therapy beyond 12 months. Nevertheless, in selected patients at high risk for stent thrombosis, aspirin and clopidogrel may be administered for a longer period of time. The CHARISMA trial[70] did show a benefit of prolonged aspirin and clopidogrel therapy over aspirin only in the secondary prevention setting, but did not specifically address the PCI population. According to the 2011 AHA/ACC PCI, continuation of $P2Y_{12}$ inhibitor after stent implantation for ACS should be at least 12 months.[5]

53. **e.** Occlusion of the first diagonal branch. The ECG showed inferoposterolateral STEMI. Coronary angiography showed a thrombotic occlusion of mid-portion of the dominant RCA.

54. **a.** Thrombotic occlusion of the left main trunk. The coronary angiography shows thrombotic occlusion of the left main trunk artery. This lesion has been treated with thromboaspiration and implantation of a DES.

55. **c.** Anterior subacute MI. ECG reveals ST elevation of anterolateral fields. Due to persisting chest pain, the patient has been investigated with angiography. The ventriculography showed occlusion of the mid-portion of the left anterior descending coronary artery treated with thromboaspiration and implantation of a BMS. The image of the thrombus extracted is shown in Figure 4.14.

Figure 4.14

56. **b.** Occlusion of the left anterior descending coronary artery. The coronary angiography showed an occlusion of the proximal left anterior descending coronary artery. The fact that the vessel perfused the apex including the inferoapical portion of the left ventricles explains the ST elevations in the anterior and inferior leads.

57. **d.** Visible thrombus in the mid-portion of the RCA. The coronary angiography showed a subtotal stenosis of the mid-RCA followed by a filling defect compatible with a large thrombus. The thromboaspiration was successfully performed and the lesion was subsequently treated with stenting.

58. **a.** Subtotal occlusion of the left main trunk. Coronary angiography showed subtotal occlusion of the left main trunk and the lesion was treated with stenting. Ventriculography showed a severely reduced LVEF (15%) under a mechanical chest compression system. The patient did not recover and subsequently died.

59. **a.** ISR of the left descending coronary artery. Coronary angiography shows a ISR of

the mid-left anterior descending coronary artery.

QUESTIONS

Pharmacokinetics and Pharmacodynamics

1. P. M. is admitted to the coronary intensive care unit (ICU) with atrial fibrillation (AFib) and rapid ventricular rate. After controlling the ventricular rate with metoprolol, it is decided to initiate procainamide by intravenous (IV) infusion. P. M. weighs 80 kg. How much of a loading dose would be required to target a level of 8 µg/L? The average steady-state volume of distribution (V_d) for procainamide is 2 L/kg. The bioavailability of the IV formulation is 100%, whereas the oral (PO) form is only 83%.

   a. 1,000 mg
   b. 1,300 mg
   c. 1,500 mg
   d. 1,700 mg

2. L. M. has been receiving digoxin 0.25 mg PO tablets daily. Her serum drug level is 1.8 ng/mL. She is no longer able to take PO medications and needs to receive digoxin IV. By what percentage do you need to decrease the dose to maintain the current digoxin level?

   a. 10%
   b. 25%
   c. 40%
   d. 50%

3. What two pharmacokinetic parameters alter the half-life of medications?

   a. Loading dose and clearance

b. Absorption and clearance
c. V_d and clearance
d. Absorption and V_d

4. What is the relationship between drug concentration and pharmacologic effect known as?

a. Pharmacokinetics
b. Pharmacogenetics
c. Pharmacology
d. Pharmacodynamics

5. Each line in Figure 5.1 represents a β-blocker in development. Which β-blocker is the most potent?

a. A
b. B
c. C
d. Potency cannot be determined from the above graph

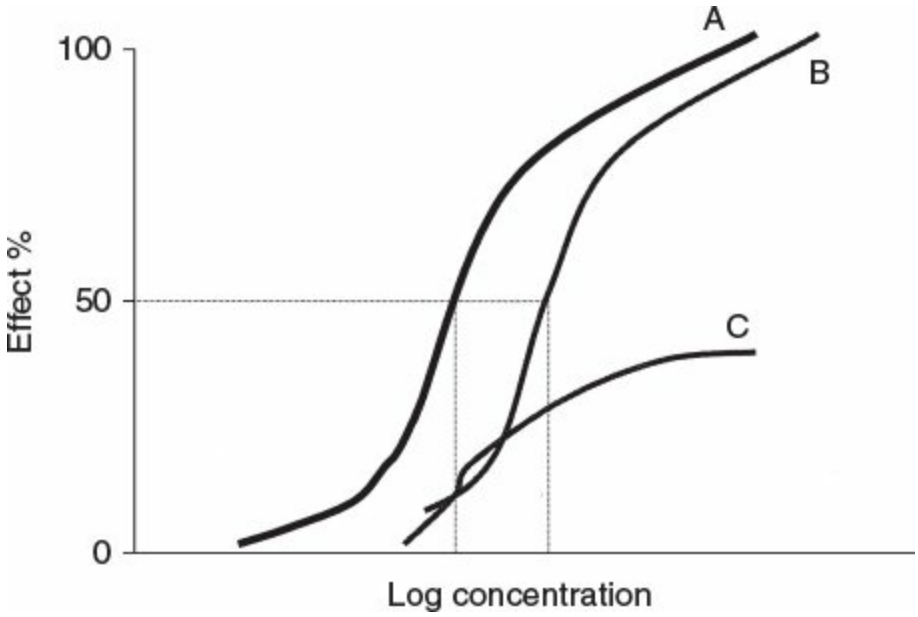

Figure 5.1 • Relationship between drug concentration and effect.

6. Ethanol alters the metabolism of warfarin. Two types of ethanol abuse are chronic ethanol abuse and binge ethanol drinking. How do these types of ethanol use alter warfarin metabolism? Chronic ethanol use _____ and binge ethanol drinking _____.

a. decreases warfarin metabolism, increases warfarin metabolism

b. decreases warfarin metabolism, decreases warfarin metabolism
c. increases warfarin metabolism, decreases warfarin metabolism
d. increases warfarin metabolism, increases warfarin metabolism

7. Which of the following drugs can significantly increase digoxin concentrations?

a. Amiodarone
b. Metoprolol
c. Simvastatin
d. Fenofibrate

Angiotensin-Converting Enzyme (ACE) Inhibitors

8. Which of the following statements is true with regard to ACE inhibitors?

a. Mortality benefit in heart failure (HF) patients is a class effect with ACE inhibitors, and all are Food and Drug Administration (FDA) approved for this indication.
b. ACE inhibitor dose is negligible in HF with regard to mortality benefit.
c. Sodium depletion is an important factor in the development of renal insufficiency associated with ACE inhibitors.
d. ACE inhibitor–associated potassium retention is related to the increase in feedback that leads to aldosterone release.

β-Blockers

9. Match the properties with the associated β-blocking agents.

1. Pindolol i. α-Blockade
2. Propranolol ii. Intrinsic sympathomimetic activity (ISA)
3. Labetalol iii. Membrane-stabilizing activity
4. Bisoprolol iv. β_1-Selectivity

a. (1) iv; (2) ii; (3) iii; (4) i
b. (1) iii; (2) i; (3) ii; (4) iv
c. (1) ii; (2) iii; (3) i; (4) iv
d. (1) ii; (2) iv; (3) iii; (4) i

Calcium Channel Blockers (CCBs)

10. By which of the following mechanisms do diltiazem and verapamil slow ventricular rate in patients with AFib?

a. They decrease the conduction velocity within the atrioventricular (AV) node.
b. They decrease the refractory period of nodal tissue.

c. They stimulate vagal tone.
d. They prolong the refractory period of atrial tissue.

11. Which of the following CCBs is indicated in patients presenting with a subarachnoid hemorrhage?

a. Verapamil
b. Diltiazem
c. Isradipine
d. Nimodipine

Diuretics

12. Which of the following loop diuretics is a not a sulfonamide and can, therefore, be given to a patient with a sulfonamide allergy?

a. Ethacrynic acid
b. Bumetanide
c. Torsemide
d. Furosemide

13. True or False: Conivaptan is indicated for the treatment of hyponatremia for patients with underlying HF.

a. True
b. False

Inotropic Agents

14. How does digoxin improve myocardial contractility?

a. Inhibition of the Na^+/K^+-adenosine triphosphatase
b. Inhibition of the breakdown of cyclic adenosine monophosphate (cAMP)
c. Increases intracellular K^+, leading to the opening of calcium channels
d. Directly stimulates calcium release from the sarcoplasmic reticulum

15. F. F. is a 75-year-old man with a history of HF and AFib and was initiated on amiodarone and warfarin. He has been treated for many years with captopril, furosemide, potassium, amlodipine, and digoxin. After 3 days in the hospital, the patient was sent home. One week after discharge, he developed nausea, vomiting, confusion, and symptomatic ventricular tachycardia (VT). His serum digoxin concentration was 3.9 ng/mL and serum potassium level was 5.8 mmol/L. The rhythm was treated with lidocaine, and the patient is now having episodes of nonsustained VT with a blood pressure (BP) of 80/40 mmHg during each episode.

What should be your next course of action?

a. Discontinue the amiodarone and digoxin and observe.
b. Discontinue the digoxin and administer digoxin-specific antibodies.
c. Decrease the dose of digoxin.
d. Discontinue digoxin and observe.

16. N. M. is a 75-year-old woman with a long-standing history of HF secondary to viral cardiomyopathy. She presents to the outpatient clinic for routine follow-up. On examination, she was short of breath and reported increasing orthopnea. She was admitted to the ICU for right heart catheterization. Initial readings show a cardiac index of 1.8 L/min/m^2, elevated pulmonary capillary wedge pressure (25 mmHg), and high pulmonary pressures (72/45 mmHg). Her initial BP was 105/55 mmHg, and she had a heart rate of 105 beats per minute (bpm). Home medications include captopril, spironolactone, metoprolol XL, and furosemide. Which of the following inotropic agents would be most appropriate?

a. Dopamine
b. Dobutamine
c. Milrinone
d. Isoproterenol

Anticoagulation

17. Which of the following statements is true regarding vitamin K administration?

a. Subcutaneously administered vitamin K exhibits the same bioavailability as oral or IV vitamin K
b. IV vitamin K is superior at lowering the INR than oral vitamin K at similar doses
c. IV vitamin K works faster to lower the INR than oral vitamin K at similar doses
d. Rates of anaphylaxis are similar between oral and IV administration of vitamin K

18. Which of the following agents bind only to factor Xa?

a. Enoxaparin
b. Fondaparinux
c. Bivalirudin
d. Unfractionated heparin (UFH)

19. A. F. is a 52-year-old man with a history of AFib, transient ischemic attacks, hypertension (HTN), and rheumatic heart disease. The recommendations from the

Sixth American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic Therapy suggest that this patient be initiated on _____ for antithrombotic therapy because of AFib.

a. aspirin, 81 mg daily
b. aspirin, 325 mg daily
c. warfarin, with a target goal international normalized ratio (INR) of 2.5
d. warfarin, with a target goal INR of 3.5

20. The patient above is going to be electively cardioverted. What is the timing of PO anticoagulant therapy?

a. Warfarin with a target INR of 3.5 for 4 weeks before cardioversion and continued for 6 weeks after cardioversion
b. Warfarin with a target INR of 3.5 for 3 weeks before cardioversion and continued for 6 weeks after cardioversion
c. Warfarin with a target INR of 2.5 for 3 weeks before cardioversion and continued for 4 weeks after cardioversion
d. Warfarin with a target INR of 2.5 for 6 weeks before cardioversion and continued for 6 weeks after cardioversion

21. Heparin must first bind to _____ to exert its anticoagulant activity.

a. antithrombin
b. thrombin
c. factor X
d. protein C

22. J. M. was initiated on heparin and was given a 5,000-unit bolus. Five minutes after the loading dose of heparin, she began to have bloody emesis, and her systolic pressure dropped to 80 mmHg. How much protamine will she require?

a. 25 mg
b. 50 mg
c. 75 mg
d. 100 mg

23. Patients who develop heparin-induced thrombocytopenia have an in vitro cross-reactivity with low-molecular-weight heparin (LMWH) by what percent?

a. 90% to 100%
b. 60% to 70%
c. 25% to 45%

d. 5% to 10%

24. A patient with a recent history of heparin-associated antibodies presents with new-onset symptomatic AFib and requires anticoagulation. Other significant past medical history includes severe renal failure secondary to long-standing HTN. The patient's baseline serum creatinine is 4 mg/dL, with an estimated creatinine clearance of 10 mL/min. Which of the following choices is the best initial therapy?

a. Lepirudin, 0.4 mg/kg bolus, then 0.15 mg/kg/h
b. Lepirudin, 0.2 mg/kg bolus, then 0.15 mg/kg/h
c. Argatroban, 2 μg/kg/min
d. Enoxaparin, 1 mg/kg SC daily

Antiplatelet Agents

25. What is the maximum dose of aspirin that can be concomitantly administered with ticagrelor?

a. 81 mg
b. 100 mg
c. 162 mg
d. 325 mg

26. All of the following are differences between clopidogrel and ticagrelor except?

a. Time to maximum platelet inhibition after bolus administration
b. Number of metabolic enzyme activations to active drug
c. Irreversible versus reversible effect at the $P2Y_{12}$ receptor
d. The number of days to discontinue therapy prior to CABG

27. Respiratory diseases should be closely monitored with the use of which of the following antiplatelet agents?

a. Clopidogrel
b. Prasugrel
c. Ticagrelor
d. Eptifibatide

28. Which of the following side effects differentiate ticlopidine from clopidogrel?

a. Diarrhea
b. Rash
c. Neutropenia
d. Thrombotic thrombocytopenic purpura

29. By which of the following mechanisms do clopidogrel and ticlopidine exert their antiplatelet effects?

a. Cyclo-oxygenase inhibitor
b. Glycoprotein IIb/IIIa inhibitor
c. Adenosine diphosphate (ADP) inhibitor
d. Direct thrombin inhibitor

30. Which of the following glycoprotein IIb/IIIa inhibitors has the highest incidence of severe thrombocytopenia?

a. Tirofiban
b. Abciximab
c. Eptifibatide
d. The incidence is not different between the different agents

31. Which of the following glycoprotein IIb/IIIa inhibitors has the shortest half-life but the longest duration of therapy?

a. Tirofiban
b. Eptifibatide
c. Abciximab
d. Lamifiban

Antiarrhythmic Agents

32. Dronedarone use is contraindicated in which patient population?

a. Post-acute myocardial infarction
b. Severe renal impairment
c. NYHA class IV heart failure
d. 1st degree AV block

33. Y.K is a 65-year-old male with symptomatic paroxysmal atrial fibrillation and heart failure recently admitted to the hospital for decompensation. The decision has been made to restore sinus rhythm and utilize antiarrhythmic therapy for rhythm control. Which of the following antiarrythmic agents is most appropraite to use in this patient for rhythm control?

a. Dofetalide
b. Dronedarone
c. Flecanide
d. Quinidine

34. Which of the following agents is effective for converting AFib to sinus rhythm and for maintaining sinus rhythm after it is restored?

a. Digoxin
b. Amiodarone
c. Diltiazem
d. Propranolol

35. M. G., a 50-year-old man, collapsed at home after shoveling his sidewalk. His son initiated cardiopulmonary resuscitation immediately, and an emergency medical service was called. When the squad arrived, it was determined that M. G. was in ventricular fibrillation (VF), and he was cardioverted with 200, 300, and 360 J. Epinephrine was given, and M. G. was shocked again. M. G. was still in VF. It was decided to initiate antiarrhythmic therapy. Choose the most appropriate agent from the list below.

a. Lidocaine
b. Amiodarone
c. Procainamide
d. Bretylium

Acute Coronary Syndromes

36. G. M. is a 45-year-old man presenting with a non-ST-segment-elevation myocardial infarction (MI). His creatinine clearance is estimated to be 30 mL/min. You would like to initiate eptifibatide. Which of the following doses would be the best choice?

a. Loading dose of 180 µg/kg and a maintenance of 2 µg/kg/min
b. Loading dose of 90 µg/kg/min and a maintenance dose of 2 µg/kg/min
c. Loading dose of 180 µg/kg and a maintenance dose of 1 µg/kg/min
d. Loading dose of 90 µg/kg/min and a maintenance dose of 1 µg/kg/min

37. M. M. is a 39-year-old man with an inferior wall non-ST-segment-elevation MI. He has a history of poorly controlled HTN and diabetes mellitus (DM). You initiate aspirin, clopidogrel, and atorvastatin. His baseline serum creatinine is 3.4 mg/dL and you estimate his creatinine clearance to be 25 mL/min. What dose of enoxaparin would you choose?

a. 1 mg/kg every 12 hours
b. 1 mg/kg daily
c. Enoxaparin is not indicated at this time
d. Fondaparinux is safer to use in M. M.

38. B. B. is a 77-year-old man who presents with typical chest pain and pressure. He has ST elevations in lead $V_{2–4}$. He is 80 kg with a serum creatinine of 0.7 mg/dL with an estimated creatinine clearance of 75 mL/min. You initiate aspirin, clopidogrel, metoprolol, and atorvastatin. You want to initiate enoxaparin and reteplase. What is the enoxaparin dose for this patient?

a. Loading dose of 30 mg IV once followed immediately by 1 mg/kg every 12 hours
b. Loading dose of 30 mg IV once followed by 0.75 mg/kg every 12 hours
c. 1 mg/kg daily
d. 0.75 mg/kg every 12 hours

39. Which of the following is not a risk factor for intracranial hemorrhage in patients receiving fibrinolytic therapy in the treatment of ST-segment-elevation MI?

a. HTN
b. Body weight
c. Age
d. Time to presentation

40. R. M. is a 65-year-old man presenting to the emergency department (ED) with an ST-segment-elevation MI. It is decided to initiate thrombolytic therapy to induce reperfusion. The patient weighs 72 kg. What is the most effective dose of alteplase for this patient?

a. 0.9 mg/kg, with a maximum of 90 mg
b. 15 mg bolus; then 54 mg over 30 minutes; then 36 mg over 60 minutes
c. 15 mg bolus; then 50 mg over 30 minutes; then 35 mg over 60 minutes
d. 60 mg over 1 hour; then 20 mg per hour for 2 hours

Hyperlipidemia

41. M. R. is a 74-year-old man with a history of hypercholesterolemia treated with simvastatin. Two months ago he had a permanent pacemaker placed for sick sinus syndrome. He now presents with a 1-month history of fever, chills, and unexplained weight loss. On physical examination he has a new tricuspid regurgitation murmur. A transesophageal echocardiogram confirms your suspicion of endocarditis. Which of the following antibiotics increases the risk of rhabdomyolysis when given with simvastatin?

a. Ceftriaxone
b. Vancomycin
c. Daptomycin
d. Linezolid

42. Put the following regimens in order according to their low-density lipoprotein (LDL)-lowering ability.

Atorvastatin, 10 mg daily (A)
Cholestyramine, 8 g daily (C)
Pravastatin, 20 mg daily (P)
Gemfibrozil, 600 mg twice daily (G)

a. A > P > C > G
b. P > A > G > C
c. A > P > G > C
d. A > C > P > G

43. D. L. is a 76-year-old white man with a past medical history significant for DM type 2 and HTN. Chronic AFib was recently diagnosed with coronary artery disease (CAD) and hypercholesterolemia and he was initiated on gemfibrozil 600 mg twice daily and atorvastatin 40 mg daily. His other medications include glyburide, metoprolol, furosemide, levothyroxine, insulin, and aspirin. Two weeks later, he began to experience pain in his right calf, with pain and stiffness throughout his back, buttocks, and thigh. After another week, he was admitted to the hospital with similar heightened symptoms. On admission, his blood urea nitrogen was elevated, and the urinalysis showed orange, cloudy urine; protein, greater than 300; glucose, greater than 1,000; ketones, 2+; hemoglobin, 3+; red blood cell count, 6 to 10; and myoglobin, 1,367. Which of the following statements is true?

a. The patient is experiencing rhabdomyolysis secondary to the drug interaction of atorvastatin and glyburide.
b. Forced diuresis with urine alkalinization and discontinuation of gemfibrozil and atorvastatin are indicated for this patient.
c. Atorvastatin is contraindicated in a patient with DM type 2 and HTN.
d. If nicotinic acid, rather than gemfibrozil, had been used for hypercholesterolemia, this reaction would have been prevented.

Hypertension

44. N. H. is a 57-year-old man status post MI with a BP of 150/88 mmHg and a heart rate of 87 bpm. He is currently on aspirin, clopidogrel, atorvastatin, and lisinopril. Which agent would be the most appropriate addition for treatment of his HTN?

a. Hydrochlorothiazide
b. Metoprolol
c. Clonidine
d. Losartan

45. B. T. is a 56-year-old woman with long-standing HTN that is difficult to control. She is currently being treated with amlodipine 10 mg daily, lisinopril 40 mg daily, hydrochlorothiazide 25 mg daily, and clonidine 0.4 mg three times daily. She presented to the emergency room, and her initial BP was 200/110 mmHg. She states she had run out of one of her medications. Which one of her medications would most likely be implicated in causing hypertensive urgency?

a. Amlodipine
b. Lisinopril
c. Hydrochlorothiazide
d. Clonidine

46. C. P. is a 46-year-old white man admitted with worsening headache, and nausea and vomiting over 48 hours. The patient is status post single-lung transplant secondary to α_1-antitrypsin deficiency. His immunosuppression regimen includes cyclosporine, prednisone, and azathioprine. As a result of the cyclosporine, he has HTN and renal dysfunction (baseline serum creatinine, 1.9 mg/dL). His BP is controlled with clonidine 0.2 mg twice daily and metoprolol tartrate 25 mg twice daily. Two months ago, he was changed to metoprolol from amlodipine because of peripheral edema. The patient was in his usual state of health until approximately 1 week ago, when he experienced diarrhea, which has since resolved. On admission, his BP was 208/110 mmHg and his serum creatinine was 3.8 mg/dL. What is the most appropriate regimen to control this patient's BP?

a. Change back to amlodipine 10 mg daily
b. Initiate nitroprusside drip and give IV fluids
c. Add captopril to the regimen and titrate to effect
d. Give sublingual nifedipine

Heart Failure

47. R. W. is a 60-year-old woman with HF (left ventricular ejection fraction <30%) who has HTN with a BP of 152/90 mmHg. Her potassium is 4.0 mg/dL and serum creatinine is stable at 1.5 mg/dL. She is currently on digoxin and furosemide. Which regimen is most appropriate to initiate in this patient?

a. Hydralazine 25 mg four times daily
b. Metoprolol tartrate 12.5 mg twice daily
c. Valsartan 20 mg twice daily
d. Lisinopril 5 mg daily

48. A. V. is a 49-year-old woman with a history of HF presenting to the ED for the

second time in a month with acutely decompensated HF. She has dyspnea at rest and 3+ edema in her lower extremities. Her serum creatinine is 1.8 mg/dL and BP is 90/60 mmHg. Her home regimen includes enalapril 20 mg twice daily, carvedilol 3.125 mg twice daily, and furosemide 40 mg PO daily. Which of the following is most appropriate for this patient?

a. Admit her to the hospital for IV furosemide therapy and hemodynamic monitoring.
b. Admit her to the hospital for diuresis with nesiritide.
c. Initiate an infusion of nesiritide in the ED and reassess in 4 hours.
d. Schedule intermittent outpatient infusions of nesiritide.

49. A patient with New York Heart Association class III HF was hospitalized 2 months ago for an exacerbation of his HF. The patient was discharged on lisinopril, furosemide, and digoxin. His lungs are clear and his vital signs are as follows: BP, 105/56 mmHg; heart rate, 84 bpm; and respiration rate, 18. Which regimen is most appropriate to initiate in this patient?

a. Atenolol 50 mg daily
b. Carvedilol 3.125 mg twice daily
c. Carvedilol 25 mg twice daily
d. Metoprolol tartrate 50 mg twice daily

50. Which β-blockers are recommended for use for patients with HF?

a. Metoprolol tartrate, pindolol, propranolol
b. Carvedilol, metoprolol succinate, bisoprolol
c. Metoprolol succinate, metoprolol tartrate, carvedilol
d. Metoprolol tartrate, carvedilol, bisoprolol

51. Y. J. is a 67-year-old African American man with HF who has been treated with lisinopril 20 mg daily, metoprolol succinate 25 mg daily, furosemide 40 mg twice daily, and spironolactone 12.5 mg daily. Despite his current therapy, he still complains of shortness of breath while conducting usual daily activities. What is the most appropriate change that should be made to his regimen?

a. Increase spironolactone
b. Start hydralazine
c. Initiate isosorbide dinitrate and hydralazine
d. Increase lisinopril

52. Which of the following statements is true?

a. Serum levels are used to guide the selection of the dose of digoxin.
b. Because spironolactone was found to have mortality benefit in the Randomized Aldactone Evaluation Study (RALES), the addition of spironolactone should be considered for all HF patients.
c. The benefit of long-term IV inotropic therapy may outweigh the increased mortality risk in refractory patients unable to be weaned from IV inotropic support.
d. Digoxin exhibits both symptomatic and mortality benefit in patients with HF.

Endocarditis

53. One month ago, a 37-year-old woman with sinus infection responded well to a 14-day course of amoxicillin/clavulanate 875/125 mg twice daily. She is scheduled for a root canal in 1 week. In the past, her dentist had prescribed one dose of clindamycin 600 mg, 1 hour prior to any dental work, for endocarditis prophylaxis because of her history of mitral valve prolapse. Realizing she has not received her prescription, the patient calls the dentist's office for an antibiotic. What prophylaxis is indicated for this patient?

a. Amoxicillin 2 g PO 1 hour before the procedure
b. Clindamycin 600 mg PO 1 hour before the procedure
c. Azithromycin 500 mg PO 1 hour before the procedure
d. No prophylaxis recommended in this patient

54. S. C. is a 59-year-old woman diagnosed with enterococcal endocarditis. She has no known drug allergies. Which of the following would exhibit standard therapy?

a. Penicillin G, 5 million units IV every 4 hours for 4 to 6 weeks, plus gentamicin, 2.5 mg/kg IV every 8 hours for 4 to 6 weeks
b. Ampicillin, 2 g IV every 4 hours for 4 to 6 weeks, plus gentamicin, 1 mg/kg IV every 8 hours for 4 to 6 weeks
c. Ampicillin, 2 g IV every 4 hours for 4 to 6 weeks, plus gentamicin, 1 mg/kg IV every 8 hours for 3 to 5 days
d. Vancomycin, 30 mg/kg per 24 hours in two equally divided doses for 4 to 6 weeks

ANSWERS

1. **b.** 1,300 mg. To determine the loading dose of a one-compartment drug, three items are needed: (a) the drug's V_d (L/kg), (b) the desired steady-state concentration (Cpss [mg/L]), and (c) the patient's weight. Loading dose = $V_d \times$ Cpss. Kilograms

and liters cancel, and you are left with the loading dose in milligrams.

2. **b.** 25%. The bioavailability of digoxin tablets is 75%. Therefore, when converting from PO to IV administration (bioavailability of 100%), there is a 25% increase in bioavailability. Without altering the dose of digoxin, this patient would most likely have an increase in digoxin level to approximately 2.4 ng/mL. This could lead to potential digoxin toxicity.

3. **c.** V_d and clearance. Half-life is a function of both clearance (Cl) and V_d. The elimination-rate constant (k_{el}) is determined by two independent factors: Cl and V_d. $k_{el} = Cl/V_d$. Half-life is determined by the equation $0.693/k_{el}$. Therefore, as the apparent V_d and Cl change, the half-life of a drug may change.

4. **d.** Pharmacodynamics. Pharmacodynamics has been defined as the study of the biologic effects resulting from the interaction between drugs and biologic systems. Pharmacokinetic principles consider drug distribution, metabolism, clearance, and bioavailability, whereas pharmacodynamic principles take this one step further and relate these factors to pharmacologic response. Pharmacogenetics is the study of heredity on variations in drug response among individuals and populations. Pharmacogenetic studies have established that genetics play an important role in the dose–concentration–response relationships of medications, whereas pharmacology is simply the study of drugs.

5. **a.** Drug A is the most potent agent. This is based on the fact that at any given concentration of this agent, the effect is greater than that of the other drugs at similar concentrations. Drug B has the same maximal effect; however, it occurs at a higher concentration. Drug C is similar to drug B; however, it is less efficacious, because its maximal effect occurs at a concentration that is 50% lower than that of drug B.

6. **c.** Increases warfarin metabolism, decreases warfarin metabolism. Chronic ethanol consumption can lead to increased hepatic metabolism of many medications that are cleared through the liver. Increased hepatic metabolism is related to enhanced enzyme function. Therefore, chronic ethanol users typically need higher-than-usual doses of warfarin to achieve therapeutic INRs. Acute ingestion of large amounts of ethanol at a time may inhibit warfarin metabolism. This may lead to elevated INRs and increase the risk of hemorrhagic complications. Moderate ingestion of ethanol does not seem to affect the metabolism of warfarin.

7. **a.** Amiodarone. Amiodarone significantly increases the levels of digoxin. Amiodarone decreases the clearance of digoxin and inhibits p-glycoprotein.

Amiodarone can increase digoxin levels by 50% to 70%. This interaction can occur in the first days of therapy and a 50% dosage reduction is required immediately. Metoprolol does not increase the levels of digoxin; however, it can have synergistic effects on lowering heart rate and should be monitored closely. Simvastatin and fenofibrate do not alter the levels of digoxin.

8. **c.** Sodium depletion is an important factor in the development of renal insufficiency associated with ACE inhibitors. Patients with hyponatremia, dehydration, and severe HF are most dependent on the maintenance of renal perfusion by angiotensin II–mediated vasoconstriction of the efferent arteriole. Prevention of hyponatremia by decreasing diuretics can reduce such risk. Numerous studies, including the Studies of Left Ventricular Dysfunction (SOLVD) treatment trial, Veterans' Administration Heart Failure Trial (V-HeFT) II, and Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS), have shown ACE inhibitors to reduce mortality in patients with ischemic and nonischemic cardiomyopathy and mild-to-moderate HF. ACE inhibitors are considered to be associated with a class benefit; however, not all ACE inhibitors carry the FDA indication for HF. The ACE inhibitors that are approved for the treatment of HF include captopril, enalapril, lisinopril, quinapril, fosinopril, and ramipril. In 1998, the Assessment of Treatment with Lisinopril and Survival (ATLAS) trial showed that high doses of lisinopril were superior to low doses in decreasing risk of death or hospitalization. Therefore, an effort to use target doses used in clinical trials is important (e.g., captopril 50 mg thrice daily, enalapril 10 mg twice daily, and lisinopril 20 mg daily). Potassium retention of ACE inhibitors is caused by a reduction in the feedback of angiotensin II to stimulate aldosterone release. Caution is necessary when initiating a potassium supplement in a patient on ACE inhibitor therapy.

9. **c.** (1) ii; (2) iii; (3) i; (4) iv. Agents exhibiting α-blockade include labetalol and carvedilol. Agents with ISA are pindolol, penbutolol, carteolol, and acebutolol. Agents with membrane-stabilizing activity are propranolol, labetalol, and acebutolol. β_1-Selective agents include bisoprolol, betaxolol, atenolol, acebutolol, and metoprolol.

10. **a.** Diltiazem and verapamil decrease conduction velocity within the AV node and increase refractory period of nodal tissue. This then causes slowing of ventricular rate.

11. **d.** Nimodipine. Nimodipine is the only agent indicated for patients with subarachnoid hemorrhage. Nimodipine decreases the influx of extracellular

calcium, thus preventing vasospasm.

12. **a.** Ethacrynic acid. Ethacrynic acid is the only loop diuretic that is not a sulfonamide. It is used only in patients allergic to other either loop or thiazide diuretics. Disadvantages of ethacrynic acid include gastrointestinal intolerance and a narrower dose–response curve.

13. **b.** False. Conivaptan is a dual vasopressin antagonist indicated for the treatment of euvolemic and hypervolemic hyponatremia. Its predominant pharmacodynamic effect is through the V_2 antagonism of vasopressin in the renal collecting ducts that results in excretion of free water. Because of the limited number of HF patients with hypervolemic hyponatremia treated with conivaptan, safety in HF patients has not been established; therefore, its use in HF patients may be considered only when the clinical benefit outweighs the risk of adverse effects.

14. **a.** Inhibition of the Na^+/K^+-adenosine triphosphatase. Digoxin inhibits the Na^+/K^+-adenosine triphosphatase pump on the myocardial cell surface. This inhibits the ability of the cell to exchange potassium for sodium and thus leads to an increase in intracellular sodium. This increase in intracellular sodium leads to exchange of sodium for calcium, increasing intracellular calcium concentrations. Increased intracellular calcium enhances contraction coupling.

15. **b.** Discontinue the digoxin and administer digoxin-specific antibodies. Digoxin-immune Fab is indicated for patients with life-threatening ventricular arrhythmias relating to digoxin toxicity. It is also indicated in patients with progressive bradyarrhythmias, such as severe sinus bradycardia or second- or third-degree heart block not responsive to atropine. It should not be used for milder forms of digoxin toxicity. Also, in the setting of hyperkalemia and digitalis intoxication, digoxin-immune Fab fragment is indicated. Digoxin-immune Fab fragment is ovine derived; there is a potential for hypersensitivity reactions, and there are no data available in regard to readministration.

16. **c.** Milrinone. Milrinone is a phosphodiesterase inhibitor classified as inodilator. Thus, milrinone produces positive inotropic effects and vasodilation. Milrinone inhibits the phosphodiesterase III enzyme, leading to an increase in intracellular cAMP, thus causing increased intracellular levels of calcium. In addition, milrinone will decrease pulmonary pressures and left ventricular (LV) end-diastolic pressures more predictably than the other agents listed. These combined effects lead to minimal increases in myocardial O_2 consumption. Also, milrinone may be useful in this patient secondary to chronic metoprolol therapy.

17. **c.** IV vitamin K works faster to lower the INR than oral vitamin K at similar doses. The onset of action of IV vitamin K is 1–2 hours compared to 6–10 hours for oral vitamin K. As a result, INR values return to normal quicker with IV vitamin K. The overall reduction in INR is dose dependent and not route dependent when comparing IV and oral formulations. Subcutaneous vitamin K has variable absorption which can lead to variations in time to onset as well as INR lowering effect.

18. **b.** Fondaparinux. Fondaparinux, a pentasaccharide, selectively inhibits activated Xa through its binding to antithrombin. Enoxaparin and UFH bind to both thrombin (IIa) and activated Xa, whereas bivalirudin binds directly to thrombin. UFH binds to thrombin and activated factor Xa in a 1:1 ratio, whereas LMWHs vary in their binding ratios.

19. **c.** Warfarin, with a target goal international normalized ratio (INR) of 2.5. This patient is at high risk for a thromboembolic event. Recommendations for antithrombotic therapy include risk stratification. Risks are stratified into high, moderate, and low. High-risk patients include patients with prior stroke or transient ischemic attack or systemic embolus, history of HTN, poor LV systolic function, age older than 75 years, rheumatic mitral valve disease, and a prosthetic heart valve. Moderate risk factors include age between 65 and 75 years, DM, and CAD with preserved LV systolic function. Low-risk patients are those younger than 65 years old with no clinical or transthoracic echocardiogram evidence of cardiovascular disease.

20. **c.** Warfarin with a target INR of 2.5 for 3 weeks before cardioversion and continued for 4 weeks after cardioversion. Recommendations from the Sixth ACCP Consensus Conference on Antithrombotic Therapy state that patients undergoing elective cardioversion for AFib should be initiated on oral anticoagulant therapy for 3 weeks before and at least 4 weeks after elective direct current cardioversion. The grade of evidence is 1C+. Also, an alternative approach would be to initiate anticoagulation, have the patients undergo a transesophageal echocardiography, and have the cardioversion performed if no thrombi are seen. Warfarin should be continued for at least 4 weeks, as long as the patient maintains normal sinus rhythm. This is a grade 1C recommendation.

21. **a.** Antithrombin. Heparin must first bind to antithrombin to exert its anticoagulant effect. This complex accelerates antithrombin effect. Heparin potentiates antithrombin's effect by binding to a glucosamine unit within a pentasaccharide sequence.

22. **b.** 50 mg. Every 1 mg of protamine will antagonize approximately 100 units of heparin. Because this patient just received the bolus, she would require 50 mg of protamine. If she had received the dose 30 to 60 minutes ago, then a dose of 0.50 to 0.75 mg of protamine per 100 units of heparin would be required. If she had been on a continuous infusion of heparin, then the dosing would be dependent on the time and dose of the last bolus of heparin and the rate of infusion. In this scenario, most patients require approximately 25 to 50 mg of protamine.

23. **a.** 90% to 100%. There have been several reports of patients who have heparin-induced thrombocytopenia being treated with LMWH. However, the cross-reactivity in vitro approaches 100%. The use of LMWH should be considered a contraindication unless there is a documented negative test for antibodies against LMWH.

24. **c.** Argatroban, 2 µg/kg/min. Argatroban is hepatically cleared and, therefore, does not require dosing adjustment for patients with renal dysfunction and may be a safer alternative for anticoagulation. Lepirudin is reasonable as well; however, patients with significant renal dysfunction require appropriate dosing adjustments. Continuous infusion should not be used in patients with a creatinine clearance <15 mL/min because of accumulation of drug. LMWHs have a high likelihood for in vitro and in vivo cross-reactivity of 80% to 100%, and there is a potential for an increase in thrombotic complications.

25. **b.** 100 mg. The Ticagrelor versus Clopidogrel in Patients with Acute Coronary Syndromes (PLATO) trial evaluated antiplatelet strategies in addition to aspirin post-ACS. The trial did not mandate a specific aspirin maintenance dose which was left to the discretion of the provider. After trial completion, a subset analysis was performed which favored ticagrelor use with low maintenance dose aspirin (≤100 mg) as higher doses resulted in decreased ticagrelor effectiveness. The package insert for ticagrelor recommends the maintenance dose of aspirin to be 75–100 mg daily if being used concomitantly with ticagrelor. An initial 325 mg dose of aspirin should still be given with ticagrelor in the ACS setting.

26. **d.** The number of days to discontinue therapy prior to CABG. The recommended number of days prior to CABG surgery to stop clopidogrel or ticagrelor is 5. Patients in both the Ticagrelor versus Clopidogrel in Patients with Acute Coronary Syndromes (PLATO) trial and the Effects of Clopidogrel in Addition to Aspirin in Patients with Acute Coronary Syndromes without ST-Segment Elevation (CURE) trial had increased bleeding if the agents were not stopped at least 5 days prior to surgery. Although the competitive antagonist property of ticagrelor at the $P2Y_{12}$

receptor and its short half-life (~7 hours) would lead clinicians to believe that ticagrelor could be stopped earlier than 5 days prior to surgery, that has not proven to be true.

27. **c.** In the Ticagrelor versus Clopidogrel in Patients with Acute Coronary Syndromes (PLATO) trial, patients were more likely to experience dyspnea in the ticagrelor arm versus the clopidogrel arm (14% vs. 8 %). Also, more patients had to discontinue ticagrelor than clopidogrel because of dyspnea (0.9% vs. 0.1%). The mechanism for increased dyspnea is hypothesized to be triggered by adenosine. Ticagrelor inhibits the clearance of adenosine thereby increasing its concentration in the circulation. Although, more dyspnea results from ticagrelor use, there were no differences in forced expiratory volume in 1 second (FEV1) between ticagrelor and clopidogrel.

28. **c.** Neutropenia. Ticlopidine causes neutropenia in 2.4% of patients who are initiated on therapy. Nearly 1% of patients develop severe neutropenia. Therefore, a complete blood count is required every 2 weeks during initiation of therapy for the first 3 months of therapy. Both agents can cause diarrhea and rash. Structurally, these two drugs are so similar that allergic cross-reactivity is expected. Thrombotic thrombocytopenic purpura has been reported with both agents. There have been >100 cases of thrombotic thrombocytopenic purpura reported with the use of ticlopidine and clopidogrel.

29. **c.** Adenosine diphosphate (ADP) inhibitor. ADP is released from red blood cells, activated platelets, and damaged endothelial cells, leading to platelet adhesion and aggregation. However, the precise mechanism of its action has not been completely identified. ADP blockade decreases the expression of the glycoprotein IIb/IIIa receptor. Platelet inhibition occurs at maximal effect within 3 to 5 days and produces approximately 40% to 50% platelet inhibition. The onset and degree of platelet inhibition can be expedited with use of loading doses (300 to 600 mg).

30. **b.** Abciximab. All glycoprotein IIb/IIIa inhibitors may cause thrombocytopenia. However, abciximab has the highest rate of all, based on the clinical trials.

31. **c.** Abciximab. Abciximab has a serum half-life of 10 to 30 minutes; however, because of its high binding affinity to the glycoprotein IIb/IIIa receptor, it maintains its activity for many hours after discontinuation of therapy, and abciximab can be detected in the serum for longer than 2 weeks. The short-acting inhibitors have half-lives of approximately 2 hours, depending on renal function; however, because of their competitive inhibiting nature, once the infusion is discontinued, their effects

wane relatively quickly.

32. **c.** NYHA class IV heart failure. The Antiarrhythmic Trial with Dronedarone in Moderate-to-Severe Congestive Heart Failure Evaluating Morbidity Decrease (ANDROMEDA) was a mortality trial comparing dronedarone to placebo in patients with moderate to severe heart failure for rhythm control. The trial was prematurely terminated as a significantly higher mortality rate was seen in the dronedarone arm versus placebo (8.1% vs. 3.8%). The risk of death was highest in patients with severely depressed left ventricular systolic function. The package insert for dronedarone states the drug is contraindicted in patients with NYHA Class IV heart failure or symptomatic heart failure with recent decompensation requiring hospitalization because it doubles the risk of death.

33. **a.** Dofetalide. Structural heart failure limits the use of antiarrythmic therapies for rhythm control in atrial fibrillation due to mortality concerns. Dofetalide has not shown to increase mortality in patients with atrial fibrillation who also have heart failure unlike dronedarone, flecanide, and quinidine. The agent of choice in this situation; however, would likely be amiodarone unless the patient has other contraindications for amiodarone therapy.

34. **b.** Amiodarone. Although amiodarone does not carry an FDA indication for the treatment of AFib, it can convert to and maintain normal sinus rhythm. The other agents listed are only used for rate control when used for AFib.

35. **b.** Amiodarone. The most recent advanced cardiac life support guidelines recommend that amiodarone be the first-line agent in patients with pulseless VT/VF. This recommendation is based on the Amiodarone for Resuscitation after Out-of-Hospital Cardiac Arrest due to Ventricular Fibrillation (ARREST) trial, which showed that amiodarone increased the likelihood of admission to the hospital after an out-of-hospital arrest. This is further supported by the recently presented Amiodarone versus Lidocaine in Pre-Hospital Refractory Ventricular Fibrillation Evaluation (ALIVE) trial. Lidocaine is now considered Class Indeterminate based on the lack of controlled trials supporting its use in pulseless VT/VF. Procainamide administration is prolonged and not suitable for rapid administration. Bretylium is no longer available secondary to lack of raw materials.

36. **c.** Loading dose of 180 µg/kg and a maintenance dose of 1 µg/kg/min. Based on product information, eptifibatide loading dose should not be changed and the maintenance infusion should be initiated at 1 µg/kg/min. Eptifibatide is contraindicated in patients on dialysis and there is limited experience using this

agent in this patient population. Tirofiban is not contraindicated in patients on dialysis; however, there are limited data to support its use in dialysis patients.

37. **b.** Enoxaparin 1 mg/kg daily. Enoxaparin is approved for both ST-segment-elevation and non-ST-segment-elevation MI. In patients with a creatinine clearance >30 mL/min then the standard dose of 1 mg/kg every 12 hours is appropriate. However, when the creatinine clearance is <30 mL/min then the dose should be reduced to 1 mg/kg once daily. Fondaparinux is contraindicated in patients with a creatinine clearance <30 mL/min.

38. **d.** Loading dose of 30 mg IV once followed by 0.75 mg/kg every 12 hours. Enoxaparin was recently approved for the treatment of ST-segment-elevation MI with fibrinolysis based on the ExTRACT-TIMI 25 trial. In the older patients, lower enoxaparin doses were used to minimize bleeding. There was a lower risk of the primary endpoint in those that received enoxaparin versus those receiving UFH. There was no difference in intracranial hemorrhage; however, there was a significantly higher rate of major bleeding with enoxaparin (2.1% versus 1.4%).

39. **d.** Time to presentation. Time to presentation is not a risk factor for intracranial hemorrhage in patients receiving thrombolytic therapy. In clinical trials, the risks for intracranial hemorrhage included age older than 65 years, low body weight (<70 kg), HTN on hospital admission, and the use of alteplase. Also, the levels of concomitant anticoagulation can also increase the risk of intracranial hemorrhage.

40. **c.** 15 mg bolus; then 50 mg over 30 minutes; then 35 mg over 60 minutes. Based on the first GUSTO trial, the most effective dosing for acute ST-segment-elevation MI is front-loaded tissue plasminogen activator. The maximum dose should be 100 mg and, therefore, Answer b may increase the risk of major bleeding, specifically intracranial hemorrhage. Answer d is standard dosing of recombinant tissue-type plasminogen activator and was found inferior to front loading. Finally, Answer a is the recommended dosing for acute ischemic stroke.

41. **c.** Daptomycin. Daptomycin may cause elevations in creatine phosphokinase (CPK) levels. The product literature for daptomycin recommends temporary discontinuation of medications that can raise CPK levels when a patient is receiving this antibiotic. Even though this adverse reaction is rare, CPK levels should be monitored weekly in patients receiving daptomycin alone and more frequently if statin therapy is continued.

42. **a.** A > P > C > G. HMG-CoA reductase inhibitors decrease LDL by 18% to 55%.

Atorvastatin is the most potent agent statin of the group. Bile-acid sequestrants decreased LDL by 15% to 30%. Fibrates decrease LDL by 5% to 20%.

43. **b.** Forced diuresis with urine alkalinization and discontinuation of gemfibrozil and atorvastatin are indicated for this patient. Rhabdomyolysis secondary to the interaction of atorvastatin and gemfibrozil is responsible for this clinical picture. Rhabdomyolysis is defined as the disintegration of muscle, associated with the excretion of myoglobin in the urine. Clinical signs and symptoms include myalgias, elevated creatine kinase, elevated urine and serum myoglobin, and dark urine. Complications of rhabdomyolysis are numerous and may include renal failure, disseminated intravascular coagulation, metabolic acidosis, and cardiomyopathy. HMG-CoA (3-hydroxy-3-methyl-glutaryl-CoA) reductase inhibitors (statins) can be considered direct myotoxins and may induce rhabdomyolysis when used alone. However, the risk of toxicity increases when statins are used in combination with fibric acid derivatives (gemfibrozil or fenofibrate), nicotinic acid, cyclosporine, itraconazole, or erythromycin, to name a few. Treatment of the underlying cause, in this case discontinuation of the offending agents, is necessary. In addition, renal failure caused by products of tissue degradation must be combated with urinary alkalinization and maintenance of a high urine volume.

44. **b.** Metoprolol. The American College of Cardiology (ACC) and American Heart Association (AHA) recommend the use of β-blockers in patients after surviving an MI to decrease mortality, sudden death, and reinfarction. Therefore, if this patient is not already on a β-blocker, one would be indicated, not only for HTN but also for secondary prevention.

45. **d.** Clonidine. Abrupt withdrawal of an α2-agonist is the most likely cause of severe rebound HTN. Typically, this is seen within 24 to 48 hours of discontinuation of clonidine and typically occurs in patients taking large doses for longer than 3 months. The best treatment for this is to restart clonidine. β-Blockers could make the situation worse by causing unopposed α1-stimulation.

46. **b.** Initiate nitroprusside drip and give IV fluids. Hypertensive emergencies are defined by the presence of end-organ damage in the face of high BP. This patient was dehydrated from diarrhea and had uncontrolled BP because of the medication change that occurred. Use of nitroprusside would be most appropriate in this patient because of the emergent situation of the renal insufficiency and possible cerebrovascular involvement exhibited by the headache. Typically, parenteral antihypertensive agents are initiated for hypertensive emergencies. In addition, it is necessary to correct the underlying cause of the hypertensive episode, if it can be

identified; therefore, rehydration in this patient is prudent. Nitroprusside is the drug of choice because it has a quick onset of action yet is easily titratable. Sublingual nifedipine is no longer advocated because of the precipitous drop in BP and the subsequent adverse effects.

47. **d.** Lisinopril 5 mg daily. Because the patient is not already receiving ACE inhibitor therapy, an ACE inhibitor is indicated in patients with HF and a reduced ejection fraction (less than 35% to 45%) to decrease morbidity and mortality, as shown in the SOLVD, V-HeFT, and CONSENSUS trials. The patient has no contraindications to such therapy. If the patient's renal function were changing, thereby making an ACE inhibitor inappropriate, then hydralazine plus a nitrate would be indicated, because V-HeFT I showed mortality benefit compared with placebo and an α-blocker. An angiotensin receptor blocker (ARB), like valsartan, would be indicated if the patient were intolerant to ACE inhibitors in the past. Both ACE inhibitors and ARB should be initiated at low doses, and titrated (as tolerated) to doses proven in clinical trials to reduce cardiovascular events.

48. **a.** Admit her to the hospital for IV furosemide therapy and hemodynamic monitoring. Nesiritide is contraindicated for use in patients with systolic BP <90 mmHg. However, based on meta-analyses that raised questions of increased renal dysfunction and mortality associated with nesiritide, the FDA convened a panel to assess available data and provide recommendations regarding appropriate use of nesiritide. These recommendations state that nesiritide should be limited to hospitalized patients with decompensated HF with dyspnea at rest and it should not be used to replace diuretics. Furthermore, because of insufficient evidence, nesiritide should not be used for intermittent outpatient infusions, for scheduled repetitive use, to improve renal function, or to enhance diuresis. A large-scale clinical trial to assess outcomes and further assess the risks of nesiritide versus standard therapy is currently being conducted.

49. **b.** Carvedilol 3.125 mg twice daily. All patients with stable, class II or III HF should be initiated on a β-blocker, unless a contraindication (bronchospastic disease, symptomatic bradycardia, or advanced heart block) or intolerance is exhibited. Initiation of β-blocker therapy is recommended in stable patients with mild-to-moderate HF and a low ejection fraction (less than 35% to 40%). The mortality benefit of β-blocker use was seen when added to a preexisting regimen of an ACE inhibitor and diuretic, with or without digoxin. It should be noted that β-blockers must be initiated at very low doses and only gradually increased if low doses have been well tolerated.

50. **b.** Carvedilol, metoprolol succinate, bisoprolol. Overwhelming mortality benefit in patients with chronic HF has been proven in clinical trials for carvedilol, metoprolol succinate, and bisoprolol when added to standard HF therapy. These agents are specifically recommended in the ACC/AHA guidelines for the management of chronic heart failure. Despite survival benefit with each of these β-blockers, a class effect with all β-blockers should not be assumed as demonstrated by the Carvedilol or Metoprolol European Trial (COMET). The COMET compared carvedilol with metoprolol tartrate in HF patients and concluded that carvedilol exhibited superior mortality benefit. β-Blockers with ISA should not be used on patients with HF. Pindolol and others with ISA (such as penbutolol, carteolol, and acebutolol) are partial β-agonists and can maintain normal sympathetic tone. This activity prevents the benefits seen with the reduced heart rate, cardiac output, and peripheral blood flow caused by other β-blockers.

51. **c.** Initiate isosorbide dinitrate and hydralazine. The ACC/AHA guidelines recommend the initiation of isosorbide dinitrate and hydralazine as a reasonable addition to standard therapy in blacks with New York Heart Association class III/IV HF. The A-HeFT trial evaluated a proprietary drug combination (hydralazine 37.5 mg and isosorbide dinitrate 20 mg per tablet) in African Americans with HF along with standard treatment; because of significant mortality benefit, the study was prematurely discontinued.

52. **c.** The benefit of long-term IV inotropic therapy may outweigh the increased mortality risk in refractory patients unable to be weaned from IV inotropic support. Because long-term IV positive inotropic therapy may cause an increased risk of death, such therapy is not regularly recommended. This risk, however, may be outweighed in patients who cannot be weaned from continuous support. Such patients with refractory HF may experience an improved quality of life because of the relative clinical stability afforded by the inotrope; therefore, IV positive inotropic therapy may be considered as a palliative measure in end-stage HF. The DIG (Digitalis Investigation Group) trial showed that digoxin's benefit in HF was the alleviation of symptoms and improvement in clinical status. These findings were associated with a decreased morbidity (fewer hospitalizations) but not mortality. Because digoxin has negligible effect on survival, it is recommended that digoxin be used in conjunction with diuretics, ACE inhibitors, and β-blockers to decrease the clinical symptoms of HF. Furthermore, little evidence supports the practice of dosing digoxin according to serum levels. This is because of the lack of data exhibiting a relationship between digoxin serum concentrations and therapeutic effect. In the RALES trial, spironolactone was shown to be associated with reduced mortality and morbidity. However, the patients who were included in this trial

were patients with class IV HF. Therefore, it would only be prudent to consider spironolactone in patients with recent or current severe HF symptoms. Efficacy and safety of spironolactone's use in patients with mild-to-moderate HF is yet to be determined.

53. d. No prophylaxis is recommended in this patient. The recommendations according to the 2007 Guidelines for Prevention of Infective Endocarditis no longer recommend prophylactic antibiotics prior to dental procedures for people with mitral valve prolapse, rheumatic heart disease, bicuspid valve disease, calcified aortic stenosis, or congenital heart conditions such as ventricular septal defect, atrial septal defect, and hypertrophic cardiomyopathy.

54. b. Ampicillin, 2 g IV every 4 hours for 4 to 6 weeks, plus gentamicin, 1 mg/kg IV every 8 hours for 4 to 6 weeks. Treatment of enterococcal endocarditis is complicated because of the high levels of resistance to penicillin, extended-spectrum penicillins, and vancomycin. However, penicillin, ampicillin, or vancomycin in combination with an aminoglycoside causes synergistic bactericidal effect on these organisms. Treatment with an aminoglycoside for the full 4 to 6 weeks at a synergistic dose (1 mg/kg IV every 8 hours) in addition to the penicillin agent or vancomycin is required.

QUESTIONS

Case 1 (Questions 1 to 3)

A 78-year-old woman is referred to cardiology clinic for management of aortic regurgitation. The patient has no cardiac risk factors except mild hypertension (HTN) on monotherapy and has not previously undergone cardiac testing. A review of systems is notable for recent onset of headaches and myalgias.

Physical Examination

Blood pressure (BP)—138/78 mmHg in both arms; pulse—62 bpm.

Funduscopic examination reveals no changes consistent with hypertensive retinopathy. The heart examination is notable for a normal S_1 and increased intensity S_2 (A_2). An S_4 gallop, II/VI diastolic decrescendo murmur heard best at the right sternal border, and III/VI early-peaking systolic ejection murmur heard at the left sternal border are present. There is no systolic ejection click. The carotid pulse is of normal intensity and contour and the pulses in the upper and lower extremities are strong and equal.

Electrocardiogram (ECG) reveals sinus rhythm with nonspecific ST changes.

1. What is the most likely explanation for the patient's heart murmur?

   a. Bicuspid aortic valve with severe aortic regurgitation
   b. Bicuspid aortic valve with severe aortic stenosis and moderate aortic regurgitation
   c. Degenerative severe aortic valve stenosis and moderate aortic regurgitation
   d. Aortic dilatation with moderate aortic regurgitation and mild aortic stenosis

A transthoracic echocardiogram (TTE) is performed showing normal left ventricular

(LV) size and function with a trileaflet aortic valve. Aortic measurements are as follows: sinus of Valsalva—4.0 cm; sinotubular junction—4.4 cm; mid-ascending aorta —4.5 cm with moderate effacement of the sinotubular junction. Peak and mean aortic gradients are 22/13 mmHg with moderate (2+) aortic regurgitation. A small circumferential pericardial effusion is present. Laboratory tests reveal an erythrocyte sedimentation rate of 74.

2. What additional test would be most helpful in determining the etiology of the patient's aortic dilatation and aortic regurgitation?

   a. Coronary angiogram and aortography
   b. Magnetic resonance angiography (MRA) of the great vessels
   c. Computed tomographic angiography (CTA) of the ascending aorta
   d. Transesophageal echocardiography (TEE)

3. What is the most likely diagnosis to explain the patient's aortic dilatation and aortic regurgitation? See Figure 6.1.

   a. Takayasu arteritis
   b. Degenerative aortic disease
   c. Connective tissue disorder
   d. Giant cell arteritis

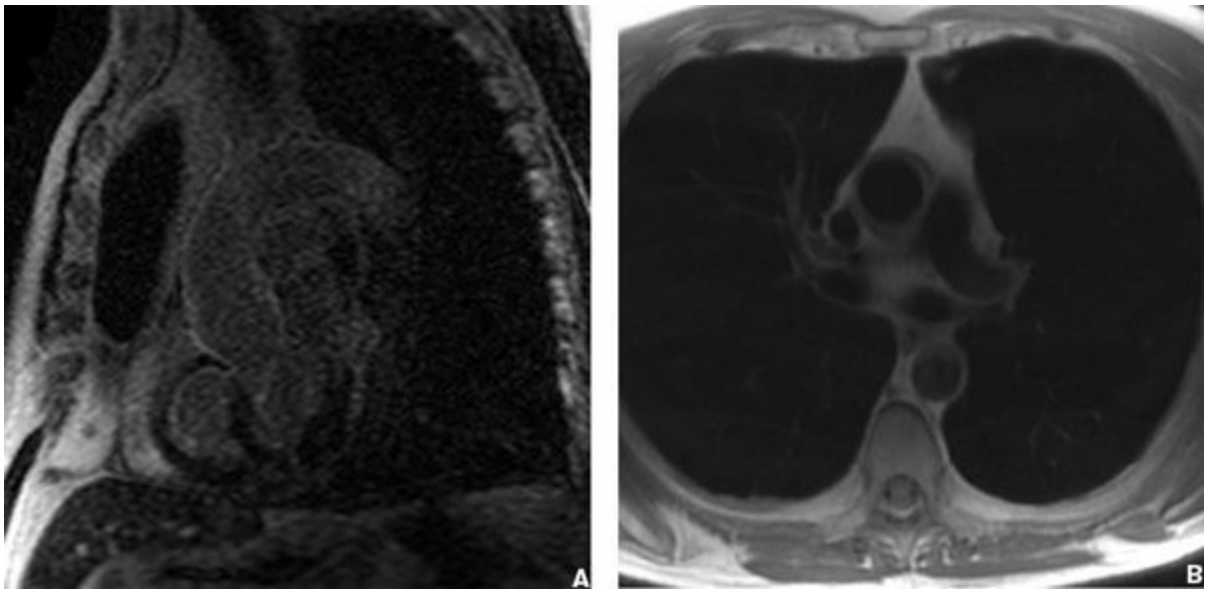

Figure 6.1

Case 2 (Questions 4 to 6)

An 18-year-old woman presents for her annual physical examination. She had a brother with Marfan syndrome who was 24 years old when he died suddenly. She is active and asymptomatic.

Physical Examination

5 feet 7 inches (170 cm) and 150 pounds (68 kg).
Arm span-to-height ratio = 1.07.
Head and neck examination is notable for a high-arched palate and a slit-lamp examination shows ectopia lentis. Musculoskeletal examination is notable for a pectus carinatum and positive wrist and thumb sign. Cardiac examination is notable for a mitral valve click and a soft murmur of mitral regurgitation.

4. What additional testing is needed to determine whether this young woman has Marfan syndrome?

   a. TTE
   b. Genetic testing
   c. CT angiogram of the aorta
   d. No additional testing

A TTE is performed that shows mitral valve prolapse with mild (1+) mitral regurgitation. The aortic root is dilated at 5.0 cm with effacement of the sinotubular junction and a mid-ascending aortic measurement of 3.6 cm. The aortic valve is trileaflet with no aortic regurgitation.

5. What is the most important recommendation to be made to this patient?

   a. Repeat the TTE in 6 months
   b. Initiate a β-blocker
   c. Avoid strenuous exertion, contact sports, and pregnancy
   d. Elective aortic replacement

The patient wishes to schedule surgery but prefers to wait 2 months until the end of the school year. Her father who is an internal medicine physician has read about the potential benefit of angiotensin receptor blockers (ARBs) for patients with aneurysms and asks your advice regarding treatment.

6. What is the postulated mechanism of action whereby ARBs reduce progression of aortic disease in Marfan syndrome?

   a. Reduction of BP through angiotensin II type 1 receptor blockade
   b. Complete blockade of the renin–angiotensin–aldosterone system
   c. Reduction in activity of transforming growth factor (TGF)-β
   d. Increase production of matrix metalloproteinases (MMPs)

Case 3 (Questions 7 and 8)

A 67-year-old man with long-standing HTN presents to the emergency room (ER) with sudden-onset chest pain described as ripping in quality, subsiding since its onset. He

underwent a cardiac catheterization 6 months previously that showed a 40% lesion in the mid-left anterior descending coronary artery. His medications include aspirin, gemfibrozil, and nifedipine.

Physical Examination

He appears diaphoretic. HR—110 bpm; BP—106/54 mmHg (right arm); 72/35 mmHg (left arm). Jugular venous pressure—12 cm H_2O. Heart sounds are soft and there is no audible systolic or diastolic murmur. Left radial and brachial pulses are weak.

ECG on presentation shows ST elevations in the inferior leads and low voltage.

Chest X-ray (CXR) shows cardiomegaly with a globular-shaped heart and interstitial edema.

7. Which of the following is the first diagnostic test that should be performed?

- **a.** Cardiac enzymes
- **b.** MRA of the aorta
- **c.** TTE
- **d.** Cardiac catheterization

A TTE was performed showing a pericardial effusion and signs of cardiac tamponade. A CT angiogram is also performed and shown in Figure 6.2.

8. What intervention should be performed next for the management of this patient?

- **a.** Cardiac catheterization
- **b.** Emergent aortic surgery
- **c.** Swan-Ganz catheterization
- **d.** Pericardiocentesis

Case 4 (Questions 9 and 10)

A 36-year-old man with a bicuspid aortic valve develops sudden onset of headache, mental status changes, and unequal pupils. He is rushed to an ER and a head CT scan is done that shows an intracranial bleed. BP on presentation is 158/78 mmHg.

Figure 6.2

Except for a history of HTN, he has no known medical problems and no history of drug abuse. A visit to his physician's office 1 week earlier revealed a BP of 120/75 mmHg on metoprolol and ramipril.

9. What is the most likely reason for the patient's intracranial bleed?

- **a.** Hypertensive crisis
- **b.** Aortic dissection
- **c.** Cerebral aneurysm rupture
- **d.** Mycotic aneurysm associated with endocarditis

10. What other structural abnormality is most commonly associated with coarctation of the aorta?

- **a.** Atrial septal defect
- **b.** Ventricular septal defect
- **c.** Pulmonary stenosis
- **d.** Mitral valve prolapse

Case 5 (Questions 11 and 12)

A 74-year-old man presents to the ER with upper back pain ongoing for 3 hours. The pain is described as sharp and severe occurring at rest. He has no associated symptoms of shortness of breath, chest pain, or presyncope. His past medical history is notable for

a coronary artery bypass graft (CABG) 2 years previously, HTN, and ongoing tobacco use. At the time of his CABG, he was noted to have a 4.4-cm ascending aortic aneurysm that was not repaired. His medications include aspirin, an angiotensin-converting enzyme inhibitor, and a β-blocker.

Physical Examination

BP—180/110 mmHg.
Pulse rate—90 bpm.
Lung and cardiac examinations are unremarkable and no cardiac murmur is heard. The abdomen is mildly tender with no bruit. Pulses are equal but diminished in the lower extremities.
ECG shows sinus rhythm with nonspecific ST changes and an old inferior myocardial infarction (MI).
Laboratory tests including cardiac enzymes, liver function tests, amylase, and lipase are normal.

11. What is the most appropriate diagnostic procedure to perform next?

a. TTE
b. TEE
c. CTA of the chest and abdomen
d. Aortography

A CT scan demonstrates an ascending aortic aneurysm of 4.8 cm and a descending thoracic aortic aneurysm of 6.0 cm but no evidence of dissection. There is no abdominal aortic aneurysm (AAA). The patient continues to have ongoing pain despite high doses of β-blockers, sodium nitroprusside, and opioid analgesics.
ECG and cardiac enzymes remain normal.
D-dimer level is >500 ng/mL.

12. What is the most appropriate next decision for management?

a. Cardiac catheterization
b. MRA of the chest/aorta
c. TEE
d. Intensify medical therapy

Case 6 (Question 13)

A 62-year-old man presents for a routine annual examination. He has a history of HTN that is managed with monotherapy. He is active and has no symptoms.

Physical Examination

BP—162/88 mmHg in both arms. Pulse rate—70 bpm. Heart and lung examination is

unremarkable. Abdominal examination reveals a pulsatile mass.
ECG shows sinus rhythm and a complete right bundle branch block.
Abdominal ultrasound shows an infrarenal AAA of 4.2 cm.

13. What is the most appropriate management step?

a. Initiate a β-blocker and repeat ultrasound in 6 months
b. Initiate a β-blocker and repeat ultrasound in 3 months
c. No medical therapy and repeat ultrasound in 1 year
d. No medical therapy and repeat ultrasound in 2 years

Case 7 (Questions 14 and 15)

A 76-year-old man presents to the ER with severe sharp chest pain that began 2 hours previously. He has a history of HTN and had CABG 3 years ago after an MI. He continues to smoke. The CABG was performed off-pump because of severe atheroma in the ascending aorta seen by intraoperative TEE. The patient's pain has not subsided with the initiation of IV heparin, nitroglycerin, and β-blockers. The pain is different in character from the pain before his MI.

Physical Examination

BP—160/94 mmHg.
Pulse—76 bpm.
Heart and lung sounds are normal. Pulses are diminished in the lower extremities.
ECG shows a left bundle branch block.
Cardiac enzymes are normal × 1.

Despite severe atheroma in the aorta, the physician taking care of the patient is not convinced that he does not have an acute coronary syndrome and performs a cardiac catheterization. It shows that the grafts are patent and there is no culprit lesion in the native vessels. He then decides to perform aortography and a focal outpouching is seen in the aortic wall in the distal ascending aorta (Fig. 6.3A). Contrast dye collects slowly in this region. The patient's chest pain is intensifying. A TEE is also performed (Fig. 6.3B).

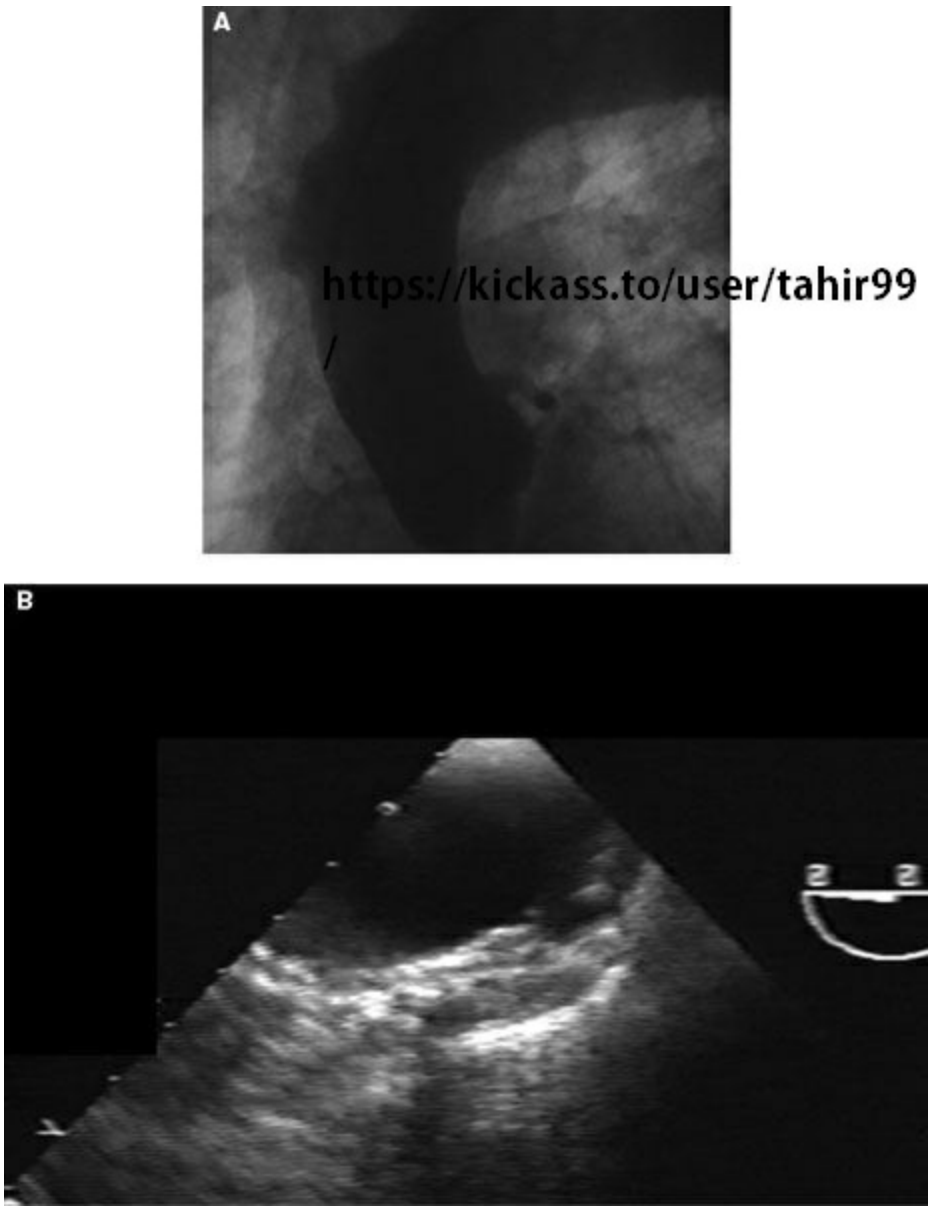

Figure 6.3

14. What is the correct diagnosis?

a. Aortic dissection
b. Aortic aneurysm
c. Intramural hematoma
d. Penetrating aortic ulcer

15. What is the most appropriate next management step to take?

a. Medical management with β-blockers and afterload reduction
b. Transfer to the operating room immediately for replacement of the ascending aorta
c. Medical management and obtain a CT chest/aorta

d. Medical management and obtain an MRA of the aorta

Case 8 (Questions 16 and 17)

A 45-year-old woman presents with discomfort in her left leg with walking, dizziness, headaches, and a cold right hand. She has no chest pain or shortness of breath. There is no significant past medical history and she does not smoke.

Physical Examination

BP—170/82 mmHg (left arm) and 140/68 mmHg (right arm). Lung sounds are clear. Cardiac examination is notable for a normal S_1 and S_2 and II/VI diastolic decrescendo murmur at the left sternal border. The right brachial pulse is diminished and lower extremity pulses are diminished. A bruit is heard over the left carotid artery and right subclavian artery.

16. What test would be most useful for diagnosing the patient's condition?

a. TEE
b. Carotid duplex ultrasound
c. Magnetic resonance imaging (MRI) of the head
d. Angiography

17. What is the most likely diagnosis?

a. Behçet disease
b. Relapsing polychondritis
c. Giant cell arteritis
d. Takayasu arteritis

Case 9 (Questions 18 to 21)

A 21-year-old woman with Turner syndrome has a history of surgical repair for periductal coarctation of the aorta at age 4 years. Her presentation was for HTN and heart failure, both of which resolved after the procedure. She was lost to follow-up after childhood and recently reestablished with a cardiologist. She has been experiencing dyspnea and claudication in the past year.

Physical Examination

BP—188/94 mmHg (left arm); 192/100 mmHg (right arm); 100/60 mmHg (right leg). Pulses are notable for normal upper extremity and reduced lower extremity pulses with a brachial–femoral delay. Cardiac examination is notable for normal S_1 and paradoxically split S_2 with an ejection click and S_4 gallop. A continuous murmur III/VI in intensity is heard under the left scapula.

18. Which of the following statements is correct regarding the echocardiographic image

from this patient obtained from the suprasternal notch (Fig. 6.4)?

a. Pressure gradients are usually underestimated using the simplified Bernoulli equation
b. Pressure gradients are usually accurate using the simplified Bernoulli equation
c. Pressure gradients shown are not consistent with severe coarctation
d. Presence of systolic and diastolic flow is consistent with severe coarctation

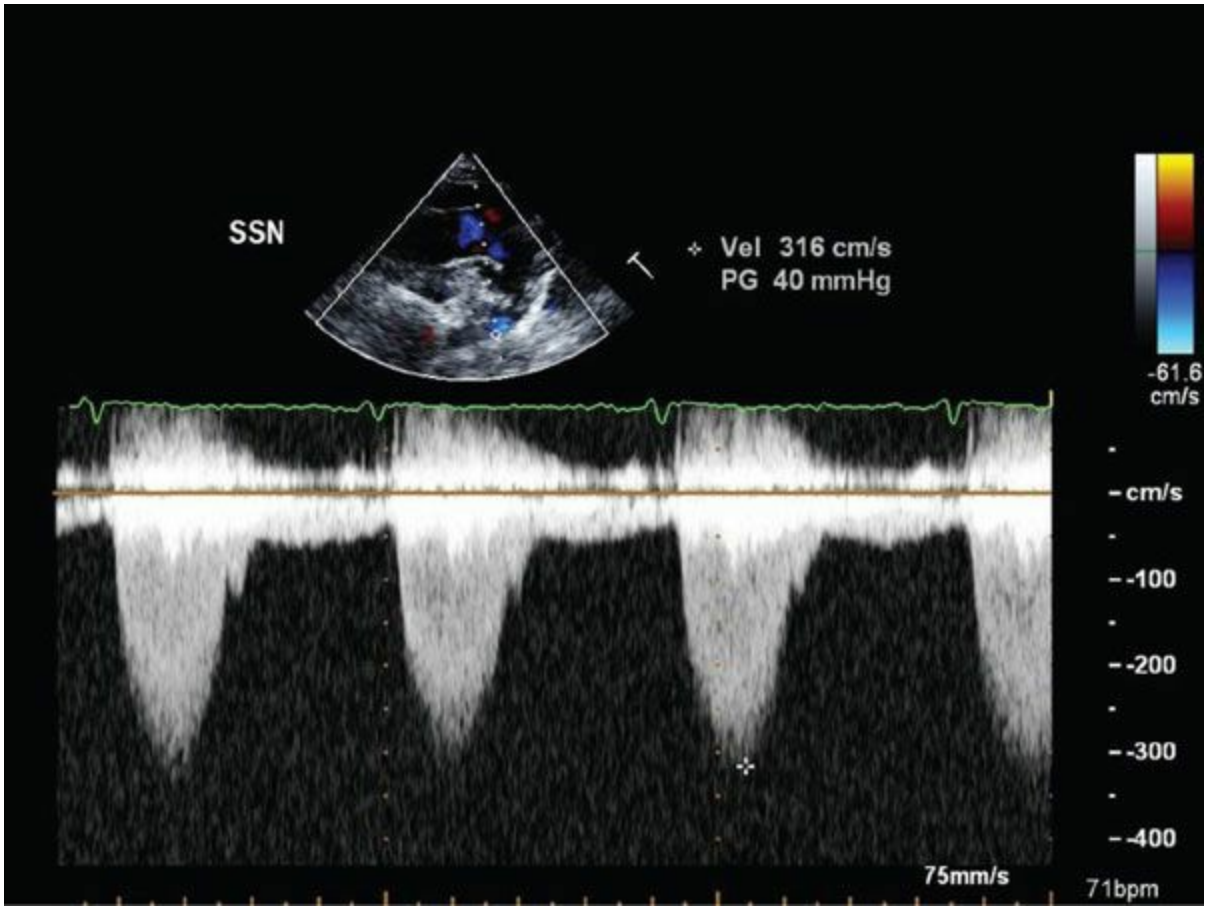

Figure 6.4

19. Which of the following statements is correct regarding the echocardiographic image from this patient obtained from the abdominal aorta (Fig. 6.5)?

a. The hallmark of coarctation is the presence of low systolic velocities
b. The presence of coarctation cannot be determined without knowing the timing of the pulse delay relative to aortic ejection
c. The hallmark of coarctation is the presence of persistent antegrade flow in diastole
d. The presence of coarctation cannot be determined without additional Doppler images proximal to the coarctation site

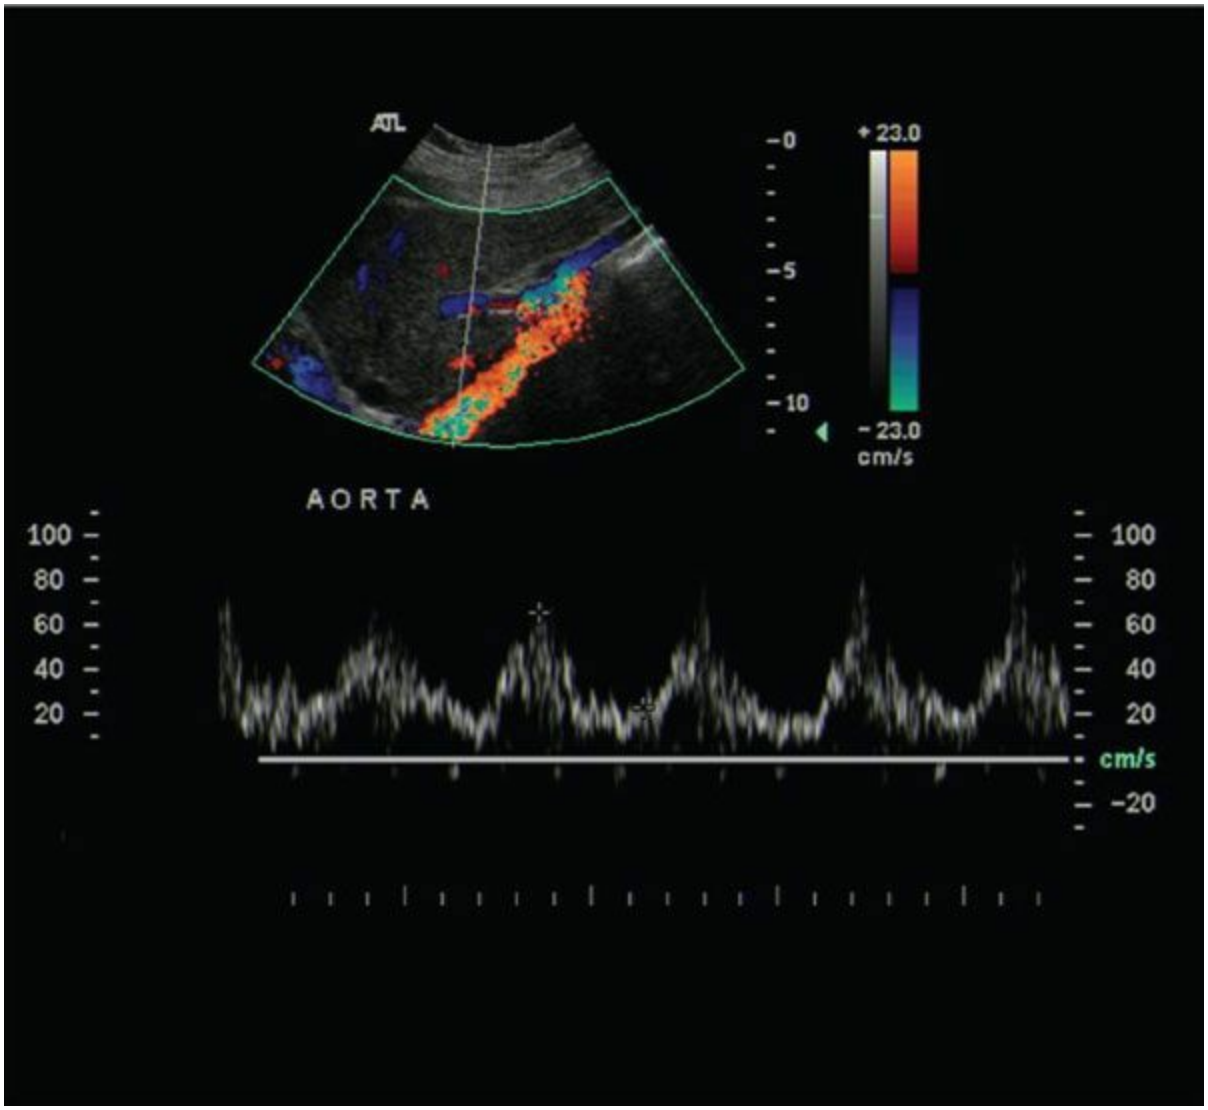

Figure 6.5

20. Which of the following recommendations is most appropriate regarding reintervention in this patient (Fig. 6.6)?

a. Surgery is generally recommended
b. No intervention should be performed until maximal medical therapy is attempted
c. Balloon angioplasty with or without stents is generally recommended
d. There is no consensus and either surgery or balloon aortoplasty (with or without stenting) are equal options

Figure 6.6

21. Which of the following is an indication for aortic coarctation intervention?

- **a.** Symptomatic patient with dyspnea at rest, regardless of the coarctation gradient
- **b.** Asymptomatic patient with normal BP at rest and with exercise and a peak-to-peak gradient across the coarctation site of 19 mmHg
- **c.** Asymptomatic patient with a peak-to-peak gradient across the coarctation site of 15 mmHg with extensive collaterals
- **d.** Symptomatic patient with a bicuspid aortic valve and severe aortic regurgitation undergoing aortic valve replacement and a peak-to-peak gradient across the coarctation of 15 mmHg

Case 10 (Question 22)

A 30-year-old man is referred to cardiology clinic for evaluation of a heart murmur. He had an uneventful childhood except that on four separate occasions he fractured his arms or legs requiring multiple surgical repairs. He has no family history of heart disease or congenital abnormalities.

Physical Examination

Normal stature. Vital signs are normal. Arm span-to-height ratio is normal.

No pectus deformity, scoliosis, wrist sign. Cardiac examination is notable for a decreased S_1 and normal S_2 intensity with a III/VI diastolic decrescendo murmur and no gallops. Pulses are normal and the extremities are hypermobile. No abnormality of the skin is present.

TTE shows a dilated sinus of Valsalva of 4.7 cm with severe aortic regurgitation. Left ventricular ejection fraction (LVEF) = 65% with LV dimensions of (diastole 6.4 cm; systole 5.1 cm).

22. What is the most likely diagnosis for this patient?

- **a.** Ehlers-Danlos syndrome
- **b.** Marfan syndrome
- **c.** Osteogenesis imperfecta
- **d.** Homocystinuria

Case 11 (Questions 23 and 24)

A 65-year-old man presents to the ER with severe, tearing lower back pain that started while he was shoveling snow. He has a history of poorly controlled HTN and coronary artery disease with a stent to the left anterior descending coronary artery 4 months previously. Other medical problems include severe O_2-dependent chronic obstructive pulmonary disease.

Physical Examination

BP—190/110 mmHg.

Pulse—90 bpm.

Cardiac examination is notable for a normal S_1 and S_2 with an S_4 gallop and II/VI early-peaking systolic ejection murmur at the left sternal border.

ECG shows sinus rhythm and no ST changes.

An initial set of cardiac enzymes is normal.

23. What is the most appropriate initial medical therapy?

- **a.** Intravenous metoprolol
- **b.** Intravenous diltiazem
- **c.** Intravenous enalapril
- **d.** Intravenous nitroprusside

A CT angiogram is performed (Fig. 6.7).

24. Which of the following statements regarding the appearance of this form of acute aortic syndrome is most accurate?

- **a.** There is low attenuation of the aortic wall

b. It is not continuous
c. Intimal calcium is nondisplaced
d. It is circumferential or crescentic

Case 12 (Questions 25 to 28)

A 44-year-old man is admitted to the hospital because of a left hemisphere stroke with right arm and leg weakness. He has no history of HTN or smoking, although his total cholesterol level is 334. ECG shows sinus rhythm. Carotid duplex ultrasound shows less than 20% obstruction bilaterally. Head CT demonstrates a recent stroke in the left cortex in the region of the middle cerebral artery. A TTE shows normal valves, chamber sizes, and LV function.

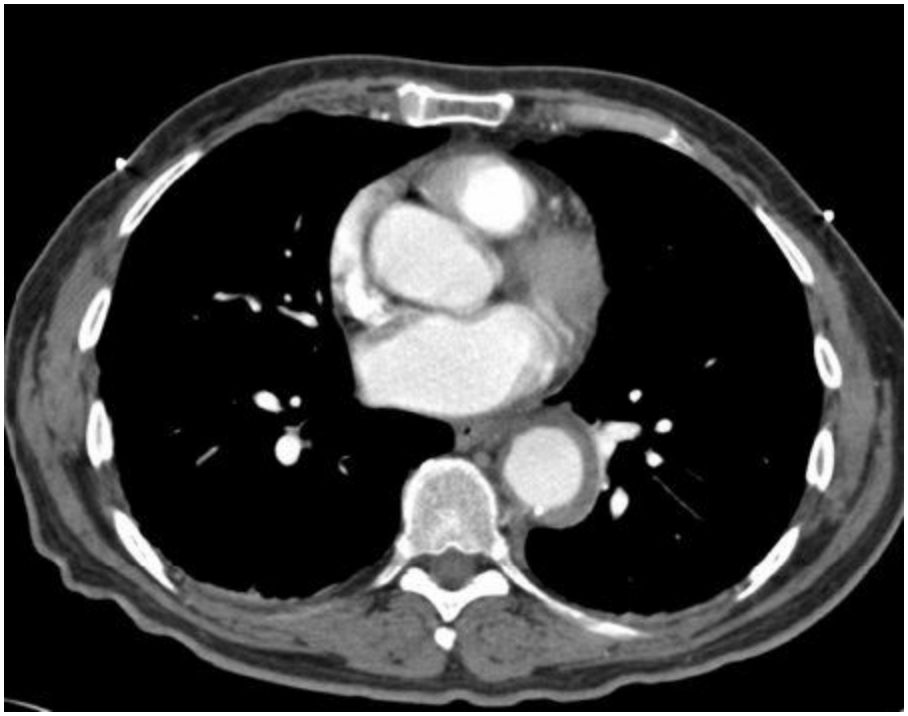

Figure 6.7

25. Which test is most likely to reveal the etiology of the patient's stroke?

a. TTE with bubble study
b. 30-Day event recorder
c. MRA of the head and neck
d. TEE

26. Which of the following medical regimens is most appropriate for a patient with a cardioembolic stroke and the following finding seen on TEE (Fig. 6.8)?

a. Statin and aspirin
b. Statin and warfarin

c. Aspirin and dipyridamole
d. Statin, antiplatelet agent, and warfarin

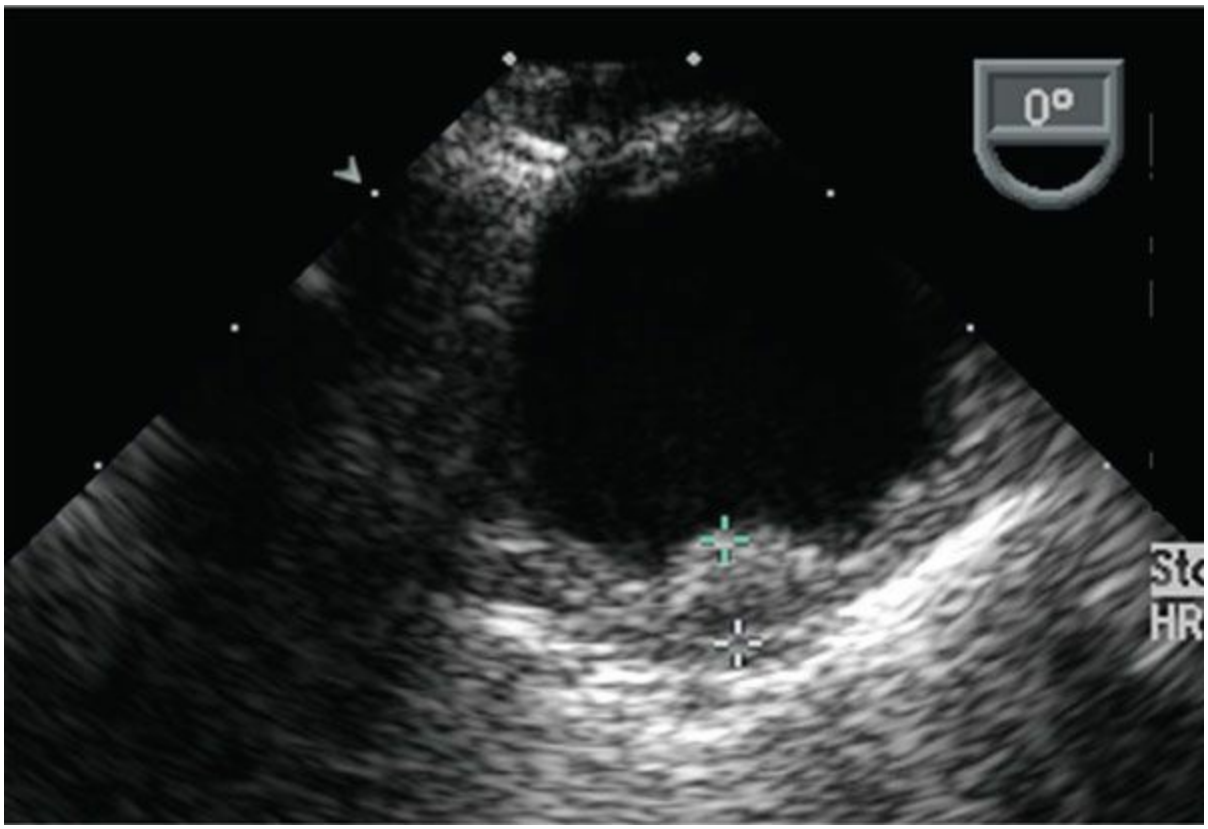

Figure 6.8

27. Which of the following atheromatous plaques is least likely to be associated with a cardioembolic event?

a. 3-mm plaque with severe calcification and no mobile components
b. 4-mm plaque with small mobile components and no calcification
c. 5-mm plaque with multiple mobile components, no calcification, and a small ulceration
d. 2-mm plaque with calcification, a small mobile component, and large ulceration

28. Which statement is correct regarding performing CABG in a similar patient with aortic arch atheroma and focal areas of atheroma in the ascending aorta?

a. Palpation of the aorta by the surgeon for calcified plaque correlates with findings of atheroma by TEE.
b. Alternative sites for cross-clamping or cannulation may reduce stroke risk.
c. Aortic arch endarterectomy is recommended.
d. Replacement of the ascending aorta is recommended because of increased likelihood of stroke.

Case 13 (Question 29)

A 21-year-old man is referred to a cardiology clinic for exertional dyspnea. As a child he was evaluated for a heart murmur by a pediatric cardiologist.

Physical Examination

BP—140/84 mmHg (left arm); 120/68 (right arm).

Cardiac examination is notable for a normal S_1 and increased intensity S_2/A_2, absence of an ejection click, and III/VI systolic ejection murmur heard best in the first right intercostal space radiating to the neck and increases with expiration. There is a thrill in the suprasternal notch. The left carotid and brachial pulses are diminished relative to the right carotid and brachial pulses.

29. What diagnosis best explains the patient's disorder?

a. Patent ductus arteriosus
b. Coarctation of the aorta
c. Supravalvular pulmonary stenosis
d. Williams syndrome

Case 14 (Questions 30 to 32)

A 30-year-old man with a history of congenital heart disease is referred to you because of symptoms of dysphagia and an abnormal CXR. As a child he was told that his CXR was abnormal because of an "aortic anomaly" and that it was benign.

Physical Examination

Vital signs are normal.

Cardiac examination is notable for normal intensity S_1 and S_2 heart sounds. An ejection click is heard in the right upper sternal border (RUSB) though no murmur is audible. Upper and lower extremity pulses are equal.

30. The CXR (Fig. 6.9) shows what abnormality?

a. Bovine aortic arch
b. Cervical aortic arch
c. Right-sided aortic arch
d. Aberrant right subclavian artery

Figure 6.9

31. What is the most common congenital defect associated with the aortic anomaly seen in Question 30?

- **a.** Tetralogy of Fallot
- **b.** Truncus arteriosus
- **c.** Atrial septal defect
- **d.** Transposition of the great vessels

32. The patient's dysphagia is likely caused by what abnormality associated with his aortic anomaly?

- **a.** Aberrant left subclavian artery and diverticulum of Kommerell
- **b.** Coarctation of the aorta
- **c.** Isolated aberrant right subclavian artery
- **d.** Interrupted aortic arch

Case 15 (Questions 33 and 34)

A 30-year-old man presents for follow-up after undergoing a surgical coarctation repair at age 9. He has no records and is uncertain of the type of repair. He has not had any testing done in the past 10 years. He has used antibiotic prophylaxis for dental

procedures. He takes no other medications. He feels well, is active, and has no complaints.

Physical Examination

BP—138/72 mmHg (right arm); 126/70 mmHg (left arm); pulse—80 bpm, regular.

Heart sounds are of normal intensity. An aortic ejection click is present in the RUSB. There is a brief, short duration systolic ejection murmur in the RUSB without a diastolic murmur. Upper and lower extremity pulses are equal and there is no radial or brachial to femoral delay.

33. Which test would be least appropriate for this patient?

a. TTE
b. CTA of the chest/aorta
c. Exercise treadmill stress test
d. 24-Hour Holter monitoring

34. How often should the coarctation repair site be evaluated by chest imaging in this patient (CTA or MRA)?

a. Generally every 5 years
b. Generally every 10 years
c. Generally every 2 years
d. Not recommended unless there is specific concern

Case 16 (Questions 35 and 36)

A 38-year-old man is referred for a cardiac surgical evaluation for bicuspid aortic regurgitation. He has a long-standing aortic valve disorder for 10 years. He is fully active with no limitations. He plays tennis on a regular basis.

Physical Examination

BP—120/40 mmHg; pulse—68 bpm. Cardiac examination is notable for a reduced intensity S_1 and increased intensity S_2/A_2. Three murmurs are present, a mid-peaking crescendo/decrescendo systolic ejection murmur beginning after an ejection click, a long-duration high-pitched diastolic decrescendo murmur along the left sternal border and a low-pitched mid-diastolic rumble heard at the apex.

Stress echocardiography is performed and shows a bicuspid aortic valve with right–left fusion. There is calcification of the raphe between the conjoined leaflets. Peak/mean gradients = 30/15 mmHg. Holodiastolic flow reversal is present in the descending aorta. The aortic root measures 4.0 cm and the mid-ascending aorta is 3.9 cm with no sinotubular junction effacement. LV cavity measurements are as follows: LVIDd—5.8 cm; LVIDs—3.9 cm; LVEF—58%. There is reduction in LV cavity size with 13

metabolic equivalents of exercise and no symptoms.

35. What is the most appropriate surgical recommendation?

- **a.** Elective aortic valve surgery and ascending aortic grafting
- **b.** Elective aortic valve surgery without ascending aortic grafting
- **c.** Medical therapy/observation and add a β-blocker
- **d.** Observation only

Six months later the patient has developed dyspnea with moderate exertion and a significant reduction in exercise tolerance. Repeat echocardiogram shows similar LV cavity dimensions and LVEF calculated at 57%. Aortic root dimension is 4.0 cm and the mid-ascending aorta is 4.6 cm.

36. What is the appropriate recommendation at this time?

- **a.** Aortic valve replacement
- **b.** Aortic valve repair
- **c.** Aortic valve replacement and aortic graft
- **d.** Stress echocardiogram to confirm change in exercise tolerance

Case 17 (Questions 37 to 40)

A 66-year-old man is seen by his internist for an annual evaluation. Past medical history is notable for HTN and tobacco use. His BP is 136/80 mmHg on monotherapy. Cardiac and abdominal examinations are unremarkable.

He has a friend who was detected to have an AAA on routine screening and asks his physician whether it is indicated for him to be screened.

37. Which of the following statements regarding AAA screening is correct?

- **a.** Consensus guidelines recommend routine screening of all women >60 years of age or older
- **b.** Screening men >65 years old is associated with a reduction in aneurysm-related deaths compared with unscreened males of similar ages
- **c.** Sensitivity and specificity of ultrasound screening in appropriate patients in accredited laboratories are >70%, respectively
- **d.** After a negative screening examination in a man aged 65 years or older, a repeat examination should be performed 5 years later

A screening abdominal ultrasound is performed in this patient and shows an infrarenal AAA of 5.5 cm. The patient is advised to undergo repair though wishes to consider the option of an endovascular stent graft (EVAR) rather than an open repair.

38. Which of the following statements is true regarding recommendations for AAA

repair?

a. Repair is indicated for any AAA > 5.0 cm
b. Size cutoffs for AAA repair should be based on age, weight, and height
c. Inflammatory or infectious aneurysms should be repaired at any size
d. Women should undergo repair only for AAA > 5.5 cm

39. Which statement regarding EVAR is correct?

a. Open repair and EVAR are associated with similar 30-day mortality
b. Open repair and EVAR are associated with similar long-term mortality
c. EVAR is associated with decreased late complications compared with open repair
d. EVAR is associated with less repeat interventions compared with open repair

40. Which of the following statements regarding endoleaks is correct?

a. They occur with a similar prevalence with EVAR and open procedures
b. Endoleaks may occur as a result of retrograde flow of small arterial branches back into the aneurysm sac
c. They are rare and generally do not lead to repeat procedures
d. Type IV endoleaks (leakage through graft material) are the most common

Case 18 (Questions 41 and 42)

A 38-year-old woman is admitted to the internal medicine service for chest pain. She is experiencing sharp chest pain unrelated to exertion and dyspnea for 2 days. Her family history is unknown since she was adopted. Past medical history is not well defined but notable for an uncharacterized connective tissue disorder. She was told at a younger age to avoid pregnancy.

Admission ECG and cardiac enzymes are negative. She is unable to exercise because of her symptoms and therefore is sent for an adenosine nuclear stress test. The test shows mild anteroseptal ischemia with no ECG changes.

The cardiology service is consulted for a cardiac catheterization.

Physical Examination

She is thin and in mild distress. Vital signs are normal. General examination and skin examination are notable for a translucent appearance to the skin, joint hypermobility, hyperextensible skin, and bruises. There are no findings suggestive of Marfan syndrome. Cardiac examination reveals a normal S_1 and S_2 and a soft diastolic decrescendo murmur at the right sternal border.

41. What do you recommend?

a. Coronary angiography
b. No further testing
c. Cardiac MRI to assess for coronary anomalies
d. CTA of the chest and aorta

42. What should be done to more definitively characterize the patient's condition?

a. Diagnosis based on clinical criteria
b. DNA sequencing
c. Blood analysis for chromosomal abnormalities
d. Clinical laboratory markers of inflammation

Case 19 (Questions 43 to 45)

A 24-year-old man is referred to cardiology clinic for consultation regarding an aortic aneurysm. He has a family history of ascending aortic aneurysms. Echocardiography showed a trileaflet aortic valve and mid-ascending aortic aneurysm of 4.4 cm that is confirmed by CTA.

Physical Examination

BP—120/64 mmHg; pulse—70 bpm. Head and neck examination is notable for widely set eyes. The oropharynx is shown (Fig. 6.10). Cardiac and skin examinations are normal.

Figure 6.10

43. What is the patient's diagnosis?

a. Cogan syndrome
b. Loeys-Dietz syndrome

c. Ormond disease
d. Behçet disease

44. What is the gene defect associated with this condition?

a. COL3A1
b. TGFBR1 or TGFBR2
c. ACTA2
d. FBN1

45. What further recommendation is correct regarding management of this patient?

a. Start a β-blocker
b. Start an ARB
c. Recommend aortic repair
d. Observation only

Case 20 (Question 46)

A 40-year-old man is transferred via air ambulance to a level 1 trauma center after a motor vehicle accident (MVA). He had a head-to-head collision with another car traveling at a high speed and was propelled forward but was partially restrained by his seat belt and deployed air bags.

Physical Examination

BP—162/62 mmHg (right arm); HR—110 bpm. General condition notable for intubated, sedated man with a cervical collar. Cardiac examination is notable for normal heart sounds and a soft systolic murmur. Lower extremities are mottled and pulseless.

ECG shows sinus tachycardia with no ST changes.

CXR shows no broken ribs bilaterally, a widened mediastinum, and left pleural effusion.

46. Which of the following diagnoses are most likely for this patient?

a. Complete aortic transection
b. Ascending aortic dissection and cardiac tamponade
c. Descending aortic partial transection with pseudoaneurysm
d. Descending aortic intramural hematoma/dissection

Case 20 (Questions 47 and 48)

A 79-year-old man with HTN underwent a routine CXR and is found to have a thoracic aneurysm. He is asymptomatic with well-controlled BP on a β-blocker. A CT angiogram of the chest is performed showing a descending thoracic aortic aneurysm of

5.4 cm distal to the left subclavian artery with a chronic dissection. The aneurysmal segment does not extend into the abdomen. The ascending aorta is 4.5 cm in the mid-portion and 4.0 cm in the mid-arch. The patient has no other comorbid conditions.

47. What recommendation is most appropriate for this patient based on current guidelines?

- **a.** Open repair is recommended
- **b.** TEVAR (thoracic endovascular aortic repair) is recommended
- **c.** Medical therapy is recommended
- **d.** An elephant trunk procedure is recommended

48. Which statement is correct comparing TEVAR with open repair for thoracic aortic aneurysms?

- **a.** TEVAR is associated with higher rates of hospital mortality
- **b.** TEVAR is associated with higher risks of paraplegia
- **c.** TEVAR is associated with a 30-day risk of endoleaks of 10%
- **d.** TEVAR is associated with lower long-term mortality in randomized trials

Case 21 (Questions 49 and 50)

A 45-year-old woman with a history of fibromuscular dysplasia presents to the ER with an acute ST-elevation inferior MI. She is taken immediately to the cardiac catheterization laboratory for primary percutaneous intervention of the right coronary artery (RCA). The first injection of the RCA shows a dissection extending from the ostium to the posterior descending artery. A subsequent aortogram after stenting of the RCA is performed (Fig. 6.11).

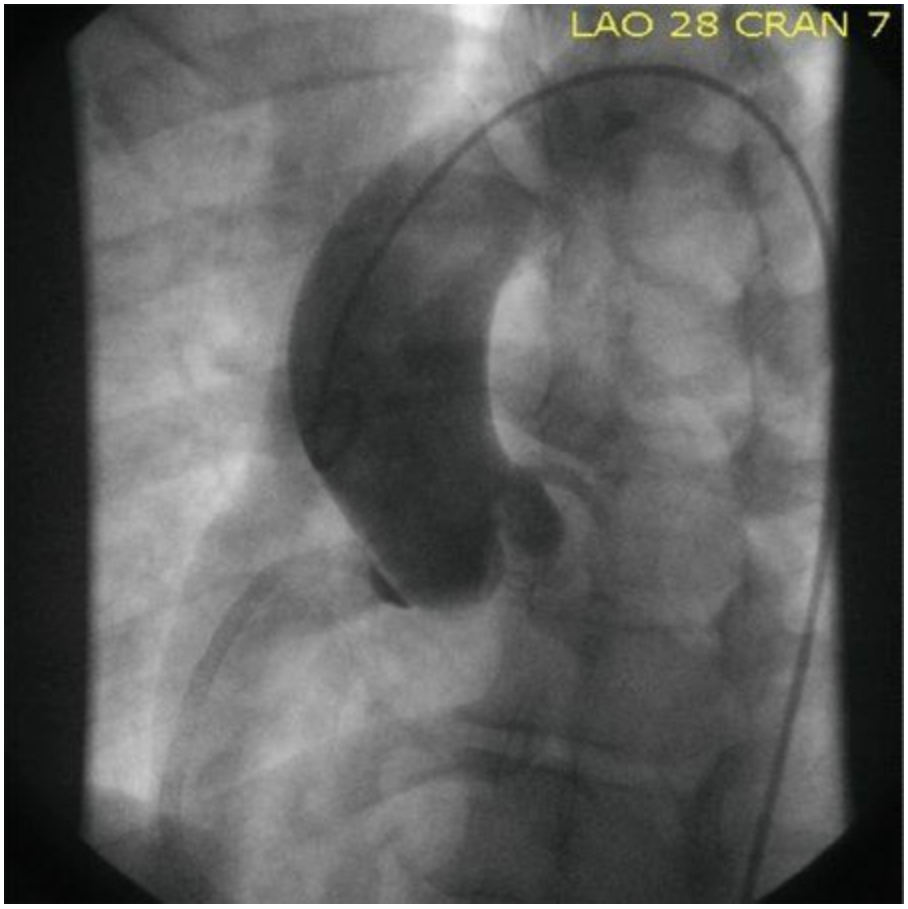

Figure 6.11

49. What does the aortogram show?

- **a.** Aortic root aneurysm
- **b.** Aortic root pseudoaneurysm
- **c.** Anomalous RCA from the left cusp
- **d.** Aortic root localized dissection

50. What further evaluation or management do you recommend for this patient?

- **a.** Observation and medical therapy
- **b.** Open heart surgery
- **c.** Intravascular ultrasound of the RCA
- **d.** TEE

ANSWERS

1. **d.** Aortic dilatation with moderate aortic regurgitation and mild aortic stenosis. A bicuspid aortic valve is not likely in a 78-year-old with an initial presentation of aortic valve disease. An aortic ejection click is often present in patients with

bicuspid aortic valve disease when the valve is still pliable and is not heard in this patient. Furthermore, the examination is not consistent with severe aortic regurgitation because the diastolic BP is normal (not reduced), the S_1 sound is normal in intensity (not reduced as a result of premature closure of the mitral valve), and the carotid pulsations are normal (not bisferiens). The examination is not consistent with severe aortic stenosis because the murmur is early peaking and S_2 (A_2) is audible and not reduced in intensity. The intensity of a systolic ejection murmur is related in part to the stroke volume and not a good single indicator of severity of stenosis. Therefore, the most likely explanation for the heart murmur is aortic dilatation with nonsevere aortic regurgitation and stenosis. Of note, aortic regurgitant murmurs originating from aortic abnormalities are generally heard best along the right sternal border and those originating from valvular disease heard best along the left sternal border.

2. **b.** Magnetic resonance angiography (MRA) of the great vessels. The presence of a pericardial effusion and an elevated erythrocyte sedimentation rate in a patient with aortic dilatation suggests an inflammatory etiology. Etiologies of aortic aneurysms are listed in Table 6.1. Inflammatory aortitis includes systemic diseases and primary large-vessel vasculitis. Numerous systemic diseases may involve the aorta, including systemic lupus erythematosus, rheumatoid and psoriatic arthritis, inflammatory bowel disease, ankylosing spondylitis, systemic sclerosis, relapsing polychondritis, Behçet syndrome, and Reiter syndrome. Primary vascular disorders include Takayasu and giant cell arteritis. MRA of the aorta may distinguish characteristic thickening and tissue edema that are diagnostic of aortitis.

3. **d.** Giant cell arteritis. The presence of systemic symptoms including headaches and myalgias with an elevated sedimentation rate in an elderly woman is suggestive of temporal arteritis. Temporal arteritis affects women twice as often as it does men and is most commonly seen after age 55 years. Temporal artery tenderness may be present with the potential for blindness to occur. Biopsy of the temporal arteries is diagnostic. Associated giant cell arteritis with involvement of the aorta and branch vessels with aneurysm formation may occur. Diagnostic criteria are sensitive and specific for giant cell arteritis if at least three of the following findings are present: (a) >50 years of age, (b) recent onset of localized headaches, (c) temporal artery tenderness or pulse attenuation, (d) erythrocyte sedimentation rate >50 mm/h, and (e) arterial biopsy showing necrotizing vasculitis.

   The MRA of this patient shows features of vessel thickening of the ascending aorta and arch with “edema”-weighted characteristics and mural enhancement suggestive of an inflammatory aortitis and consistent with giant cell aortitis. Corticosteroids therapy can be used to reduce inflammation seen with aortitis with

guidance from serial MRA imaging. Cardiac MRI. Sagittal delayed enhancement (phase-sensitive inversion recovery) image (**A**) and axial black-blood (double IR) (**B**) images demonstrating diffuse mural enhancement (**A**) and thickening of the ascending aorta and arch (**B**) consistent with an inflammatory arteritis. This patient has giant cell arteritis of the aorta (see Figure 6.1).

TABLE 6-1 Etiologies of Aortic Aneurysms

- Degenerative (HTN, arteriosclerosis, age related)
- Systemic connective tissue disorders
- Trauma (deceleration injury, dissection)
- Infectious diseases (syphilitic, mycotic)
- Primary vasculitis (Takayasu and giant cell aortitis, postoperative aortitis)
- Genetic (Marfan syndrome, Loeys-Dietz syndrome, Ehlers-Danlos type IV, familial thoracic aneurysm and dissection syndrome/FTAAD, Turner and Noonan syndrome)
- Congenital (unicuspid, bicuspid aortic valve, coarctation)
- Miscellaneous conditions (pregnancy, polycystic kidney disease, idiopathic, cocaine, steroids)

HTN, hypertension; FTAAD, familial thoracic aortic aneurysm disease.

4. **d.** No additional testing. The revised Ghent criteria are based primarily on clinical criteria although genetic testing for the FBN1 mutation can aid in diagnosis. There are criteria for individuals with and without a family history of Marfan syndrome (see Table 6.2). The patient presented has ectopia lentis and a family history of Marfan syndrome. Therefore, no additional information is required to make a diagnosis. She does additionally have systemic criteria that are consistent with the diagnosis, including pectus carinatum, wrist and thumb sign, high-arched palate, and mitral valve prolapse. An increased arm span-to-height ratio is no longer considered a diagnostic criterion for Marfan syndrome.

5. **d.** Elective aortic replacement. The timing of surgery for patients with ascending aortic aneurysms caused by Marfan syndrome is addressed in the 2010 guidelines for thoracic aortic diseases. Surgery is recommended for asymptomatic patients with Marfan syndrome or other genetic etiologies for thoracic ascending aortic aneurysms between 4.0 and 5.0 cm (class I) or when the ratio of the maximal ascending aortic or aortic root area ($\pi \times \text{radius}^2$) in cm^2 divided by the patient's

height in meters exceeds 10 (class IIa). In this patient, the calculation would be as follows: ($\pi \times 2.5^2 = 3.14 \times 6.25 = 19.6$ cm^2/1.70 m = 11.5), well above the 10:1 ratio. For women anticipating pregnancy, elective surgery should be performed when the ascending aortic dimension is >4.0 cm. Additional factors of importance include rate of change of aortic size >0.5 cm/year, presence and severity of aortic regurgitation, family history of dissection or sudden cardiac death, and the extent of aortic involvement. See Table 6.3 for timing of surgery in aortic diseases. An open-label study of adult patients with aortic dilatation and Marfan syndrome who were randomized to propranolol or no treatment showed less aortic dilatation and aortic complications among patients on propranolol. Therefore, β-blockers should be advised for this patient although this is not the most important recommendation.

TABLE 6-2 Revised 2010 Ghent Criteria for Marfan Syndrome

In the absence of family history or findings consistent with other syndromes—the following criteria are sufficient for the diagnosis of Marfan syndrome:

1. Aortic root dilatation or dissection and ectopia lentis
2. Aortic root dilatation or dissection and FBN1 mutation
3. Aortic root dilatation or dissection and systemic score ≥7 points
4. Ectopia lentis and FBN1 mutation

In the presence of family history—any of the following criteria are sufficient for the diagnosis of Marfan syndrome:

1. Ectopia lentis
2. Systemic score ≥7 points
3. Aortic root dilatation

Systemic score:

3 points = wrist and thumb sign

2 points = pectus carinatum deformity, hindfoot deformity, spontaneous pneumothorax, dural ectasia, protucio acetabulae

1 point = wrist or thumb sign, pectus excavatum or chest asymmetry, plain flat foot, scoliosis or thoracolumbar kyphosis, reduced elbow extension, three of five facial features, skin striae, severe myopia, mitral valve prolapse

TABLE 6-3 Timing of Surgery for Thoracic Aortic Aneurysms

Aortic Root or Ascending Aorta	Size
Degenerative etiology	≥5.5 cm or >0.5 cm growth/yr
Chronic aortic dissection	≥5.5 cm
Genetic etiology[a]	4.0–5.0 cm, >10:1 ratio[b] or >0.5 cm growth/yr
Bicuspid aortic valve	4.0–5.0 cm, >10:1 ratio[b] or >0.5 cm growth/yr
	>5.5 cm[c]
	>5.0 cm[c] (and ≥ 0.5 cm growth/yr or FH dissection
Loeys-Dietz syndrome	≥4.4 cm
Marfan syndrome (anticipating pregnancy)	>4.0 cm
Aortic valve repair or replacement (bicuspid valve or genetic etiology)	>4.5 cm
Aortic Arch	
Low risk	>5.5 cm
Descending Aorta	
Low risk	>5.5 cm
High risk (limited endovascular options)	>6.0 cm
Abdominal Aorta	
All patients	>5.5 cm
Women and smaller men	>5.0 cm

[a]See Table 6.1 for genetic etiologies.
[b]Ratio of maximal aortic root or ascending aortic area (πr^2) in cm^2 divided by the patient's height in meters.
[c]2014 American Heart Association/American College of Cardiology Guideline for the Management of Patients with Valvular Heart Disease
FH = family history

6. **C.** Reduction in activity of transforming growth factor (TGF)-β. The ARB losartan has been associated with a reduction in the rate of aortic dilatation and aneurysm growth in both experimental mouse studies and recently an open-label randomized trial of Marfan syndrome patients (COMPARE trial). A larger prospective randomized trial comparing atenolol versus losartan sponsored by the NIH is in progress. The postulated mechanism of action is independent of BP lowering. Because of defective production in fibrillin due to the FBN1 mutation, there is overexpression of TGF-β activity. TGF-β activity leads to an increase in destructive MMPs, which cause aortic wall weakening. Losartan appears to block the overproduction of TGF-β and MMPs so that aortic wall integrity is maintained.

7. **C.** TTE. A TTE should be performed immediately in this patient since the clinical findings are highly suggestive of a proximal ascending aortic dissection (character

of chest pain, differential BPs, and weak pulses) and cardiac tamponade (tachycardia, elevated jugular venous pressure, soft heart sounds, and globular-shaped heart on CXR with interstitial edema). Cardiac enzymes may determine the presence of myocardial injury but not reveal the cause. An acute inferior MI is likely due to the aortic dissection involving the origin of the RCA and not due to occlusive coronary artery disease.

The advantages and disadvantages of CTA, MRA, and TEE for the diagnosis of aortic dissection have been reviewed in detail. Each of these tests has high diagnostic accuracy for diagnosing aortic dissection. The test of choice for a given patient should be determined based on the relative expertise of each institution, the rapid availability of the test and its interpretation, and the specific individual circumstances of a patient. Given the likelihood of an aortic dissection and the possibility of cardiac tamponade in this patient, a TTE or a TEE is best suited for this patient. A limited TTE could assess whether a pericardial effusion and cardiac tamponade are present followed by either a TEE or CTA of the aorta to confirm and determine the location and extent of dissection.

8. **b.** Emergent aortic surgery. A proximal aortic dissection with hypotension or cardiac tamponade should be treated by emergent aortic surgery. A rapid confirmatory test can be performed on the way to or in the operating room. Small retrospective reviews have raised concerns regarding pericardiocentesis in patients with cardiac tamponade and aortic dissection. Rapid decompensation and death can occur in some patients due to propagation of dissection and increased bleeding into the pericardium. Most importantly, the presence of cardiac tamponade with aortic dissection should mandate immediate surgery. Pericardiocentesis can be performed if the patient is deteriorating rapidly and surgical assistance is not readily available or if the patient is in pulseless electrical activity.

Controversy also exists regarding cardiac catheterization for patients with proximal aortic dissection. Proponents of cardiac catheterization argue that patients with severe obstructive coronary disease require grafting at the time of surgery and that failure to do so will increase the risk of perioperative and postoperative cardiac events. Those who favor not performing cardiac catheterization argue that any delay may increase the risk of death and that an invasive procedure will add further risk of dissection, tamponade, or rupture. One study comparing outcomes of patients undergoing surgery for aortic dissection found that those not undergoing cardiac catheterization had similar mortality than those undergoing the procedure. The 2010 guidelines for thoracic aortic diseases recommend that coronary angiography should be considered if the patient is over 40 years of age, stable, and has either known CAD, significant risk factors for CAD, or an ischemic presentation. Computed tomographic angiography of the chest. Sagittal oblique

reconstruction shows an ascending aortic and aortic arch aneurysm with a dual lumen consistent with a type A aortic dissection (see Figure 6.2).

9. **c.** Cerebral aneurysm rupture. The history of HTN requiring treatment in a young man with a bicuspid aortic valve suggests the likelihood of an aortic coarctation. Given his recent well-controlled BP, aortic dissection, hypertensive crisis, and endocarditis are unlikely. A known association between aortic coarctation and cerebral aneurysms involving the circle of Willis is well established. Testing for this abnormality with MRA or CTA of the brain should be performed for coarctation patients when any neurologic symptoms are present. However, at least a 1 time scan of the brain for intracranial aneurysms is recommended for all patients with coarctation accordingly to the 2008 guidelines for management of congenital heart disease.

10. **b.** Ventricular septal defect. Several cardiac structural lesions are associated with coarctation of the aorta. The most common is a bicuspid aortic valve occurring in up to 85% of patients. Valvular, subvalvular, or supravalvular stenosis may occur. Aortic ectasia or aneurysm involving the ascending thoracic aorta and arch is often present. Other associated structural abnormalities include patent ductus arteriosus, perimembranous ventricular septal defect, and mitral stenosis (parachute mitral valve) as part of the Shone complex of left heart obstructive lesions.

11. **c.** CTA of the chest and abdomen. The patient's history is most suggestive of a thoracic aortic aneurysm or AAA or dissection. He is known to have thoracic aortic dilatation and atherosclerosis, and presents hypertensive with back pain and diminished pulses. Although TEE may be accurate for diagnosis of aortic dissection above the diaphragm, a CT scan may extend imaging to the entire aorta including the abdominal aorta and provide information regarding the involvement of branch vessels. Therefore, CT imaging would be preferable. Aortography is invasive and could cause further injury to the aorta. However, it could provide useful information along with angiography regarding the patency of the patient's bypass grafts and native circulation.

12. **b.** MRA of the chest/aorta. The patient is experiencing ongoing pain refractory to medical therapy and the clinical history remains suggestive of an acute aortic syndrome. The types of acute aortic syndromes are listed in Table 6.4. Although CT imaging is highly accurate in diagnosing aortic dissection, there are false-negative readings. In the International Registry of Aortic Dissection (IRAD) registry, many patients with suspected aortic dissection required more than one imaging test. Therefore, additional imaging should be performed in this patient especially since

an alternative diagnosis for the patient's symptoms is not available. An acute coronary syndrome is not likely in view of recent CABG and unremarkable ECG and cardiac enzymes. Biomarkers are emerging as a diagnostic aide in diagnosing acute aortic syndromes. A D-dimer level <500 ng/mL and a low C-reactive protein make aortic dissection unlikely.

13. **a.** Initiate a β-blocker and repeat ultrasound in 6 months. To determine the stability of an AAA between 4.0 and 4.9 cm (4.2 cm in this patient), it is generally recommended to do an initial follow-up ultrasound in 6 months. However, most patients with AAA size = 4.5 cm should be referred to a vascular surgeon for subsequent follow-up and risk assessment for surgical consideration and have a baseline CT of the aorta to assess for anatomic feasibility for endovascular repair. β-Blockers have been shown to delay the rate of AAA enlargement and would be indicated for this patient with suboptimal control of BP.

TABLE 6-4 Types of Aortic Syndromes

- Classic dissection (intimal tear with double lumen)
- Intramural hematoma (no intimal tear)
- Limited dissection (rare without hematoma, most often in Marfan syndrome)
- Penetrating aortic ulcer (associated localized hematoma or saccular aneurysm)
- Iatrogenic (catheter or trauma related)
- Symptomatic aneurysm

14. **d.** Penetrating aortic ulcer. A penetrating aortic ulcer occurs when aortic atheroma ruptures into the aortic media through the internal elastic lamina. Subsequently, an aneurysm, pseudoaneurysm, localized dissection, hematoma, or aortic rupture may develop. Penetrating ulcers can be diagnosed by aortography, CTA, MRA, or TEE. They more typically occur in the descending aorta. Typical findings include a focal outpouching or ulcer crater in the region of severe, calcified atheroma. Localized flow may be seen by contrast opacification or color Doppler. The aortogram in this patient shows multiple penetrating aortic ulcers, seen as outpouching on the greater curvature of the ascending aortic wall. Contrast aortogram (**A**) shows several outpouchings on the greater curvature of the ascending aorta consistent with penetrating ulcers. Transesophageal echocardiogram (**B**) showing a break in the lesser curvature of the aorta in the same patient in the region of diffuse calcific atheroma also consistent with a penetrating aortic ulcer (see Figure 6.3).

15. **b.** Transfer to the operating room immediately for replacement of the ascending aorta. The patient has an acute aortic syndrome with a symptomatic penetrating ulcer in the ascending aorta. Immediate surgery is indicated to prevent the possibility of aortic rupture. Further confirmatory imaging is not required.

16. **d.** Angiography. The patient presents with pulse deficits, bruits, and symptoms consistent with arterial insufficiency in multiple distributions, including the upper and lower extremities. Angiography (either CTA/MRA or invasive) of the arterial system would define the site and extent of arterial disease. The appearance of the lesions may also help with determining the etiology of the vascular disease (i.e., atherosclerotic versus vasculitic).

17. **d.** Takayasu arteritis. Takayasu arteritis ("pulseless disease") is an inflammatory disease of large sized arteries. Both stenotic lesions and aneurysms may be present with involvement of proximal segments of the aortic arch vessels. Aortic regurgitation is not uncommon due to involvement of the aortic root and aortic valve with inflammatory disease. Although most commonly described in Japanese patients, it has been described throughout the world.

    A diagnostic classification proposed by the American College of Rheumatology requires three of six criteria: (a) age at onset younger than 40 years, (b) intermittent claudication, (c) diminished brachial artery pulse, (d) >10 mmHg difference in systolic BP between arms, (e) bruit of the subclavian arteries or the aorta, or (f) angiographic narrowing or occlusion of the aorta or branches.

18. **d.** Presence of systolic and diastolic flow is consistent with severe coarctation. The peak Doppler pressure gradient as obtained from the simplified Bernoulli often overestimates the gradient obtained across the coarctation as measured by invasive hemodynamics. Since the pre-coarctation velocity is often increased due to abnormality of aortic valve, it must be accounted for in the Bernoulli equation. This requires using the modified Bernoulli equation, where pressure = $4\ (V_2^2 - V_1^2)$, in which V_2 is the peak Doppler velocity across the coarctation and V_1 is the pre-coarctation velocity. The typical sawtooth pattern of aortic coarctation is shown in this example with an elevated systolic velocity and a lower velocity forward flow in diastole. The presence of a continuous flow across the coarctation is consistent with severe obstruction regardless of the peak pressure gradient. Transthoracic suprasternal notch (SSN) view with continuous Doppler in the upper descending aorta. The Doppler profile shows a high-velocity antegrade velocity of 316 cm/s consistent with a 40-mmHg systolic gradient. There is a lower velocity antegrade flow during diastole. These findings are consistent with coarctation of the aorta (see Figure 6.4).

19. **C.** The hallmark of coarctation is the presence of persistent antegrade flow in diastole. The image is a pulsed Doppler spectral recording from the abdominal aorta consistent with coarctation of the aorta. The findings consistent with coarctation are a blunted or low-velocity systolic flow and persistent antegrade flow in diastole (absent retrograde flow). The presence of early diastolic reversal excludes significant coarctation. Other findings consistent with coarctation include a low systolic-to-diastolic velocity ratio, decreased pulsatility, and a prolonged pulse delay. Transthoracic subcostal view with pulsed Doppler in the abdominal aorta. A blunted or low-velocity systolic flow and persistent antegrade flow in diastole (absent retrograde flow) are specific features consistent with coarctation of the aorta (see Figure 6.5).

20. **C.** Balloon angioplasty with or without stents is generally recommended. The patient has severe recoarctation of the aorta after surgical repair. The choice of intervention for coarctation remains controversial and should be made in a center experienced with congenital heart disease among a team of surgical and interventional specialists. However, for recurrent coarctation after surgical repair, catheter intervention with or without stents is generally preferred if the anatomy is suitable. Favorable anatomy is a discrete, nontortuous short segment of narrowing without aneurysms, pseudoaneurysm, or hypoplasia of the aorta. Additional consideration should be given to women considering pregnancy where there is concern regarding the tissue fragility and risk of aortic complications with residual coarctation tissue. In that setting, surgery may be considered. Cardiac MR angiography. Sagittal oblique maximum intensity projection showing a discrete, short region of coarctation in the upper descending aorta without associated dilatation of the adjacent segments (see Figure 6.6).

21. **C.** Asymptomatic patient with a peak-to-peak gradient across the coarctation site of 15 mmHg with extensive collaterals. According to the American College of Cardiology (ACC)/American Heart Association (AHA) 2008 guidelines for adults with congenital heart disease intervention for coarctation of the aorta is recommended if (a) peak-to-peak gradient across the coarctation is ≤20 mmHg or (b) peak-to-peak gradient across the coarctation is <20 mmHg but there is anatomic evidence of severe obstruction and radiologic evidence of collateral flow. For the patient undergoing aortic valve replacement for bicuspid severe aortic regurgitation, the coarctation of the aorta should be reassessed after surgery to determine whether it is clinically significant.

22. **C.** Osteogenesis imperfecta. The patient has osteogenesis imperfecta, a heritable disease of the connective tissue with mutations in procollagen that are associated

with bone fragility (with multiple fractures), ocular changes (most notably blue sclerae), abnormal dentition, and hearing loss. Cardiovascular manifestations may occur and are similar to Marfan syndrome with aortic root dilatation, aortic regurgitation, and mitral valve prolapse.

23. **b.** Intravenous diltiazem. The initial management of aortic dissection is aimed at reduction in heart rate, BP, LV wall stress, and the force of LV contraction (d_p/d_t). The goals are a heart rate less than 60 bpm and BP less than 120 mmHg systolic. β-Blockers are the drug of choice if contraindications are not present. The patient described has severe COPD and therefore if a β-blocker is used it should be short-acting esmolol and not metoprolol. Otherwise, nondihydropyridine calcium-channel blocking agents such as diltiazem and verapamil are alternative options. Vasodilator therapy such as intravenous nitroprusside is contraindicated when initiated prior to atrioventricular blockade because of associated increase in reflex tachycardia, aortic wall stress, and LV force of contraction.

24. **d.** It is circumferential or crescentic. The CT demonstrates an intramural hematoma involving the descending aorta. The mechanism for intramural hematomas is thought due to rupture of the vasa vasorum in the media or small intimal tears. Typical features as seen by CT include the following: (a) absence of an intimal flap; (b) circumferential, focal, or crescentic appearance; (c) displacement of intimal calcium; and (d) high-attenuation thickening consistent with hematoma. Additional features that are seen by TEE include echolucent regions with flow consistent with intramural blood vessels.

Of note, the 2010 guidelines for thoracic aortic diseases state that intramural hematoma should be treated similar to aortic dissection in the corresponding segment of the aorta. Computed tomographic angiography axial image showing a descending thoracic aortic intramural hematoma. The intramural hematoma is evident given the circumferential appearance of high attenuation density of the aortic wall (see Figure 6.7).

25. **d.** TEE. A cardioembolic source of stroke is most likely given the territory of a middle cerebral artery event. The patient has a cholesterol level >300 suggestive of a heritable dyslipidemia and premature atherosclerosis and therefore aortic atheroma would be the most likely finding. A patent foramen ovale may be an alternative source of emboli in this young patient and would be the most likely etiology if the patient did not have a lipid disorder. Intracranial small-vessel disease detected by MRA would be less likely despite a dyslipidemic disorder. There is no information to suggest atrial fibrillation and therefore an event recorder would not likely be revealing.

26. **a.** Statin and aspirin. The TEE shows a large protruding sessile atheroma in the distal descending aorta/distal aortic arch. Treatment for aortic atheroma remains controversial. Antiplatelet therapies such as aspirin and statins are the mainstay of treatment. Systemic anticoagulation with warfarin or warfarin alternatives is unproven due to limited data. However, several observational reports particularly for aortic arch atheroma demonstrate resolution or reduction of large mobile thrombus/atheroma and embolic events in patients on warfarin. Transesophageal echocardiogram with a short-axis view of the upper descending aorta. A large sessile protruding atheromatous plaque is seen (see Figure 6.8).

27. **a.** 3-mm plaque with severe calcification and no mobile components. Predictors of embolic events in patients with aortic atheroma include (a) plaque thickness >4 mm, (b) mobile components, (c) ulceration, and (d) lack of calcification. Therefore, a smaller atheroma without mobile debris and with calcification is the least likely to be associated with an embolic event.

28. **b.** Alternative sites for cross-clamping or cannulation may reduce stroke risk. Alternative sites for cross-clamping and cannulation such as femoral and axillary arteries may reduce the risk of stroke in a patient with significant ascending aortic atheroma. Aortic arch endarterectomy has been found to increase the risk of perioperative stroke and is seldom recommended. Replacement of the ascending aorta is not generally recommended as a prophylactic measure to reduce the risk of stroke in patients with severe atheroma of the ascending aorta because of the additive surgical morbidity and mortality. Palpation of the aorta by the surgeon is usually not accurate in finding noncalcified atheroma that may be detected by TEE.

29. **d.** Williams syndrome. The physical examination findings are classic for supravalvular aortic stenosis, with a left-sided systolic ejection murmur (increase with expiration) heard best in the first right intercostal space, an increased intensity S_2/A_2 heart sound, increase in right-sided BP and pulses relative to the left side, and thrill in the suprasternal notch. Differential BP and pulses in the upper extremities is due to the Coanda effect with preferential deflection of blood flow toward the right brachiocephalic artery. Patent ductus arteriosus and severe coarctation of the aorta typically have continuous murmurs and would not typically have arm pulse differences. Supravalvular pulmonary stenosis would also not have pulse differences and the ejection murmur would decrease with expiration. Supravalvular aortic stenosis typically occurs in association with the Williams syndrome and associated mental retardation, and hypercalcemia. Supravalvular aortic stenosis is a form of aortopathy where obstruction occurs above the aortic sinuses usually at the sinotubular junction and is due to mutation in the elastin gene.

The obstructive aortopathy is due either to a fibrous diaphragm, hour-glass deformity, or diffuse hypoplasia of the aorta.

30. **c.** Right-sided aortic arch. The CXR (Fig. 6.9) shows a right-sided aortic arch with the aortic knob on the right side and absence of a left-sided aortic knob. A bovine aortic arch is an anatomic variant where the origin of the innominate artery and the left carotid artery arises from a common origin or the left carotid artery arises from the innominate artery. This variant occurs in approximately 13% of individuals and has no clinical significance. A cervical arch refers to the takeoff of the aortic branch vessels above the sternum into the soft tissues of the neck before turning downward to the descending aorta. It may present as a pulsatile mass in the neck or supraclavicular region and be associated with compressive symptoms and other vascular anomalies.

31. **a.** Tetralogy of Fallot. A right-sided aortic arch is most commonly associated with tetralogy of Fallot, particularly for the mirror image form. There are several types of right-sided aortic arch, but the mirror image and the non-mirror image variety are the most common. With the non-mirror image type, the order of branches from left to right are as follows: left carotid, right carotid, right subclavian, and left subclavian artery. The left (aberrant) subclavian artery arises from the descending aorta. The mirror image type is much more frequently associated with congenital anomalies than the non-mirror image type. Chest X-ray PA projection shows tracheal deviation to the left and round opacity on the right with absence of a distinct aortic knob on the left. This is most consistent with a right-sided arch (see Figure 6.9).

32. **a.** Aberrant left subclavian artery and diverticulum of Kommerell. Aortic arch anomalies may result in dysphagia, stridor, or wheezing associated with vascular rings that compress the esophagus or trachea. With the non-mirror image right aortic arch, the left subclavian artery arises from the right side and crosses posterior to the esophagus and trachea. This causes a vascular ring that may cause compressive symptoms. Aberrant vessels such as the left subclavian artery may arise from an aneurysmal segment called a diverticulum of Kommerell. An aberrant right subclavian artery may be an isolated anomaly in a normal left-sided aortic arch and is the most common aortic arch abnormality. Although generally asymptomatic, it may also be associated with a vascular ring.

33. **d.** 24-Hour Holter monitoring. CTA or MRA of the aorta is required to assess postoperative complications of prior coarctation repair. Complications include recoarctation and aneurysms in the ascending aorta, aortic arch, or descending aorta

in the region of the repair. In adults, a TTE does not adequately visualize the descending thoracic aorta, although gradients can be obtained to assess hemodynamic significance. Exercise-induced HTN may occur late after coarctation repair even among patients who are normotensive at rest and should be assessed for by exercise stress testing. TTE is important to assess the aortic valve and the possibility of a bicuspid valve, as well as associated structural abnormalities. Arrhythmias are an infrequent consequence of a corrected coarctation in an asymptomatic patient and therefore Holter monitoring is not necessary.

34. a. Generally every 5 years. The ACC/AHA 2008 guidelines for adults with congenital heart disease recommend at least a one-time CT or MR angiogram for repaired or unrepaired coarctation for complete evaluation of the thoracic aorta. In addition, follow-up should be performed at intervals of 5 years or less depending on the prior findings.

35. d. Observation only. Based on examination and echocardiography, the patient has mixed but predominantly severe congenital bicuspid aortic regurgitation. Holodiastolic flow reversal in the descending aorta is the key confirmatory finding supporting severe aortic regurgitation. The three murmurs described include the systolic murmur of bicuspid aortic stenosis and the diastolic murmurs of aortic regurgitation with the associated Austin Flint murmur. There are no clinical or echocardiographic indications for surgery based on aortic valve or aortic disease. β-blockers for aortic root dimensions >4.0 cm should generally be used only if severe aortic regurgitation is not present because of concern of increasing regurgitant volume and fraction with slower heart rates.

36. c. Aortic valve replacement and aortic graft. Surgery is indicated in this patient both for symptomatic aortic regurgitation and because of significant progression in aortic size. ACC/AHA valvular heart disease guidelines for bicuspid aortic valves recommend replacement of the aortic root or ascending aorta if the diameter is greater than 4.5 cm at the time of aortic valve replacement. Aortic valve repair can be performed successfully in select patients with bicuspid aortic regurgitation but is usually not performed when stenosis is present or if there are unfavorable anatomic findings such as calcification. Therefore, aortic valve replacement with either a mechanical or bioprosthetic valve is indicated along with an aortic graft. The aortic graft may incorporate the aortic root or may be in the supracoronary position.

37. b. Screening men >65 years old is associated with a reduction in aneurysm-related deaths compared with unscreened men of similar ages. Guidelines to screen for AAA vary among different governing bodies. The United States Preventive

Services Task Force (USPSTF) recommends one-time screening for any male former or present smoker between ages 65 and 75 years. They do not recommend screening in women based on the lower expected prevalence of AAA. Other vascular societies have less restrictive screening recommendations for men and women. However, screening in patients with first-degree relatives with AAA is recommended. Randomized controlled trials of ultrasound screening for AAA in predominantly men aged 65 to 75 years show a reduction in aneurysm-related mortality compared with unscreened age-matched controls. Ultrasound screening of at-risk patients in accredited laboratories is associated with sensitivities and specificities of over 90%, respectively. Repeat screening after a negative study is not recommended.

38. **c.** Inflammatory or infectious aneurysms should be repaired at any size. Two large trials of predominantly males showed that early elective AAA repair for aneurysms (4.0 to 5.5 cm) resulted in a similar mortality compared with medical therapy. Therefore, repair is generally indicated for asymptomatic AAA if (a) >5.5 cm; (b) increase in size ≤0.5 cm in 1 year; (c) inflammatory, traumatic, or infectious etiology; or (d) there is a family history of rupture. However, since AAAs may rupture at smaller sizes in women and smaller men, repair should be considered at 5.0 cm or even smaller in low-risk candidates for repair.

39. **b.** Open repair and EVAR are associated with similar long-term mortality. Endovascular repair of AAA is an alternative to open repair. Comparative trials including EVAR and DREAM have demonstrated a lower short-term morbidity and mortality (at 30 days) for EVAR compared with open repair. However, in long-term follow-up mortality was similar for the two procedures. EVAR is associated with more complications including endoleaks and need for repeat interventions and may require conversion to an open procedure.

40. **b.** Endoleaks may occur as a result of retrograde flow of small arterial branches back into the aneurysm sac. Endoleaks refer to the occurrence of repressurization of the excluded aneurysmal sac after an EVAR procedure. There are four main types: I—proximal or distal stent attachment site bleeding around the graft; II—leaking back into the sac from branch arterial vessels; III—mechanical failure of stent graft components; IV—leakage of blood through the graft material. Type II leaks are most common. Types I and III may require immediate reintervention, whereas type II can be monitored by repeat surveillance but may require repeat intervention if the aneurysm sac continues to expand.

41. **d.** CTA of the chest and aorta. The patient's history and examination has several

features suggestive of Ehlers-Danlos syndrome. Since she has a low pre- and posttest probability of coronary ischemia, a cardiac catheterization is not advisable. The vascular type of Ehlers-Danlos syndrome (type IV) is associated with spontaneous or iatrogenic arterial or organ rupture (e.g., rupture of gravid uterus or intestines). Aortic complications including dissection and rupture can occur and therefore arterial puncture is generally contraindicated. A CTA of the chest and aorta would exclude pathologies found in Ehlers-Danlos syndrome, including aortic and pulmonary aneurysm and dissection.

42. **b.** DNA sequencing. Diagnosis of Ehlers-Danlos type IV is generally made based on clinical and family history and DNA sequencing for the COL3A1 gene mutations. However, a negative test does not definitively rule out disease since not all causative mutations are known. A punch biopsy of the skin to obtain fibroblasts for culture and detection of defective type III collagen can also be performed.

43. **b.** Loeys-Dietz syndrome. Loeys-Dietz is an autosomal dominant genetic aortic aneurysm syndrome. It predominantly involves children and young adults with risk of rapid progression to aneurysms, arterial tortuosity, and dissection. It is associated with a bifid uvula (shown in Fig. 6.10), cleft palate, and hypertelorism. Other clinical findings similar to Marfan syndrome may be present. Cogan syndrome is a rare large-vessel vasculitis that involves the aorta and is associated with vestibular and ocular abnormalities including uveitis and keratitis. Ormond disease is an inflammatory form of aortitis associated with retroperitoneal fibrosis. Behçet disease is an instead of a arteritis associated with oral and genital ulcers and skin lesions. Image of the oropharynx of a young boy with Loeys-Dietz syndrome showing a bifid uvula (see Figure 6.10).

44. **b.** TGFBR1 or TGFBR2. The genetic defect associated with Loeys-Dietz syndrome is a mutation in transforming growth factor β-receptor, TGFBR1 or TGFBR2. Table 6.5 shows the most common gene mutations associated with aortic diseases.

TABLE 6-5 Most Common Mutations Associated with Aortic Diseases

Condition	Mutation
Marfan syndrome	FBN1
Loeys-Dietz syndrome	TGFBR1/TGFBR2
Ehlers-Danlos syndrome	COL3A1
Familial aortic aneurysms/dissections	ACTA2

45. C. Recommend aortic repair. Because of high risk of aortic dissection in patients with Loeys-Dietz, surgery is recommended at smaller aortic sizes. The 2010 guidelines for thoracic aortic diseases recommend aortic repair based on CTA or MRA for a dimension ≤4.4 cm.

46. C. Descending aortic partial transection with pseudoaneurysm. The patient experienced blunt cardiac trauma with injury to the aorta. This type of deceleration MVA as occurs with a head-to-head car collision may result in catastrophic aortic transection, rupture, or pseudoaneurysm. The typical site of injury occurs at the aortic isthmus (level of the ligamentum arteriosum or junction of the aortic arch and descending thoracic aorta) as a result of fixation of the aorta to the spine by intercostal arteries. The favorable hemodynamics in this patient are not suggestive of either aortic transection or cardiac tamponade. The preserved upper extremity BP and reduced perfusion in the lower extremities are suggestive of partial transection of the descending aorta with a pseudoaneurysm. The pseudoaneurysm is suggested by the widening of the mediastinum on CXR.

47. C. Medical therapy is recommended. Medical therapy should be recommended for this patient. The timing of surgery for descending thoracic aneurysms is addressed by the 2010 guidelines for thoracic aortic diseases. Most descending thoracic aneurysms or chronic dissections (not including thoracoabdominal aneurysms) that are of degenerative, traumatic, or connective tissue etiologies should be repaired when the size is >5.5 cm if comorbidity-related risks are acceptable.

48. C. TEVAR is associated with a 30-day risk of endoleaks of 10%. There are no randomized trials comparing TEVAR with open aortic repair. However, nonrandomized comparisons show a lower rate of hospital complications including paraplegia and death relative to open repair. Despite TEVAR patients generally being older with more comorbid conditions, long-term mortality seems similar. The

estimated rate of type I endoleaks with TEVAR is approximately 10% due to difficulties achieving an adequate proximal anastomosis.

49. d. Aortic root localized dissection. Localized staining of contrast dye is seen in the region of the right sinus of Valsalva. This finding is consistent with an iatrogenic localized dissection. In this patient, it is likely due to either catheter trauma or retrograde propagation of the RCA dissection into the corresponding sinus of Valsalva. Coronary dissection is commonly associated with fibromuscular dysplasia. Contrast aortogram with staining of contrast seen in the right sinus of Valsalva that occurred post MI and following percutaneous coronary stenting in a young woman with fibromuscular dysplasia and RCA dissection. Contrast aortogram with staining of contrast seen in the right sinus of Valsalva that occurred post MI and following percutaneous coronary stenting in a young woman with fibromuscular dysplasia and RCA dissection (see Figure 6.11).

50. a. Observation and medical therapy. Most localized iatrogenic intramural hematomas or dissections occurring in the cardiac catheterization laboratory can be observed and managed medically even when involving the ascending aorta. In general, the site of tear seals and propagation or expansion does not occur. However, repeat aortic imaging should be performed to confirm stability.

Peripheral Vascular Disease

Douglas E. Joseph • Hemantha K. Koduri

QUESTIONS

1. A 53-year-old man with a history of obesity, obstructive sleep apnea, hypertension, and hypercholesterolemia presents to the clinic complaining of a nonhealing ulcer on his left ankle present for the past month. His blood pressure is 160/78 mmHg. His physical examination is remarkable for mild bilateral lower leg edema as well as lipodermatosclerosis and hyperpigmentation around the ankles. A mildly tender, superficial ulceration is observed with an irregular pink base above his medial malleolus. His feet and toes are warm, pink, and have 2-second capillary refill and intact sensation. Laboratory tests on this patient include a random blood sugar of 160 mg/dL, creatinine of 1.1 mg/dL, calcium of 10.4 mg/dL, phosphorus of 4.4 mg/dL, and serum intact parathyroid hormone level of 50 pg/mL. What is the most likely etiology of the ulceration?

   a. Diabetes mellitus
   b. Chronic venous insufficiency
   c. Peripheral arterial disease (PAD)
   d. Calciphylaxis
   e. Brown recluse spider bite

2. A 49-year-old woman with a 60-pack per year history of smoking presents to the emergency department (ED) with complaints of constant, worsening right foot pain and tingling in the toes for several hours. She denies a history of trauma. On examination, she is in moderate distress from pain and has a regular cardiac rhythm at a rate of 104 bpm. Her right lower extremity has a palpable femoral pulse and cool, pale foot with nonpalpable pedal pulses. There is a faint dorsalis pedis arterial signal with continuous-wave handheld Doppler evaluation. Strength is intact in the foot and toes, but she reports pain during examination. What is the most

appropriate next step?

a. Admit to the hospital; begin a heparin infusion and antiplatelet therapy. Obtain an urgent echocardiogram to identify the source of embolism.
b. Obtain urgent ankle–brachial indices (ABIs) and pulse volume recordings to determine the severity of disease and begin aggressive risk-factor–modifying medical therapy.
c. Admit to the hospital for an urgent diagnostic abdominal aortogram with runoff and potential endovascular revascularization.
d. Admit to the hospital for pain control and obtain a lumbar magnetic resonance imaging to evaluate for lumbar canal stenosis and pseudoclaudication.
e. Obtain ABIs at rest and with exercise to assess for lower extremity PAD and a venous plethysmography of the lower extremities with exercise to evaluate for venous claudication.

3. A 65-year-old man presents with progressive, short-distance, intermittent claudication in his right leg and a declining ABI. He undergoes an abdominal aortic angiogram with runoff demonstrating a discrete 90% stenotic lesion of the superficial femoral artery. Percutaneous transluminal angioplasty followed by placement of a self-expanding nitinol mesh stent is performed with good post-procedural angiographic results. Which of the following is the most appropriate post-procedure surveillance program for this patient?

a. Regular visits with assessment for interval change in symptoms, vascular examination, and ABI measurement beginning in the immediate post-procedure period and at intervals for at least 2 years
b. Regular visits with assessment for interval change in symptoms, vascular examination, and arterial duplex at 1 month, 3 months, and at month 12
c. Regular visits with assessment for interval change in symptoms, vascular examination, and ABI measurement at 3 months, 6 months, 9 months, and at month 12
d. Regular visits with assessment for interval change in symptoms, vascular examination, and arterial duplex at 3 months, 6 months, 12 months, and 2 years
e. Annual visits with assessment for interval change in symptoms, vascular examination, ABI measurement, and arterial duplex

Case 1 (Questions 4 and 5)

A 59-year-old morbidly obese woman is admitted for cholecystectomy and postoperatively is placed on deep venous thrombosis (DVT) prophylaxis with mini-dose subcutaneous heparin. On hospital day 2, a peripherally inserted central venous catheter is placed in the right arm. The patient is discharged to a rehabilitation facility on hospital day 5 after removal of the venous catheter. Two days later she presents to

the emergency room with right upper extremity pain and swelling. She reports she has not felt well enough to participate with physical therapy since being discharged from the hospital. Venous duplex of the right arm demonstrates acute thrombosis of the right cephalic vein. Complete blood count (CBC) and chemistries are within normal range with a platelet count of 180 K/μL.

4. What is the most appropriate management of this patient?

   a. Admit to the hospital and start on intravenous (IV) anticoagulation with heparin or a direct thrombin inhibitor (DTI).
   b. Prescribe enoxaparin 1 mg/kg every 12 hours and coumadin. Admit for 4 to 5 days of overlap and discontinue enoxaparin once the international normalized ratio (INR) is within therapeutic range for 2 consecutive days. Continue anticoagulant therapy for 3 months.
   c. Prescribe enoxaparin 1 mg/kg every 12 hours and coumadin. Discharge with instructions for 4 to 5 days of overlap and discontinue enoxaparin once the INR is within therapeutic range for 2 consecutive days. Continue anticoagulant therapy for 6 months.
   d. Prescribe enoxaparin 1 mg/kg every 12 hours and coumadin. Discharge with instructions for 4 to 5 days of overlap and discontinue enoxaparin once the INR is within therapeutic range for 2 consecutive days. Continue anticoagulant therapy for 12 months.
   e. Warm compresses and nonsteroidal anti-inflammatory drugs for pain.

5. What should the target activated partial thromboplastin time (aPTT) be to achieve optimal efficacy and safety if anticoagulation with a DTI were to be initiated in this patient?

   a. An aPTT of 3.0 to 4.0 times the baseline value
   b. An aPTT of 2.5 to 3.0 times the baseline value
   d. An aPTT of 2.0 to 3.0 times the baseline value
   e. An aPTT of 1.5 to 2.0 times the baseline value

Case 2 (Questions 6 to 8)

A 15-year-old man presents to the clinic accompanied by his mother for evaluation of "red hands." He earned money last winter clearing sidewalks of snow and plans to do so again in the upcoming weeks. He reports developing red discoloration of his hands after returning home from the cold. The discoloration persisted for a few minutes until his hands were rewarmed. He denies weakness, paresthesia, pain, or skin lesions. He is otherwise healthy. At the time of consultation, inspection of his hands is unrevealing. Radial and ulnar pulses are 2+/2 bilaterally. The Allen test and reverse Allen test reveal return of color to the hands in 7 seconds bilaterally. His mother reports that she

and her mother both have Raynaud phenomenon. The patient's mother expresses concern that her son may have systemic lupus and she requests further testing.

6. What is the most likely diagnosis?

   a. Raynaud disease
   b. Raynaud phenomenon
   c. Normal physiologic cold response
   d. Acrocyanosis
   e. Thermal injury

7. Of the following, which is the most appropriate next step to objectively evaluate this patient?

   a. Obtain an upper extremity angiogram with selective imaging of the digital vessels and before and after administration of nitroglycerin.
   b. Obtain digital pulse volume recordings and transcutaneous partial pressure of oxygen measurements of the digits.
   c. Order a C-reactive protein level, erythrocyte sedimentation rate, and perform nailfold capillaroscopy.
   d. Order a C-reactive protein level, erythrocyte sedimentation rate, and plasma homocysteine level.
   e. Order antinuclear antibodies, erythrocyte sedimentation rate, and perform nailfold capillaroscopy.

8. When would be the most appropriate time to schedule a follow-up appointment?

   a. 5 years
   b. 3 years
   c. 2 years
   d. 1 year
   e. As needed

Case 3 (Questions 9 and 10)

A 49-year-old man presents to the clinic with complaints of progressive exertional dyspnea for several weeks. His speech is mildly breathless. Neck veins are distended bilaterally and there is moderate lower extremity edema. He denies chest pain. Electrocardiogram (ECG) shows sinus tachycardia without ST-segment abnormality. Physical examination reveals a parasternal heave and systolic ejection murmur. Past medical history is significant for splenectomy after a car accident several years ago.

9. Which of the following will most accurately confirm the underlying cause of this patient's symptoms?

a. Chest computed tomography (CT) with IV contrast
b. Transthoracic echocardiogram
c. Transesophageal echocardiogram
d. Pulmonary arteriogram
e. Ventilation–perfusion scan

10. Which of the following statements is most accurate concerning this patient's underlying diagnosis?

a. Inflammatory mechanisms have not been implicated in the pathogenesis.
b. Patients should be anticoagulated with a vitamin K antagonist and target INR of 2.5 to 3.5.
c. IV epoprostenol is an effective therapy in patients with advanced disease.
d. Inhaled iloprost has been demonstrated to improve exercise capacity.
e. Bosentan has been shown to improve exercise capacity in patients with mild-to-moderate liver disease.

11. You are consulted for recommendations regarding a deep vein thrombosis in a patient who is status post aortic valve replacement with a bioprosthetic valve 4 days prior. Earlier on the day of consult he complained of pain and was diagnosed with a partially occlusive left femoral vein thrombosis. His postoperative course has been otherwise uncomplicated. On examination, the patient is tender around the surgical site. There is moderate pitting edema in the legs bilaterally. He has palpable pulses in all extremities. What do you recommend?

a. Bolus subcutaneous low-molecular-weight heparin (LMWH) 80 mg/kg, then dose at 1 mg/kg subcutaneously every 12 hours
b. Placement of a retrievable inferior vena cava filter
c. Catheter-directed thrombolysis
d. Begin a DTI
e. Begin a weight-based unfractionated heparin infusion

12. A patient with a history of heparin-induced thrombocytopenia (HIT) 8 years ago presents to your office for preoperative evaluation for bioprosthetic aortic valve replacement and coronary artery bypass grafting. He requires anticoagulation while on cardiopulmonary bypass pump during surgery. A recent ELISA (enzyme-linked immunosorbent assay) antiplatelet factor-4 antibody test is negative (<0.400 optical density). He has had no subsequent heparin exposures over the last 8 years. What is the most appropriate anticoagulation regimen you should recommend for this patient?

a. Administration of IV fondaparinux intraoperatively with subsequent daily monitoring of platelet counts
b. Administration of IV LMWH intraoperatively with subsequent daily monitoring of platelet counts
c. Administration of IV argatroban intraoperatively with subsequent daily monitoring of platelet counts
d. Administration of IV hirudin intraoperatively with subsequent daily monitoring of platelet counts
e. Administration of IV unfractionated heparin intraoperatively with subsequent daily monitoring of platelet counts

13. A patient comes to your office 1 month after a hospital stay for gastric bypass surgery. She was diagnosed with a mesenteric vein thrombosis postoperatively. She denies a prior history of venous thromboembolism (VTE). She and her husband have questions about the duration of anticoagulant therapy. They bring copies of laboratory results showing she was checked for a hypercoagulable condition. One laboratory test indicates she is heterozygous for a mutation of the methylenetetrahydrofolate reductase (MTHFR) enzyme. All other laboratory tests are within normal range. She asks you how these results impact duration and intensity of anticoagulation. The most accurate reply is

a. all first-episode DVTs are treated similarly; thus, the discovery of this genetic mutation is of doubtful clinical significance.
b. given the clinical circumstances the laboratory finding is of doubtful clinical significance and you advise she should be anticoagulated with a vitamin K antagonist for 3 months with a target INR of 2.0 to 3.0.
c. she should be anticoagulated with a vitamin K antagonist for 3 months with an increased target INR of 2.5 to 3.5 because of increased thrombogenicity induced by the genetic mutation.
d. she should be anticoagulated with a vitamin K antagonist with a target INR of 2.0 to 3.0 for an extended duration of therapy to 6 months because of increased thrombogenicity induced by the genetic mutation.
e. she should be anticoagulated with a vitamin K antagonist with an INR target of 2.0 to 3.0 indefinitely because of the high rate of recurrent VTE associated with the heterozygous form of this genetic mutation.

14. A 34-year-old woman with a history of deep vein thrombosis who is chronically anticoagulated with warfarin discovers she is pregnant. Her due date is 34 weeks from now. Currently, she is on warfarin and has an INR of 2.2. She presents to the clinic for recommendations regarding her anticoagulation management. Which of the following is true regarding venous thromboembolic disease, anticoagulation

therapy, and pregnancy?

a. When deep vein thrombosis of the lower extremities complicates a pregnancy, the right leg is affected significantly more often than the left, presumably because of exaggeration of the compressive effects of the left iliac artery compressing on the right iliac vein during pregnancy.
b. The incidence of teratogenic complications of pregnancy caused by warfarin, including nasal hypoplasia and stippled epiphyses, is greatest if warfarin exposure occurs during weeks 14 through 24.
c. Warfarin is contraindicated in the nursing mother because of a high incidence of inducing an anticoagulant effect in the infant fed with breast milk from a mother on warfarin therapy.
d. Fatal pulmonary embolism is a leading cause of maternal mortality in the Western world.
e. LMWHs have been proven safe and efficacious in pregnant woman with prosthetic heart valves, and supplanted unfractionated heparin as the standard of care in this setting.

Case 4 (Questions 15 and 16)

A 65-year-old man presents to the clinic with complaints of episodic burning pain involving the soles of his feet and toes. He reports symptoms are most severe when the weather becomes hot and generally occurs when he is outside in the heat. His feet and toes turn red and feel hot to touch during episodes. When he returns to an air-conditioned area, symptoms begin to dissipate or some episodes may take hours for complete resolution. Elevating his legs relieves symptoms as does walking barefoot on cold tile floors. His past medical history includes hypertension, well controlled with atenolol, and he takes once daily low-dose aspirin for primary prevention.

Physical Examination

Blood pressure is 120/70 mmHg and pulse is 84 bpm.
The cardiac and lung examinations are normal.
The abdomen is soft and nontender with a normal-sized palpable aortic pulsation.
No bruit can be heard over the neck, abdomen, or either groin.
Radial, dorsalis pedis, and posterior tibial pulses are 2+/2 bilaterally.
A mild erythema and increased warmth are noted in toes and soles of the feet.

15. Which of the following is the most likely diagnosis?

a. Heat urticaria
b. Erythromelalgia
c. Chilblains (perniosis)
d. Raynaud phenomenon

16. What laboratory values should be followed serially in patients with this condition?

a. Electrolytes, blood urea nitrogen, and creatinine
b. Erythrocyte sedimentation rate
c. Ionic calcium
d. Complete blood count with differential (CBC with diff)

17. A 17-year-old boy was involved in a motor vehicle accident, which resulted in multiple fractures as well as internal injuries that necessitated multiple abdominal surgeries over a 2-week period. He is expected to recover fully. An intraluminal filling defect was incidentally identified consistent with DVT of the right external iliac vein on a contrast-enhanced abdominal CT scan. Anticoagulation was contraindicated because of a retroperitoneal hemorrhage. It was determined that placement of an inferior vena cava filter was necessary. Of the following types of filters, which filter is most appropriate in this case?

a. Bird's Nest vena cava filter
b. Gunther Tulip retrievable vena cava filter
c. TrapEase inferior vena cava filter
d. Greenfield vena cava filter
e. Simon Nitinol inferior vena cava filter

Case 5 (Question 18)

You are called to the bedside of a 68-year-old man in mild distress who underwent cardiac catheterization earlier in the day. He is complaining of increasing right groin pain. He complains of weakness and tingling in his foot and toes. He is presently on a heparin infusion because of atrial fibrillation. On inspection you note a large area of skin in his right groin and proximal thigh to be dark blue and there is a large, palpable, hard pulsatile mass. With ultrasound using color Doppler you note an irregular shaped area of flow measuring 4.0 cm × 3.3 cm near the common femoral artery, approximately 4.0-cm deep and connected to the artery by a 0.5-cm neck. There is surrounding hematoma observed. Spectral waveform analysis of the neck demonstrates a to-and-fro pattern.

18. What is the best treatment option for management of this patient's condition?

a. Placement of a femoral compression device overnight and analgesics for pain
b. Injection of thrombin by ultrasound guidance
c. Ultrasound-guided compression for 30 minutes
d. Surgical evacuation of the hematoma and suture repair of the artery
e. Placement of a compression dressing with snugly applied bandages around the leg and serial duplex scans to monitor for resolution

19. A 74-year-old man is in the ICU (intensive care unit) recovering from coronary artery bypass surgery and has developed a hemorrhagic pericardial effusion. He is currently stable, but has noted swelling and pain in his left leg. An ultrasound is ordered and reveals acute thrombus in the left peroneal vein. Which of the following is the best management option?

a. No action is required because calf vein thrombus is not clinically important
b. Pneumatic compression stockings and enoxaparin 40 mg every 24 hours
c. Follow up with serial duplex ultrasound scans
d. Initiate a continuous unfractionated heparin infusion
e. Proceed with placement of an inferior vena cava filter

Case 6 (Questions 20 and 21)

A 25-year-old man presents to the clinic with complaints of pain in his feet with walking. He reports this has been going on for several months and has progressively worsened in the past few weeks. He is beginning to develop symptoms in his right calf and earlier this week noticed a black area on his great toe. He has no medical problems, takes no medications, and is in good health overall. He is a smoker and works as a computer salesman. He reports a family history of VTE; his mother had a pulmonary embolism at the age of 50 and was diagnosed with the antiphospholipid antibody syndrome.

20. What is the most likely cause of his symptoms?

a. Elevated anticardiolipin antibodies
b. Thromboangiitis obliterans (TAO, Buerger disease)
c. Takayasu arteritis
d. Premature atherosclerosis
e. Livedoid vasculitis (atrophie blanche)

21. What is the most important aspect of therapy for this patient?

a. Anticoagulation with a vitamin K antagonist
b. Cessation of exposure to all forms of tobacco
c. Initiate immunosuppressive therapy with glucocorticoids
d. Antiplatelet therapy with aspirin
e. Admit to the hospital to begin tissue plasminogen activator therapy

Case 7 (Questions 22 and 23)

A 24-year-old woman presents with complaints of a swollen, painful left leg. She has a history of two episodes of deep vein thrombosis in the past. She recalls that they were both on the left side, but is unsure of which veins were involved. She was on warfarin in the past but discontinued it when she began attempting to conceive. Venous duplex

demonstrates an acute deep vein thrombosis of the left femoral vein. You initiate treatment with LMWH.

22. What is the most likely diagnosis?

a. Heterozygous prothrombin gene mutation
b. Heterozygous factor V Leiden mutation
c. May-Thurner syndrome
d. Klippel-Trenaunay syndrome
e. Klippel-Trenaunay-Weber syndrome

23. Which of the following is the best management option?

a. Indefinite anticoagulant therapy with warfarin
b. Indefinite monotherapy with enoxaparin
c. Venography for thrombus removal and stent placement
d. Placement of an inferior vena cava filter and discontinue anticoagulants
e. Anticoagulate with either warfarin or enoxaparin for 6 months

24. A 68-year-old gentleman underwent coronary artery bypass surgery using the saphenous vein harvested from his left leg. He has done well postoperatively except for failure of the left leg incision to heal completely. Four months after surgery, his leg is still not fully healed and a peri-incisional ulcer is now present. He has significant edema in his leg, which was present prior to surgery. There are no symptoms or physical findings suggestive of infection. His ABI is 0.94 on the right and 0.89 on the left. You order an ultrasound, which is negative for acute thrombus but does reveal significant venous valvular incompetence in the deep veins. Which of the following is most likely to improve this patient's wound healing?

a. Whirlpool therapy
b. Antibiotics and topical steroids
c. Compression stockings
d. Plastic surgery consult
e. Revascularization

25. You are providing postoperative care for a patient who is in the cardiovascular surgery postoperative ICU, status post coronary artery bypass surgery. A venous duplex ultrasound was performed to evaluate for new-onset bilateral leg swelling. Results are reported as negative for DVT, but with monophasic flow noted within the bilateral common femoral veins. Which of the following is the next best step?

a. CT venogram of the lower extremities

b. CT venogram of the abdomen and pelvis
c. Enoxaparin therapy 1 mg/kg subcutaneous injections every 12 hours
d. Enoxaparin therapy 40 mg subcutaneous injections every 24 hours

Case 8 (Questions 26 and 27)

A 39-year-old man presents to the ED with shortness of breath and tachycardia. He eventually develops hypotension with a systolic blood pressure of 80 mmHg. A stat CT scan of the chest reveals a saddle pulmonary embolism involving the main pulmonary artery trunk.

26. Which of the following is the next most appropriate step?

a. Begin an IV unfractionated heparin infusion at 18 U/kg/h
b. Begin alteplase 100 mg IV over 2 hours
c. Begin enoxaparin subcutaneous injections 1 mg/kg every 12 hours
d. Insert an inferior vena cava filter

27. Which of the following findings or laboratory values could be used to predict his prognosis?

a. C-reactive protein
b. Atrial arrhythmia
c. Left ventricular dysfunction
d. Prolonged QT interval
e. Elevated serum myoglobin

28. A 52-year-old man with metastatic prostate cancer has developed left lower extremity swelling. You order an ultrasound and a left acute external iliac deep vein thrombosis is visualized. You hospitalize the patient and his initial labs reveal hemoglobin 14.5 g/dL and creatinine 1.0 mg/dL. Which of the following treatment options is most appropriate?

a. Begin a weight-based unfractionated heparin infusion and bridge to warfarin.
b. Begin enoxaparin 1 mg/kg subcutaneous injections every 12 hours.
c. Place an inferior vena cava filter.
d. Begin unfractionated heparin 5,000 units subcutaneous injections every 8 hours.

29. A 55-year-old man is admitted to the hospital with upper gastrointestinal bleeding. He is transfused with 2 units of packed red blood cells and undergoes esophagogastroduodenoscopy. A bleeding gastric ulcer is discovered and treated with epinephrine injection. Several days into his admission he begins complaining of right calf discomfort. Venous duplex ultrasound is performed demonstrating acute deep vein thrombosis of the popliteal and posterior tibial veins. What is the

next appropriate step in the management of this patient?

a. No action is required because calf vein thrombus is not clinically important.
b. Pneumatic compression stockings and enoxaparin 40 mg every 24 hours.
c. Follow up with serial duplex ultrasound scans.
d. Initiate a continuous unfractionated heparin infusion.
e. Proceed with placement of an inferior vena cava filter.

30. A 58-year-old man presents to the clinic with a complaint of bilateral lower extremity cramping muscular pain with exertion relieved after a few minutes of rest. His medical history includes coronary artery disease status post left anterior descending artery stent 2 years ago, diabetes mellitus type 2, and essential hypertension. An ABI is performed in your office demonstrating a right ABI of 1.10 and left ABI of 1.04. What is the most appropriate next step in the evaluation of this patient?

a. Reassurance and suggest low-impact exercise, i.e., swimming
b. Referral to a peripheral vascular interventionalist for lower extremity angiogram
c. Order bilateral ABI measurements in the vascular laboratory at rest and following an exercise protocol
d. Order magnetic resonance imaging of the lumbosacral spine to confirm the likely diagnosis of pseudoclaudication
e. Have him return in 6 months and repeat the resting ABI measurements

31. A 68-year-old woman recently diagnosed with PAD presents to the clinic for follow-up. A fasting lipid profile obtained prior to the appointment demonstrates a low-density lipoprotein (LDL) level of 145 mg/dL. You decide to initiate therapy with a hydroxymethyl glutaryl coenzyme-A reductase inhibitor (statin). Which of the following LDL target levels is most appropriate?

a. Less than 150 mg/dL
b. Less than 130 mg/dL
c. Less than 100 mg/dL
d. Less than 50 mg/dL
e. There is no defined LDL target

32. A 52-year-old woman with a history of PAD, diabetes mellitus type 2, and active smoking presents to the clinic with a blood pressure of 150/95 mmHg. What blood pressure target should you recommend for this patient?

a. Less than 150/90 mmHg
b. Less than 140/90 mmHg
c. Less than 130/80 mmHg

d. Less than 120/75 mmHg
e. Less than 100/70 mmHg

33. For the above patient you decide to start her on a new antihypertensive medication. Which of the following class of medications are contraindicated?

a. β-Adrenergic blockers
b. Thiazide diuretics
c. Angiotensin-converting enzyme inhibitors
d. Angiotensin II receptor blockers
e. None of the above

Case 9 (Questions 34 and 35)

A 68-year-old man with a 30 pack-year history of smoking is seen in the clinic for follow-up after a non-ST-elevation myocardial infarction (NSTEMI). Because of his smoking history and age you order an ultrasound of his abdomen to rule out abdominal aortic aneurysm (AAA). He is discovered to have an infrarenal AAA measuring 5.0 cm × 4.9 cm.

34. After this initial baseline study, how often should you repeat the ultrasound of the abdomen?

a. Every 3 months
b. Every 3 to 6 months
c. Every 6 to 12 months
d. Every 12 months
e. Every 24 months

35. At what size measurement should you refer a patient for repair of an asymptomatic infrarenal AAA?

a. 4.0 to 5.0 cm
b. 4.5 to 5.0 cm
c. 5.0 to 5.4 cm
d. 5.5 cm or greater
e. 6 cm or greater

36. Which of the following population groups is it appropriate to do a screening ultrasound of the abdomen for an AAA?

a. Men >60 years of age with a first-degree relative with an AAA
b. Women >60 years of age with a first-degree relative with an AAA
c. Men 65 to 75 years of age with a smoking history

d. Women 65 to 75 years of age with a smoking history
e. All of the above groups are appropriate to screen for an AAA

Case 10 (Questions 37 and 38)

A 70-year-old man presents for follow-up in the clinic 1 month after undergoing right internal carotid artery stenting.

37. When should you get a post-procedure baseline carotid duplex ultrasound?

a. Four weeks after the intervention
b. Six weeks after the intervention
c. Two months after the intervention
d. Six months after the intervention
e. Twelve months after the intervention

38. A baseline carotid duplex ultrasound demonstrates patency of the stent and no evidence of residual stenosis or restenosis of the right internal carotid artery after the procedure. One year after the carotid intervention, how often is it recommended to perform repeat carotid ultrasound surveillance in an asymptomatic patient?

a. Every 6 months
b. Every 12 months
c. Every 18 months
d. Every 24 months
e. Every 36 months

Case 11 (Questions 39 to 42)

A 65-year-old man presents for a routine physical examination. During the interview he complains about swelling behind his right knee. You order an ultrasound of the area (findings illustrated in Fig. 7.1).

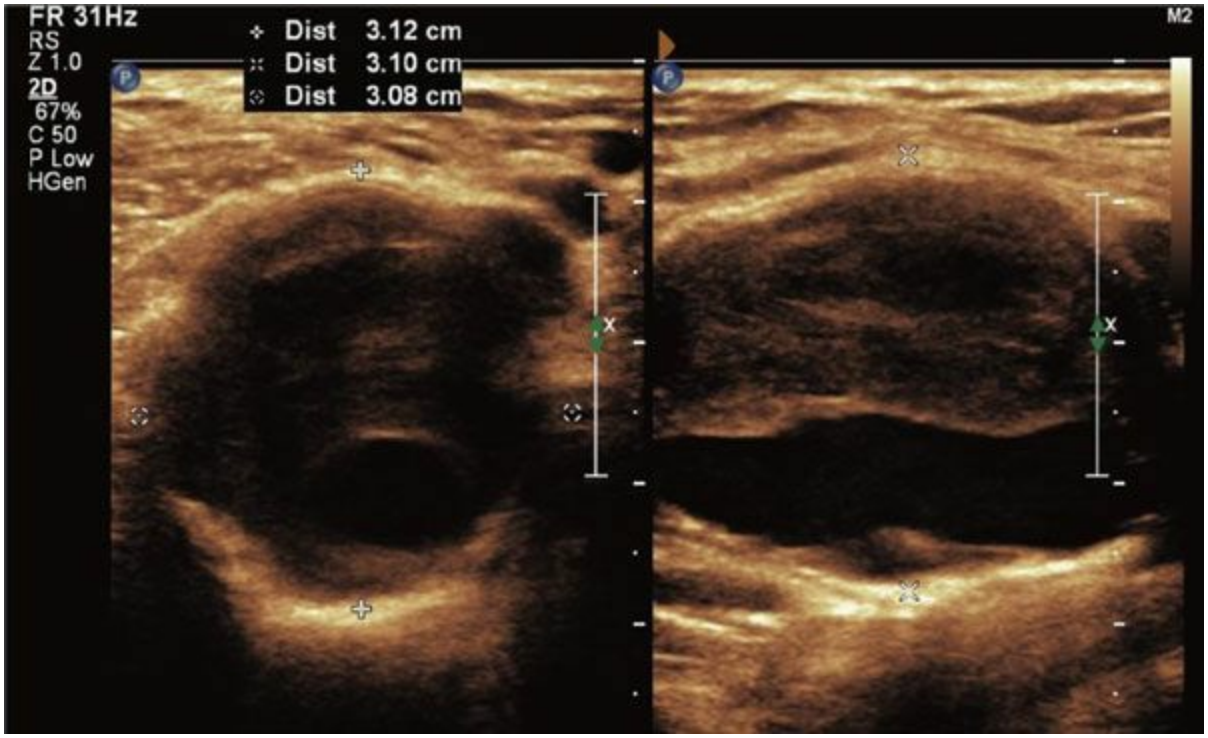

Figure 7.1

39. What is the most likely diagnosis?

- **a.** Abscess
- **b.** Baker cyst
- **c.** Popliteal artery aneurysm
- **d.** Enlarged lymph node
- **e.** Lipoma

40. What percentage of patients with a popliteal artery aneurysm have concomitant AAA?

- **a.** 10%
- **b.** 20%
- **c.** 40%
- **d.** 50%
- **e.** 60%

41. After finding the results illustrated in Figure 7.1 you refer the patient for ultrasound of the abdomen and contralateral popliteal artery. No additional abnormalities are discovered. What is the next appropriate step in his management?

- **a.** The finding is benign and no intervention is indicated.
- **b.** Repeat the ultrasound in 3 months.
- **c.** Repeat the ultrasound in 6 months.

d. Repeat the ultrasound in 1 year.
e. Refer for the repair of the aneurysm.

42. What is the most common complication of untreated, symptomatic popliteal artery aneurysms measuring more than 2.5 cm in greatest dimension?

a. Rupture
b. Thromboembolism
c. Infection
d. No complications
e. Popliteal vein thrombosis

43. During rounds in the telemetry unit you evaluate a 55-year-old woman 1 day after she underwent a left heart catheterization. She complains of right groin pain and swelling at the vascular access site. You order a duplex ultrasound of the right groin. Findings of the ultrasound are illustrated in Figure 7.2A and B. What is your diagnosis?

a. Hematoma
b. Arteriovenous fistula
c. Abscess
d. Pseudoaneurysm
e. Enlarged lymph node

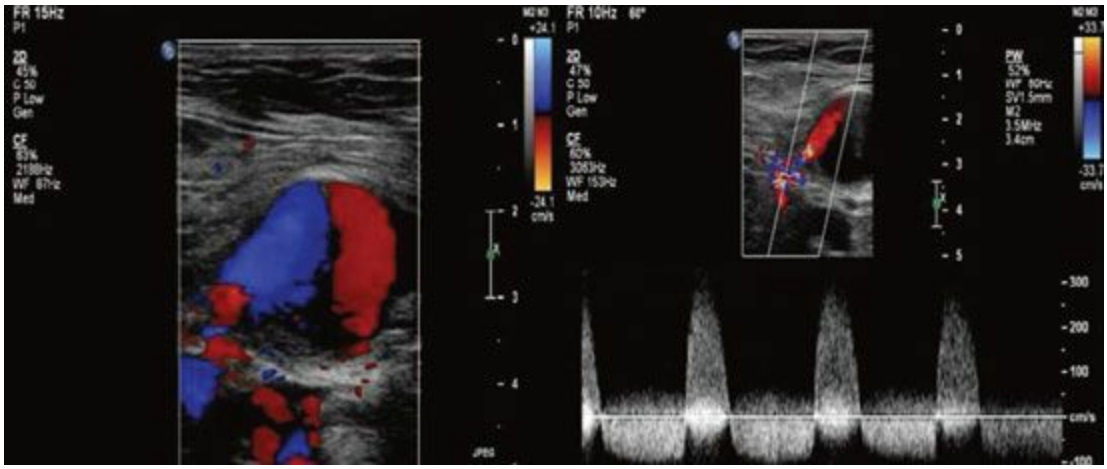

Figure 7.2

44. A 64-year-old woman presents to the clinic for evaluation prior to coronary artery bypass surgery. She underwent carotid duplex ultrasound demonstrating normal bilateral internal carotid arteries. Images from her scan are illustrated in Figure 7.3. What unexpected condition is demonstrated by her ultrasound images?

a. Subclavian artery aneurysm

b. Subclavian artery thrombosis
c. Subclavian artery stenosis
d. Subclavian vein thrombosis
e. Hematoma surrounding the subclavian artery

45. A 55-year-old woman with a history of deep vein thrombosis 2 months ago for which she was on warfarin was admitted to the hospital for chest pain. She underwent chest CT angiography which was negative for pulmonary embolism. She underwent a left heart catheterization after her INR normalized. During her procedure she received IV heparin. Her coronary arteries were free of disease. Following the procedure she was prescribed 10 mg of warfarin daily for 3 days. During this time her CBC was monitored and her hemoglobin and platelet counts showed minor fluctuations. A day later she developed a lesion on her abdomen illustrated in Figure 7.4. What is the likely cause of the skin lesion?

a. Heparin-induced skin necrosis
b. Vasculitis
c. Warfarin skin necrosis
d. Eczema
e. Allergic reaction

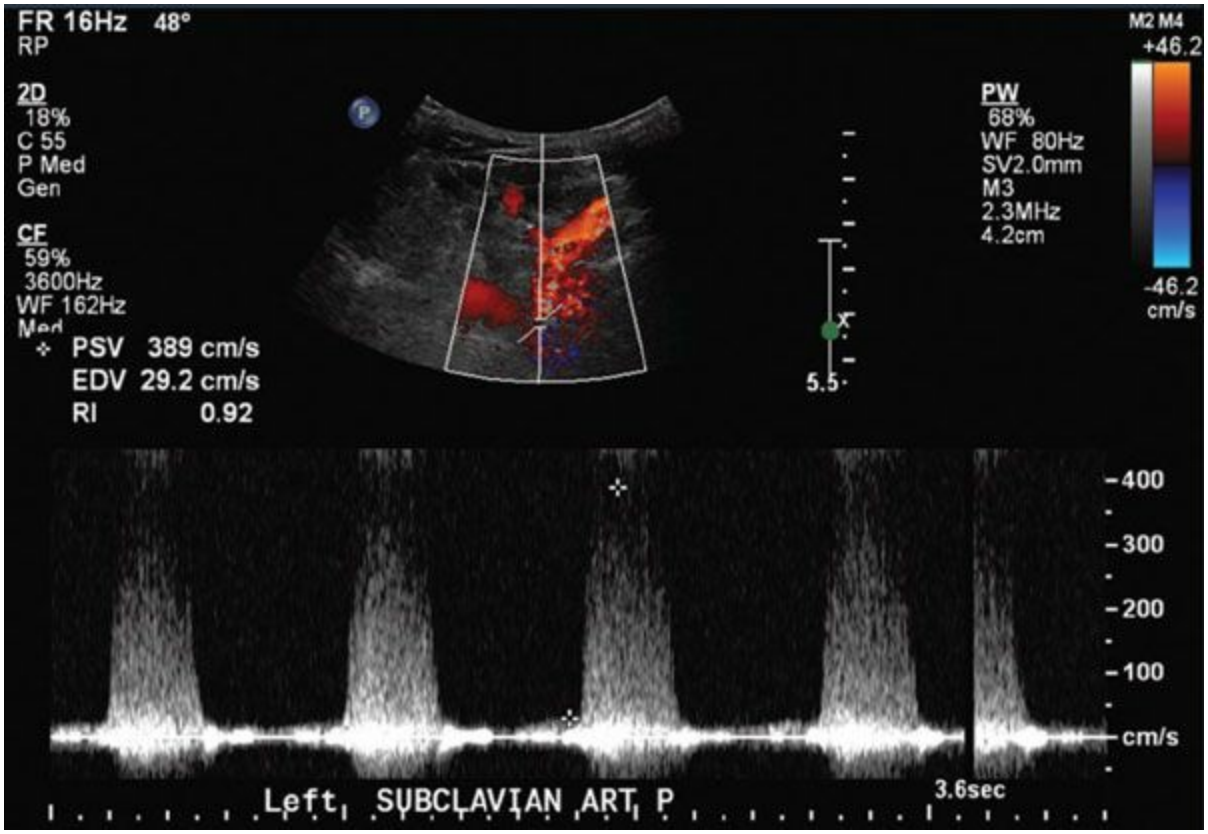

Figure 7.3

Figure 7.4

46. A 70-year-old man is admitted to the telemetry unit for workup of dizziness of 2 days' duration. He denies chest pain or shortness of breath. His heart rate is 60 bpm and blood pressure is 130/50 mmHg. On physical examination, a systolic murmur is heard over the left sternal border. Carotid duplex ultrasound is performed demonstrating the spectral waveforms of the bilateral internal carotid and vertebral arteries illustrated in Figure 7.5. Which of the following conditions is suggested by the carotid duplex waveforms?

a. Pulmonary valve stenosis
b. Systolic heart failure
c. Pericardial tamponade
d. Aortic valve stenosis
e. Mitral regurgitation

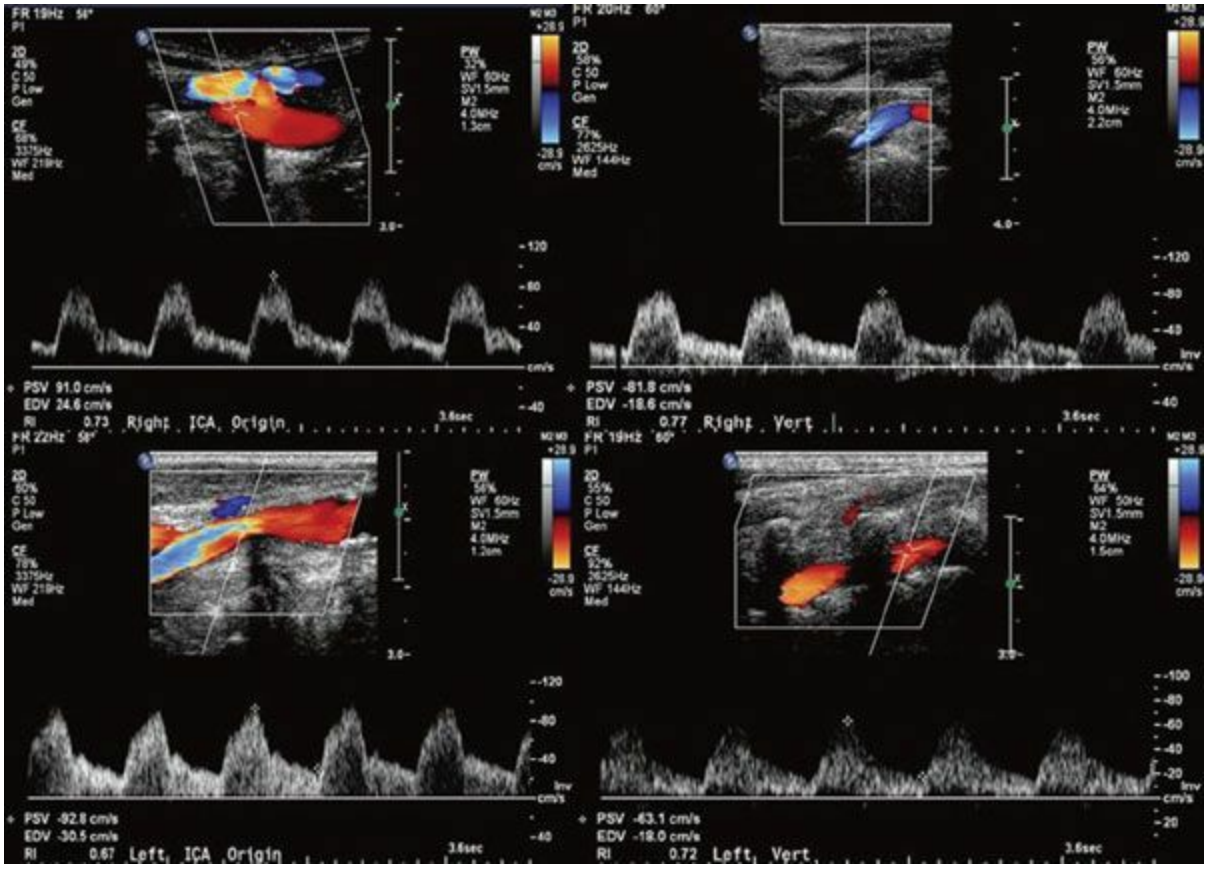

Figure 7.5

47. A 55-year-old woman presents to the ED with precordial chest discomfort and shortness of breath. Her body mass index is 34. Her medical history includes essential hypertension, diabetes mellitus type 2, and a 30 pack-year smoking history. Laboratory results include a troponin of 2.4 mg/mL and a B-type natriuretic peptide of 840 pg/mL. An ECG reveals no ST-segment elevation and nonspecific ST-T wave changes. The ED physician requests cardiology consultation for an NSTEMI. When you arrive to see the patient you order an IV contrast-enhanced chest CT scan of the lungs. Findings are demonstrated in Figure 7.6. What is the diagnosis?

a. Type A aortic dissection
b. Myocarditis
c. Pneumonia
d. Saddle pulmonary embolism
e. Interstitial lung fibrosis

48. Which of the following cardiovascular risk factor assessment tools has not been demonstrated to be useful in the risk assessment for a first atherosclerotic cardiovascular event?

a. High-sensitivity C-reactive protein
b. Coronary artery calcium score
c. Carotid intima-media thickness
d. ABI
e. Family history of premature coronary vascular disease

Figure 7.6

ANSWERS

1. **b.** Chronic venous insufficiency. This patient has no history of neuropathy and has intact sensation, making a neurotrophic ulcer often associated with diabetes unlikely. While his glucose is elevated, inadequate information is provided to make the diagnosis of diabetes mellitus. Bilateral leg edema, hyperpigmentation of the ankles, and the location of the ulcer over the medial malleolus ("gaiter distribution") are findings consistent with a venous stasis wound. Ulcers secondary to arterial disease are usually painful, involve the toes, and are well circumscribed. The information provided suggests adequate arterial supply. Wounds associated with calciphylaxis may be anywhere. They are usually very painful, involve large areas of skin, and are associated with black eschar formation. These wounds are most often seen in patients with renal impairment and hyperparathyroidism, neither of which is true in this case. Nothing in the clinical vignette is suggestive of a brown recluse spider bite.[11]

2. **c.** Admit to the hospital for an urgent diagnostic abdominal aortogram with runoff and potential endovascular revascularization. The patient described is suffering from acute critical limb ischemia. The hallmarks of acute limb ischemia are the five "P's", which are suggestive of impending tissue necrosis. They are pain, paralysis, paresthesia, pulseless, and pallor and some add poikilothermia (coldness) for a sixth "P." Our patient exhibits all but paralysis. Based on the Society for Vascular Surgery/International Society for Cardiovascular Surgery classification scheme for clinical categories of acute limb ischemia, her limb is marginally to intermediately threatened. Acute limb ischemia requires prompt diagnosis and intervention to avoid limb loss and life-threatening systemic illness resulting from tissue gangrene.[12]

3. **a.** Regular visits with assessment for interval change in symptoms, vascular examination, and ABI measurement beginning in the immediate post-procedure period and at intervals for at least 2 years. Unlike follow-up of autologous vein bypass grafts, well-established evidence-based guidelines for surveillance of post-endovascular revascularization patients do not exist. However, it is considered standard of care to evaluate these patients with interval history, examination, and measurement of the ABI regularly for at least 2 years after their percutaneous revascularization procedure.[13]

4. **e.** Warm compresses and nonsteroidal anti-inflammatory drugs for pain. Empiric anticoagulation, including outpatient anticoagulation, for superficial vein thrombosis is not routinely recommended. The clinical scenario may represent HIT and she should have a follow-up platelet count in 2 days. Her prior platelet counts from her recent hospitalization should be evaluated for a drop in platelets of ≥50% from baseline.[15]

5. **e.** An aPTT prolongation of 1.5 to 2.0 times the baseline value. Although the recommended range for therapeutic anticoagulation for VTE with a DTI is 1.5 to 2.5 times the baseline, which is not given as an option, published data indicate that anticoagulation with a DTI target aPTT of 1.5 to 2.0 times the baseline is just as efficacious and is associated with less bleeding risk.[16]

6. **c.** Normal physiologic cold response. This patient is exhibiting a normal response to prolonged exposure to cold. The diagnosis of Raynaud phenomenon is clinical and includes the presence of pallor or acrocyanosis and pain with cold exposure. Redness of the hands with warming after prolonged cold exposure, without concomitant pain, may be a normal response in a healthy young individual. He should be counseled to wear gloves and report any change in his symptoms, as his

family history does predispose him to development of Raynaud phenomenon.[17]

7. **e.** Order antinuclear antibodies, erythrocyte sedimentation rate, and perform nailfold capillaroscopy. If all these tests are normal, it is very unlikely that this patient has secondary Raynaud phenomenon and no further testing is necessary.[18]

8. **e.** As needed. Although the patient does not have Raynaud phenomenon, he should be encouraged to follow up as needed because of his family history. Patients who have primary Raynaud phenomenon should have clinical follow-up for a minimum of 2 years after diagnosis.[17]

9. **d.** Pulmonary arteriogram. An arteriogram is the test most likely to confirm pulmonary artery hypertension in this patient presenting with cor pulmonale, although a right heart catheterization is usually done first. This patient most likely has chronic thromboembolic pulmonary hypertension (CTEPH), a condition seen in otherwise healthy postsplenectomy patients. Other predisposing conditions include history of pulmonary embolism, myeloproliferative disorders, and chronic inflammatory conditions.[19]

10. **c.** IV epoprostenol is an effective therapy in patients with advanced disease. Patients with CTEPH may be bridged to pulmonary endarterectomy with IV epoprostenol. The other answers are incorrect. Anticoagulation with a vitamin K antagonist is indicated; however, the INR target of 2.0 to 3.0 is recommended. The Aerosolized Iloprost Randomization (AIR) study did not demonstrate improved exercise capacity with inhaled iloprost. Bosentan does improve exercise capacity and decreases pulmonary vascular resistance, but is not advocated for use in patients with moderate-to-severe hepatic dysfunction.[19]

11. **e.** Begin a weight-based unfractionated heparin infusion. Although LMWH may be appropriate as the initial anticoagulant of choice for the treatment of an acute DVT in the ambulatory as well as hospitalized patient, it does not require a bolus. In the setting of the postoperative state where rapid reversal of anticoagulation may be required, unfractionated heparin is favored. An inferior vena cava filter would be an appropriate recommendation if anticoagulation could not be administered at therapeutic levels. Thrombolytic therapy is contraindicated in the setting of recent open heart surgery. Use of a DTI is not indicated for routine anticoagulation.[22]

12. **e.** Administration of IV unfractionated heparin intraoperatively with subsequent daily monitoring of platelet counts. The nature of immune response to heparin is

anamnestic; this means a second exposure in the absence of positive antibodies is not associated with the development of a clinical hyperacute immune response. Perioperatively, heparin products should be avoided in patients with a history of HIT even with undetectable antiplatelet antibodies prior to cardiac surgery or vascular surgery. Nevertheless, heparin is favored over DTIs in cardiac and vascular surgery because of its reversibility and relative ease of use. Acute HIT is unlikely to occur even in patients who have a remote history of HIT as long as there has been no heparin exposure within the previous 100 days. This recommendation is based on expert opinion (level 1C) and not on randomized controlled trials.[15]

13. **b.** Given the clinical circumstances the laboratory finding is of doubtful clinical significance and you advise she should be anticoagulated with a vitamin K antagonist for 3 months with a target INR of 2.0 to 3.0. While the site of thrombosis is somewhat out of the ordinary, it was in the setting of abdominal surgery and was her first episode; therefore, a routine course of 3 months of anticoagulation with a vitamin K antagonist and an INR target of 2.0 to 3.0 is appropriate. All first-episode venous thrombotic events are not treated the same. Patients with malignancy-related thrombosis, idiopathic events, and those with certain thrombophilic conditions such as the antiphospholipid antibody syndrome require a longer duration of therapy relative to patients with transient risk factors for VTE. The MTHFR genetic mutation in the absence of hyperhomocysteinemia is not associated with increased risk of recurrence after discontinuation of anticoagulant therapy and has not been shown to increase thrombogenicity requiring a higher than usual INR target.[23]

14. **d.** Fatal pulmonary embolism is a leading cause of maternal mortality in the Western world. Thromboembolism is clearly the leading direct cause of maternal mortality according to the Seventh Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom. The May-Thurner syndrome involves compression of the left iliac vein by the right iliac artery. The greatest teratogenicity of warfarin is seen during weeks 6 through 12. Use of LMWH in pregnant women who have prosthetic heart valves is highly controversial and certainly not the standard of care.[24]

15. **b.** Erythromelalgia. The name of this condition is based on three Greek words: erythro meaning red, melos meaning extremity, and algos meaning pain. It is uncommon, affecting about 1 in 40,000. It may be primary or secondary. Primary erythromelalgia is usually bilateral, not associated with gangrene, and patients have normal pulses. Secondary erythromelalgia is often unilateral, can be associated with gangrene, and patients have variable pulses. Secondary erythromelalgia can be

associated with medications including bromocriptine, nifedipine, nicardipine, and verapamil. It may also herald the onset of a myeloproliferative disease such as polycythemia vera or essential thrombocythemia.[24]

16. **d.** Complete blood count with differential (CBC with diff). Patients with this condition should have a CBC with diff checked periodically for at least 2 to 3 years. It is important for treating physicians to recognize that erythromelalgia can precede the laboratory manifestations of a myeloproliferative disorder by up to 2 to 3 years.[28]

17. **b.** Gunther Tulip retrievable vena cava filter. This patient is young and his deep vein thrombosis is situational. He is expected to recover fully with no sequelae; thus he does not require placement of a permanent inferior vena cava filter. Proximal iliac thrombus in the setting of a hospitalized trauma patient following multiple abdominal surgeries is a very high-risk scenario for development of serious, life-threatening VTE. Anticoagulation is the treatment of choice when it can be safely administered; however, when contraindicated an inferior vena cava filter should be placed without delay. Patients with a temporary contraindication for anticoagulants should be reassessed at short intervals and, if circumstances permit, anticoagulants should be instituted for treatment of their VTE and to prevent recurrence. Of the filter types listed, only the Gunther Tulip is approved in the United States for retrieval. The OptEase is also approved for retrieval. The Bird's Nest filter is the only filter available for use in patients with a so-called megacava (vena cava greater than 28 mm). The Bird's Nest filter can be placed into an inferior vena cava of up to 42 mm in diameter. The TrapEase, Greenfield, and Simon Nitinol filters were not designed to have the option of retrieval.[25]

18. **d.** Surgical evacuation of the hematoma and suture repair of the artery. The patient complains of developing numbness in the setting of developing a large hematoma and pseudoaneurysm. To relieve the compressive effect of the hematoma, prevent irreversible injury, and relieve pain, the most appropriate method of repair in this patient is to evacuate the hematoma. Most small to moderately sized pseudoaneurysms can be treated with either ultrasound-guided compression, thrombin injection, or when very small may be observed for spontaneous resolution. Placement of a femoral compression device (Fem-Stop) is not appropriate in this setting, and bandages should not be wrapped proximally around the thigh as this will cause worsening swelling and pain.[26]

19. **c.** Follow up with serial duplex ultrasound scans. The peroneal vein is a calf vein with less propensity for clinically significant sequelae. Anticoagulant therapy for

calf vein DVT is controversial. However, in this setting there is a clear contraindication to anticoagulate. Even prophylactic doses of anticoagulants are not advisable in patients with hemorrhagic pericardial effusions status post open heart surgery. Serial ultrasound scans have been studied as an alternative to anticoagulant therapy. If no propagation after several weeks, no anticoagulant therapy is necessary. If propagation occurs, then anticoagulation versus placement of an inferior vena cava should be considered.[27]

20. **b.** Thromboangiitis obliterans (TAO, Buerger disease). TAO classically manifests in young, male patients with a recent history of heavy tobacco use. The clinical presentation is consistent with ischemia, beginning distally and involving the small- and medium-sized arteries. Usually the lower extremities are involved, with ischemia or claudication of the feet or legs. Foot or arch claudication is typical. Occasionally, the hands are involved. If the disease progresses with continued exposure to tobacco, patients are at significant risk for progressive ischemia, ulceration, gangrene, and eventually amputation. Antiphospholipid antibody syndrome is certainly possible, but it is not a hereditary condition and most often manifests with venous thrombosis. Takayasu arteritis does not usually present in this way. Nothing is suggestive of atrophie blanche, and premature atherosclerosis presenting in a 25-year-old man with claudication and ischemia would be highly unusual.[28]

21. **b.** Cessation of exposure to all forms of tobacco. The strong link between tobacco abuse and TAO is well recognized. There have been suggestions that some patients may demonstrate an abnormal sensitivity to a component of tobacco, which leads to small vessel occlusive disease. It has been shown that patients with TAO have higher tobacco consumption as well as higher carboxyhemoglobin levels than do patients with atherosclerosis.[28]

22. **c.** May-Thurner syndrome. Also known as iliac vein compression syndrome, Cockett syndrome, or iliocaval compression syndrome, May-Thurner syndrome is caused by compression of the left common iliac vein by the right common iliac artery and the underlying vertebral body. A history of chronic left lower extremity edema with or without the presence of DVT is suggestive of May-Thurner syndrome, especially in a female population. This phenomenon causes a partial obstruction caused by physical entrapment of the vein under the artery as well as by repetitive pulsatile force resulting in intimal hyperplasia of the vein. It has been estimated that this condition occurs in 2% to 5% of patients who are evaluated for lower extremity venous problems.[29]

23. **c.** Venography for thrombus removal and stent placement. May-Thurner syndrome is an anatomical anomaly that results in repeated venous trauma and often subsequent thrombus formation. Removal of thrombus followed by angioplasty, if needed, and placement of a stent is a potentially definitive treatment that could avoid the need for indefinite anticoagulant therapy in the young woman presented in this case.[29]

24. **c.** Compression stockings. The importance of edema control is often underestimated for wound healing. This patient has deep system venous reflux. He has no signs of infection complicating the healing of his incision, so antibiotics are unlikely to be helpful. Topical steroids offer no benefit in this case. His ABIs suggest adequate arterial inflow for wound healing. Whirlpool therapy is helpful in select cases, most often when multiple small wounds are present, which need cleansing and gentle debridement. Although the size of the wound is not clearly stated, these wounds are most often small and referral for skin grafting is not indicated.[30]

25. **b.** CT venogram of the abdomen and pelvis. Monophasic (loss of respiratory phasicity) flow is suggestive of proximal venous obstruction, especially in a patient with swollen limbs and under high-risk circumstances for VTE. Monophasicity is not specific to thrombosis. Other potential causes include obesity, pregnancy, and a pelvic mass. Respiratory or cardiac dysfunction may also produce an abnormal venous flow pattern.[31]

26. **b.** Begin alteplase 100 mg IV over 2 hours. The patient presented has a clinically massive pulmonary embolism with hemodynamic compromise; thus thrombolytic therapy is indicated.[32]

27. **b.** Atrial arrhythmia. There have been many laboratory, ECG, and echocardiogram findings shown to be predictive of mortality and prognosis. Right ventricular dysfunction, particularly when accompanied by hypotension, is predictive of pulmonary embolism–related hospital mortality. Elevated serum troponin and elevated brain natriuretic peptide have also been shown to predict an increased risk of death. Additional findings associated with a poorer prognosis include atrial arrhythmia, right bundle branch block, inferior Q waves and precordial T-wave inversions, and ST-segment changes. The other distracters have not been shown to predict prognosis.

28. **b.** Begin enoxaparin 1 mg/kg subcutaneous injections every 12 hours. Cancer patients are at a sixfold increased risk of developing VTE. Patients with active cancer make up about 20% of all new VTE diagnosed in the community. The risk, however, varies somewhat with cancer type, and those that incur a higher risk

include malignant brain tumors and adenocarcinoma of the ovary, pancreas, colon, stomach, lung, prostate, and kidney. Several studies have demonstrated a benefit to treatment with LMWH when compared with coumadin in this patient population. One study, which compared dalteparin with coumadin, reported 27 of 336 patients in the LMWH group had recurrent VTE when compared with 53 of 336 in the coumadin group in a 6-month follow-up period. There was no increased risk of bleeding in the LMWH group.[33,34]

29. **e.** Proceed with placement of an inferior vena cava filter. The patient has a proximal DVT with a contraindication for anticoagulation. This scenario represents an absolute indication for the placement of an inferior vena cava filter. Pneumatic compression stockings are indicated for the prevention of VTE but not for treatment. Serial duplex ultrasound scans may be an acceptable strategy for management of isolated acute calf vein thrombosis but not for proximal DVT. IV unfractionated heparin or enoxaparin 1 mg/kg subcutaneous injections would be appropriate treatment options if the patient did not have a recent gastrointestinal bleed requiring transfusion.[35]

30. **c.** Order bilateral ABI measurements in the vascular laboratory at rest and following an exercise protocol. The patient in the clinical vignette presented with classic intermittent claudication symptoms suggestive of PAD. A normal resting ABI does not rule out PAD in a patient presenting with ambulatory symptoms.[36] Performing the test following exercise often unmasks significant disease revealing markedly lower ABI values. Exercise may be an appropriate suggestion but it will not help to establish the diagnosis of this patient's presenting problem. It would be premature to refer this patient for intervention. Pseudoclaudication may present similarly, but this patient has risk factors for PAD; therefore, a post exercise ABI would be the most appropriate next step in their workup. Repeating the resting ABI in 6 months is not likely to provide new information.

31. **c.** Less than 100 mg/dL. The most recent practice guidelines for the management of PAD, updated in March 2013, recommend a target LDL of less than 100 mg/dL for patients with an established diagnosis of PAD.[36]

32. **c.** Less than 130/80 mmHg. The most recent practice guidelines for the management of PAD, updated in March 2013, recommend a target blood pressure of less than 140/90 mmHg for patients with PAD. The guidelines recommend a lower target, less than 130/80 mmHg, for patients with PAD and concomitant diabetes mellitus or renal insufficiency.[36]

33. **e.** None of the above. Thiazide diuretics, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, and β-adrenergic blockers are all acceptable medications to achieve blood pressure targets in patients with PAD.[36]

34. **c.** Every 6 to 12 months. According to the appropriate use criteria published by the intersocietal committee on peripheral vascular testing and the American College of Cardiology Foundation/American Heart Association practice guidelines for PAD, patients with an asymptomatic AAA measuring 4.0 to 5.4 cm should have surveillance imaging every 6 to 12 months in the first year.[36,37]

35. **d.** 5.5 cm or greater. The patient should be referred for repair once the infrarenal AAA reaches a diameter of 5.5 cm or greater due to an increased risk of spontaneous rupture.[36] Surveillance imaging is advised at regular intervals for aneurysms less than 5.5 cm.

36. **e.** All of the above groups are appropriate to screen for an AAA. According to the appropriate use criteria published by intersocietal committee on peripheral vascular testing all of the groups listed are appropriate for AAA screening.[37]

37. **a.** Four weeks after the intervention. All patients should get a baseline carotid duplex ultrasound within 4 weeks after a carotid artery stenting or endarterectomy procedure.[37]

38. **b.** Every 12 months. It is recommended to repeat carotid duplex ultrasound every 12 months after the first year following carotid artery stenting to assess for evidence of in-stent restenosis.[37]

39. **c.** Popliteal artery aneurysm. Shown is a transverse and longitudinal image of a large popliteal artery aneurysm containing mural thrombus. The appearance is not suggestive of an abscess, Baker cyst, lymph node, or lipoma.

40. **d.** 50%. A large number of patients with a popliteal artery aneurysm will also have an AAA. Furthermore, 50% of patients with a popliteal artery aneurysm will have an aneurysm of the contralateral popliteal artery.[38]

41. **e.** Refer for repair of the aneurysm. Popliteal artery aneurysms measuring greater than 2.5 cm are at risk for thrombosis, embolism, or rupture and therefore should be repaired.[36] Popliteal artery aneurysms measuring less than 2.5 cm are imaged at regular intervals.

42. **b.** Thromboembolism. Popliteal artery aneurysms most commonly cause thromboembolism that can lead to popliteal artery occlusion or painful distal embolic lesions. Rupture of popliteal artery aneurysms occurs infrequently.[38,39]

43. **d.** Pseudoaneurysm. The spectral Doppler waveform shown is a typical to-and-fro signal seen within the neck of the pseudoaneurysm. The incidence of pseudoaneurysm complicating percutaneous arterial procedures ranges between 0.2% and 0.5%. Patients typically present post catheter-based procedure with a painful pulsatile mass. When small these may resolve spontaneously, while others require intervention such as ultrasound-guided thrombin injection or surgical repair.[5]

44. **c.** Subclavian artery stenosis. Color Doppler imaging shows significant color aliasing, spectral broadening, and turbulent high-velocity flow within the subclavian artery. It is important to recognize severe subclavian artery stenosis prior to coronary artery bypass surgery in which the internal mammary artery may be utilized. Severe subclavian artery stenosis can lead to retrograde flow in the internal mammary artery predisposing to early graft failure. In an aneurysm usually the velocities are decreased.

45. **c.** Warfarin skin necrosis. Pictured is a large erythematous lesion with surrounding violaceous borders. Given the history of several days of high doses of warfarin without parental anticoagulation makes warfarin skin necrosis the most correct response. Heparin skin necrosis has been described but usually occurs at the site of subcutaneous injections.

    HIT can rarely be associated with necrotic skin lesions but in this case her platelets remained stable. A vasculitis can cause skin necrosis but is unlikely in the given scenario.

46. **d.** Aortic valve stenosis. The waveforms in the bilateral internal carotid and vertebral arteries have a Tardus-Parvus morphology. They have a blunted and slow upstroke, suggesting more proximal or central narrowing. In this patient, these findings along with a systolic murmur are suggestive of aortic valve stenosis.

47. **d.** Saddle pulmonary embolism. This patient has a pulmonary embolism involving both main pulmonary arteries. Massive and submassive pulmonary embolism can cause an increase in troponin and B-type natriuretic peptide as seen in acute myocardial infarction. The image shown illustrates a filling defect within the main pulmonary artery at the bifurcation. There are no findings suggestive of aortic

dissection, pneumonia, or interstitial fibrosis.

48. C. Carotid intima-media thickness. According to the latest American College of Cardiology/American Heart Association cardiovascular risk assessment guidelines, there is insufficient evidence available to recommend use of carotid intima-media thickness, ApoB, albuminuria, glomerular filtration rate, or cardiorespiratory fitness in cardiovascular risk assessment. There is adequate evidence to recommend use of high-sensitivity C-reactive protein, ABI, coronary artery calcium score, and a family history of premature cardiovascular disease for refinement of cardiovascular risk assessment.[40]

Congestive Heart Failure

Miriam S. Jacob • Gary S. Francis • Leslie Cho

QUESTIONS

1. Your patient is a 50-year-old woman with nonischemic cardiomyopathy who just received an orthotopic heart transplant. Which of the following is NOT important to help prevent transplant vasculopathy?

   a. Empirically starting statin therapy
   b. Strict control of hypertension (HTN) and diabetes
   c. Use of rapamycin as part of the immunosuppressive regimen
   d. Abstinence from smoking

2. You are taking care of a 65-year-old man with history of coronary artery disease and prior bypass surgery. He is currently taking carvedilol and lisinopril at maximum doses. He was recently hospitalized for heart failure 3 months ago. Which of the following criteria would make it reasonable to add eplerenone to his regimen?

   a. Ejection fraction (EF) of 15% with creatinine clearance of 20 mL/min/1.73 m^2
   b. EF of 20% and dyspnea while doing chores at home (New York Heart Association [NYHA] class II symptoms)
   c. EF of 35% with QRS >130 milliseconds
   d. EF of 45% and dyspnea with walking less than a block

3. For a patient with heart failure, coronary artery bypass grafting (CABG) is not reasonable for a patient with severe three-vessel coronary artery disease and

   a. chest pain on exertion.
   b. no viability found on dobutamine echo with EF of 15%.
   c. recent ST-elevation myocardial infarction (MI).
   d. heart failure with preserved EF.
   e. systolic heart failure with EF of 30% and viable myocardium.

4. A 60-year-old African American man comes to your clinic with few months' history of fatigue, dyspnea on exertion, and lower extremity edema. He has no history of prior coronary artery disease or heart failure. What features on an echo would not be consistent with amyloid heart disease?

   a. Presence of a pericardial effusion
   b. Biatrial enlargement
   c. Normal tissue Doppler measurement of the left ventricular (LV) lateral and septal walls
   d. LV hypertrophy
   e. Grade 3 diastolic dysfunction

5. Which of the following characterizes heart failure?

   a. Downregulation of β_1- and β_2-receptors
   b. Downregulation primarily of β_1-receptors with little change in β_2-receptors
   c. Downregulation of G proteins and β_1- and β_2-receptors
   d. Increase in myocardial norepinephrine stores
   e. Intact baroreceptor function

6. In the Veterans Administration Heart Failure Trial II (V-HeFT II), which combination of medications improved LV function and exercise tolerance?

   a. Angiotensin-converting enzyme (ACE) inhibitors
   b. Hydralazine plus nitrates
   c. ACE inhibitor plus hydralazine plus nitrates
   d. ACE inhibitor plus nitrates

7. A 56-year-old man presents to your clinic for follow-up after being discharged from the hospital 6 weeks ago. He underwent a successful primary angioplasty for acute anterior MI; however, his EF is now 40%. He is currently taking simvastatin (Zocor), acetylsalicylic aspirin, clopidogrel bisulfate (Plavix), metoprolol tartrate (Lopressor), and losartan (Cozaar). He states that he cannot afford all of these medications. He would like to know which medications are essential for a longer life. Which medications should you tell him are essential?

   a. All of them
   b. All of them except clopidogrel bisulfate
   c. All of them except losartan
   d. All except clopidogrel bisulfate and losartan

8. A 78-year-old woman with congestive heart failure (CHF) (EF, 25%), chronic atrial

fibrillation (AFib), gastroesophageal reflux disease, HTN, hyperlipidemia, diabetes, and osteoporosis takes 12 different pills. At the recent senior citizen day at the local church, a nurse told her that she does not need to take digoxin because she is on amiodarone. She wants to eliminate digoxin from her medication regimen, and she wants to know why you put her on it in the first place. What is your answer?

a. Digoxin improves survival.
b. Digoxin reduces hospitalization.
c. Digoxin improves contractility.
d. Digoxin decreases the volume of distribution of amiodarone.
e. Digoxin reduces sympathetic nervous system activity.

9. Recently, a 43-year-old lawyer received heart transplantation. His hospital course was unremarkable, and he was discharged. He found out from the heart failure nurses that allograft vasculopathy is the leading cause of long-term morbidity and mortality in transplant patients. He wants to know what proven treatments prevent allograft vasculopathy. Which of the following treatments should you recommend?

a. Annual cardiac catheterization, intravascular ultrasound, and percutaneous coronary intervention (PCI), as needed
b. Annual stress test
c. Biannual stress test
d. Statins
e. No known treatment

10. A 72-year-old woman is transferred from another hospital. She was initially admitted with palpitation, diagnosed with AFib, and treated with amiodarone. A transthoracic echocardiogram (TTE) showed an EF of 10% with a regional wall motion abnormality. She underwent cardiac catheterization and was found to have a heavily calcified 80% lesion in the mid–left anterior descending artery (LAD), a 40% lesion in a nondominant circumflex, and an 80% lesion in the posterior descending artery. Her children want to know what you plan to do for her. What should you recommend?

a. She has terrible EF and should be on medication only because CABG would be of too high risk.
b. She should undergo PCI because she is too high risk for CABG.
c. She should undergo CABG because this is the definitive treatment.
d. She should have a positron emission tomography (PET) scan to assess the area of viability before proceeding with CABG or PCI.

11. A 53-year-old woman with a history of CHF presents to the emergency room (ER). She is cool and clammy. She reports being short of breath. Her blood pressure (BP) is 71/40 mmHg, her heart rate (HR) is 110 bpm, and her respiratory rate is 30. She has elevated neck veins and a prominent S_3. Her echocardiogram (ECG) shows sinus tachycardia. She is admitted to the CCU (coronary care unit) with heart failure. A pulmonary artery (PA) catheterization is performed, and her hemodynamics are as follows: right atrial (RA) pressure, 12 mmHg; PA pressure, 62/30 mmHg; cardiac output, 1.9 L/min/m^2; pulmonary capillary wedge pressure (PCWP), 36 mmHg; and systemic vascular resistance (SVR), 2,000 dyne/s/cm^5. Which of the following is your next step?

a. Start furosemide (Lasix).
b. Start dopamine.
c. Insert intra-aortic balloon pump (IABP).
d. Begin dobutamine.
e. Start nesiritide.

12. This patient continues to deteriorate after your initial treatment. Her BP is 64/32 mmHg, and her HR is 132 bpm. She is now intubated on maximal pressor support and has an IABP in place. Which of the following should be your next therapeutic option?

a. There is no option. She is on maximal therapy.
b. Consider emergent cardiac transplant.
c. Consider LV assist device.
d. Consider cardiopulmonary bypass.

13. A 35-year-old man with a history of HTN presents to the ER in respiratory distress. He is intubated in the ER for respiratory distress. His BP is 73/48 mmHg, his HR is 130 bpm, and his respiratory rate is 20. He is taken to the medical ICU (intensive care unit), and a PA catheterization is performed. His hemodynamics are as follows: RA pressure, 22 mmHg; PA pressure, 20/10 mmHg; cardiac output, 3.5 L/min/m^2; PCWP, 12 mmHg; and SVR, 1,690 dyne/s/cm^5. What is your diagnosis?

a. Pulmonary embolism
b. Cardiogenic shock
c. Acute right ventricular (RV) failure
d. Decompensated heart failure
e. Hypovolemic shock

14. You receive a call from a cardiologist in a small community hospital regarding a patient in heart failure. She states that the patient was admitted last night with heart

failure and was started on intravenous (IV) nitroglycerin; IV furosemide infusion; captopril, 12.5 mg t.i.d.; and digoxin. There has been no improvement; therefore, the cardiologist placed a Swan-Ganz catheter this morning. The patient's hemodynamics are as follows: BP, 120/89 mmHg; HR, 89 bpm; cardiac output, 2.0 L/min/m^2; PCWP, 29 mmHg; and SVR, 1,766 dyne/s/cm^5. The cardiologist also added dobutamine. Which of the following additional therapies should you recommend to the cardiologist for this patient?

a. Begin patient transfer arrangement.
b. Suggest nitroprusside.
c. Suggest nesiritide.
d. Suggest dopamine.
e. Suggest IABP.

15. A 57-year-old woman, who experienced inferior wall MI in 1992, has an EF of 30% and was diagnosed with nonsustained ventricular tachycardia (VT) (four beats of VT) at another hospital on a routine ECG that she needed before cataract surgery. She has been in excellent health and has never been hospitalized for CHF. She has never had palpitation or syncopal episodes. Her doctors advised her that she would need an implantable defibrillator. She does not agree and wants a second opinion. She wants to know whether there is any evidence to support the implantable defibrillators. What is your advice?

a. Place an implantable defibrillator.
b. Do not place an implantable defibrillator: A single episode is probably insignificant.
c. Perform an electrophysiologic (EP) study.
d. Begin β-blockers with amiodarone.

16. A 49-year-old man is admitted with new-onset heart failure. He is diagnosed with dilated cardiomyopathy with an EF of 20%. On hospital day 1, he is diuresed and started on a regimen of furosemide, digoxin, acetylsalicylic aspirin, captopril, and simvastatin. A medical student wants to know why you did not start him on a β-blocker. What is your explanation?

a. β-Blockers have not been shown to decrease mortality in dilated cardiomyopathy patients. Only ischemic cardiomyopathy patients have derived benefit.
b. There have been several conflicting results from randomized trials; therefore, β-blockers are not recommended as the first line of therapy.
c. β-Blockers have been shown to improve survival but should only be used in patients with an EF greater than 25%.
d. β-Blockers should be started in stable CHF patients.

17. The same medical student wants to know whether the patient should also be started on calcium channel blockers. What is your answer?

a. There has never been a study to demonstrate the benefit of calcium channel blockers.
b. Diltiazem has proved to be of small but significant benefit in nonischemic cardiomyopathy patients and should be started.
c. Calcium channel blockers should be started after discharge once the patient has been stabilized.
d. Felodipine has proved to be of small benefit only in ischemic cardiomyopathy patients. This patient does not fit this criterion.
e. Amlodipine proved to be of small benefit in a NYHA class III or IV patient with an EF <30%. This benefit was seen more in dilated cardiomyopathy patients.

18. A 24-year-old female medical student presents to urgent care with 5 days of fever and shortness of breath. She is diagnosed with a viral infection and sent home. Five months later during her physical examination class, she is found to have an S_3 by her fellow students. She presents to your office for a second opinion. On examination, she appears healthy and in no distress. Her BP is 96/50 mmHg, with an HR of 71 bpm and a respiratory rate of 12. Her neck veins are not distended, and her examination is unremarkable except for an enlarged heart. You do not appreciate an S_3. You order a TTE, which shows an EF of 20% with a dilated heart. There is no valvular abnormality. Which of the following is your recommendation?

a. Begin ACE inhibitor, β-blockers, and steroid.
b. Begin ACE inhibitor and β-blockers.
c. Begin ACE inhibitor, β-blockers, diuretics, and digoxin.
d. Begin ACE inhibitor, β-blockers, diuretics, and spironolactone.
e. She is well compensated; nothing needs to be done.

19. A 79-year-old man with diabetes, HTN, chronic renal insufficiency, and ischemic cardiomyopathy was recently admitted with CHF exacerbation. At home, he takes captopril, 75 mg t.i.d.; digoxin, 0.125 mg per day; furosemide, 60 mg b.i.d.; aspirin; and atorvastatin calcium (Lipitor). When admitted, he was in heart failure with elevated neck veins and S_3. During his admission, he was diuresed with IV furosemide and metolazone. His baseline creatinine was 1.7 and now is 2.5, with blood urea nitrogen of 100. What is your next step?

a. Stop captopril.
b. Stop diuretics.
c. Rule out renal artery stenosis.

d. Stop aspirin and ACE inhibitor.

20. The severity of symptomatic exercise limitation in heart failure

a. is caused by elevated PCWP.
b. is caused by reduced blood flow to skeletal muscles.
c. bears little relation to the severity of LV dysfunction.
d. can be reversed by inotropic therapy.
e. is related to markers of central hemodynamic disturbance.

21. A 59-year-old woman with CHF and an EF of 30% comes to your office for follow-up. She is on carvedilol (Coreg), enalapril, aspirin, atorvastatin calcium, digoxin, and furosemide. She has been doing well without any rehospitalization. However, she wants to improve her exercise tolerance. What should you recommend?

a. Cardiac transplantation
b. IV dobutamine
c. Higher doses of ACE inhibitor
d. Adding spironolactone
e. Enrolling her in an exercise training program

22. Prognosis in heart failure correlates best with which of the following?

a. Peak $\dot{V}O_2$ during exercise
b. $\dot{V}_E/\dot{V}O_2$ slope during exercise
c. EF at rest
d. Blood gases during exercise
e. Myocardial contractility measurements

23. An 86-year-old woman is transferred from a nursing home in respiratory distress. She was found to be short of breath. On examination, she has labored breathing, and her BP is 62/34 mmHg with an HR of 60 bpm. She is intubated in the ER and admitted to the CCU. She is started on norepinephrine and dopamine at high doses without significant effect. Her ECG shows sinus bradycardia but is otherwise unremarkable. Her chest X-ray (CXR) shows pulmonary edema. The nursing home calls and says that she has mistakenly received 100 mg IV metoprolol tartrate. Which of the following should be your next step?

a. Glucagon and milrinone
b. Glucagon and dobutamine
c. IABP
d. Fluid resuscitation
e. Transvenous pacemaker

24. A 62-year-old man with an EF of 20% and chronic renal insufficiency presents to your office for follow-up. He has non-insulin-dependent diabetes mellitus and has developed worsening renal failure caused by diabetes. His medication regimen includes a β-blocker that is significantly affected by reduced renal function. Which of the following β-blockers is he taking?

a. Propranolol
b. Atenolol
c. Carvedilol
d. Metoprolol
e. Sotalol

25. A 38-year-old patient with CHF is transferred from another hospital. You are doing rounds in the CCU while the clinicians are performing a TTE. They ask you to assess his LV function. You notice that the E:A wave ratio is greater than 1.5, with an E-wave deceleration time of 120 milliseconds. Which of the following do you guess is his PCWP?

a. PCWP is 12 mmHg.
b. PCWP is 18 mmHg.
c. PCWP is 26 mmHg.
d. You cannot tell from the E:A wave ratio and deceleration time.

26. For the patient in the previous question, the E:A wave ratio and the E-wave deceleration time indicate which of the following?

a. Low filling pressure and reduced LV compliance
b. High filling pressure and increased LV compliance
c. Low filling pressure and increased LV compliance
d. High filling pressure and reduced LV compliance

27. A 67-year-old patient with HTN, hyperlipidemia, and an EF of 45% comes to your office for a second opinion. He had an exercise test and was told that his HR recovery was abnormal. His physician told him not to worry unless his heart function deteriorates. He is not convinced and wants your opinion and treatment. What should you recommend?

a. Abnormal HR recovery does not predict mortality in patients with an EF greater than 35%; therefore, no treatment is needed.
b. Abnormal HR recovery predicts mortality only in patients after MI; therefore, no treatment is needed.
c. Abnormal HR recovery predicts mortality in all patients; however, there is no

treatment.

d. Abnormal HR recovery predicts mortality in all patients, and exercise training is the treatment of choice.

28. A 41-year-old man presents to the CCU with CHF symptoms. On examination, he has elevated neck veins, severe peripheral edema, and S_3 gallop. He is started on medication and has improvement in all of his symptoms. He has a PET scan, which shows a large area of hibernating myocardium. His cardiac catheterization reveals mild disease in the right coronary artery, a focal 80% lesion in the circumflex, and a focal 70% lesion in the LAD. All of his lesions are type A American College of Cardiologists/American Heart Association score. His EF is 15%. According to randomized clinical trials, which of the following is the best treatment for this patient?

a. Percutaneous transluminal coronary angioplasty (PTCA)/stent with abciximab and clopidogrel bisulfate
b. PTCA/stent with cardiothoracic surgery backup
c. CABG
d. PTCA/stent with abciximab and IABP

29. A 28-year-old woman comes to your office for a second opinion. She had peripartum cardiomyopathy and wants to get pregnant again. You obtain a TTE, which shows a normal LV. What should you recommend?

a. She should not have another pregnancy because she is likely to have recurrent cardiomyopathy.
b. She may conceive again because her LV is normal. Her chance of having recurrent cardiomyopathy is less than 5%.
c. She may conceive again because her LV is normal. However, her chance of having recurrent cardiomyopathy is 30% to 50%.
d. She should undergo exercise testing for better assessment.

30. A 78-year-old retired federal judge comes to your office for follow-up. He has long-standing HTN and has undergone PTCA/stent for a mid-LAD lesion. He has normal LV function and is active and healthy. Currently he is on ramipril (Altace), atorvastatin, and aspirin. He heard on television that the combination of aspirin and ramipril increases mortality. He wants your opinion. What is your answer?

a. These are only observational studies, and they have not been proven. Continue the current regimen.
b. There are randomized studies to support this; however, the sample size was too small to make any conclusive recommendations. Continue the current regimen.

c. This has been shown in large trials; we should change aspirin to clopidogrel bisulfate or ramipril to metoprolol tartrate.
d. Although this has been seen in retrospective trials, it has not been validated in a randomized trial; therefore, continue the current regimen.

31. A 56-year-old man with dilated cardiomyopathy with an EF of 15% comes to your office for an opinion regarding medication. He is in NYHA class II and wants to know about biventricular pacing. He heard on television news that this may save lives. His ECG shows a sinus rate of 71, a PR interval of 210 milliseconds, a QRS duration of 188 milliseconds, and a QT/QT_C of 364:427 milliseconds. What should you recommend?

a. Refer the patient for biventricular pacing based on PR interval.
b. Refer the patient for biventricular pacing based on QRS duration.
c. Refer the patient for biventricular pacing based on QT/QT_C interval.
d. Refer the patient for exercise test to further assess.

32. A 31-year-old woman with hypertrophic cardiomyopathy presents to your office for follow-up. She has been doing well. She denies any palpitation or syncope. She has researched her disease on the Web and found out that most people die of arrhythmia. She would like to have an EP study. Which of the following is the predictive value of the EP study for ventricular arrhythmia?

a. 20%
b. 40%
c. 50%
d. 80%
e. 100%

33. A 61-year-old woman with an EF of 50% is admitted with an AFib with rapid ventricular response. She is started on metoprolol tartrate with excellent rate control and heparin. Her daughter, who is a nurse, wants to know why you did not start her on dofetilide because this is the best new drug. What is your response?

a. Dofetilide showed increased mortality when compared with amiodarone and would be a bad choice for her mother.
b. Dofetilide had safety and efficacy comparable to those of β-blockers.
c. Dofetilide was used in patients with an EF less than 35%.
d. Dofetilide has safety and efficacy comparable to those of calcium channel blockers.
e. Dofetilide is reserved for patients with chronic renal insufficiency.

34. A 79-year-old woman with HTN and non-insulin-dependent diabetes mellitus comes to your office for a second opinion. She is doing well and is currently on enalapril, aspirin, simvastatin, glipizide, and metformin. She read in her monthly American Association of Retired Persons newsletter that losartan is better than enalapril. She wants you to change her prescription. Based on trial data, which of the following is your recommendation?

a. Losartan did not show mortality benefit but did show reduced hospitalization; because she has no history of CHF, there is no reason to change her medication.
b. Losartan showed neither mortality benefit nor reduced hospitalization.
c. Losartan did not show mortality benefit but decreased the risk of MI; therefore, she should have her prescription changed.
d. Losartan did show mortality benefit, but only in patients younger than 60 years.

35. A 61-year-old woman with CHF and an EF of 25% is admitted with CHF exacerbation to your partner's service. On the day of discharge, your partner is sick, and you must explain her discharge medications. You explain to her the benefits of lisinopril, simvastatin, aspirin, digoxin, and furosemide. Finally, you want to explain the benefit of spironolactone (Aldactone) to her. What is your explanation?

a. Spironolactone in addition to standard therapy (ACE inhibitor, diuretic) does not decrease mortality or morbidity.
b. Spironolactone in addition to standard therapy only decreases rehospitalization —it does not improve NYHA functional class.
c. Spironolactone in addition to standard therapy decreases mortality and rehospitalization.
d. Spironolactone only benefits those not on standard therapy.

36. A 63-year-old man with non-insulin-dependent diabetes mellitus, HTN, hyperlipidemia, and chronic renal insufficiency is admitted with acute anterior wall MI 10 hours after symptom onset. He is taken emergently to the cardiac catheterization laboratory. He is noted to have proximal LAD occlusion, and he undergoes a successful PTCA/stent to the LAD with abciximab and heparin. His EF is noted to be 30% on a TTE performed 3 days later. On hospital day 4, he reports chest pain and is found to be in AFib with an HR of 121. His BP is 90/44 mmHg, and he is short of breath and anxious. Which of the following should you administer next?

a. Procainamide
b. Lidocaine
c. Amiodarone

d. Metoprolol tartrate
e. Cardioversion

37. An LV pressure–volume loop is shown in Figure 8.1. Label 1, 2, 3, and 4.

a. Mitral valve opening
b. End diastole
c. Aortic valve opening
d. End systole

38. A 57-year-old man with a history of CHF presents with acute pulmonary edema. His BP is 110/60 mmHg with an HR of 92 bpm. His examination is consistent with heart failure. His hemodynamics are as follows: PA pressure, 62/27 mmHg; PCWP, 12 mmHg; cardiac output, 1.8 L/min/m^2; and SVR, 1,968 dyne/s/cm^5. Which way should the LV pressure–volume loop be shifted?

a. To the right
b. To the left
c. Up
d. Down

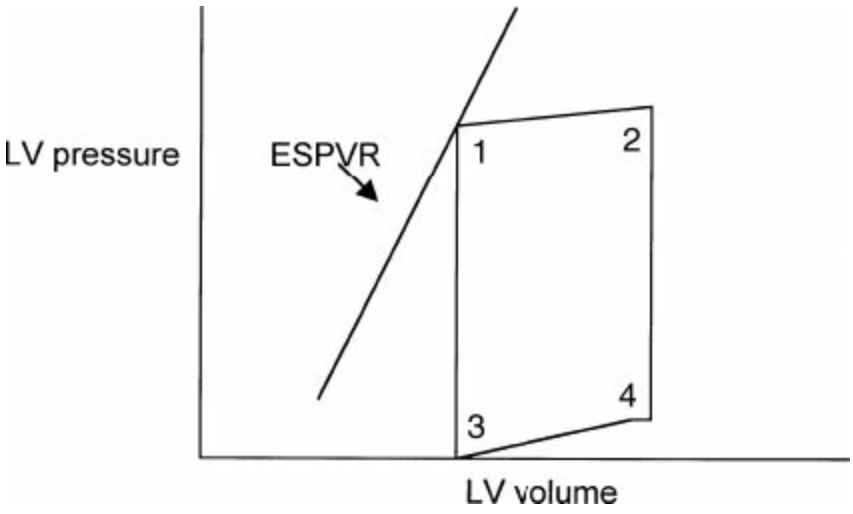

Figure 8.1 ESPVR, end-systolic pressure–volume relation (From Little WC, Braunwald E. Assessment of cardiac function. In: Braunwald E, ed. Heart Disease: A Textbook of Cardiovascular Medicine, 5th ed. Philadelphia, PA: WB Saunders; 1997, with permission.)

Questions 39 to 43

Figures 8.2, 8.3, 8.4, 8.5, and 8.6 are schematic illustrations of the carotid pulse. Match the diagnosis with the pulse.

a. Normal
b. Aortic stenosis
c. Aortic regurgitation

d. Hypertrophic cardiomyopathy
e. Severe CHF decompensation

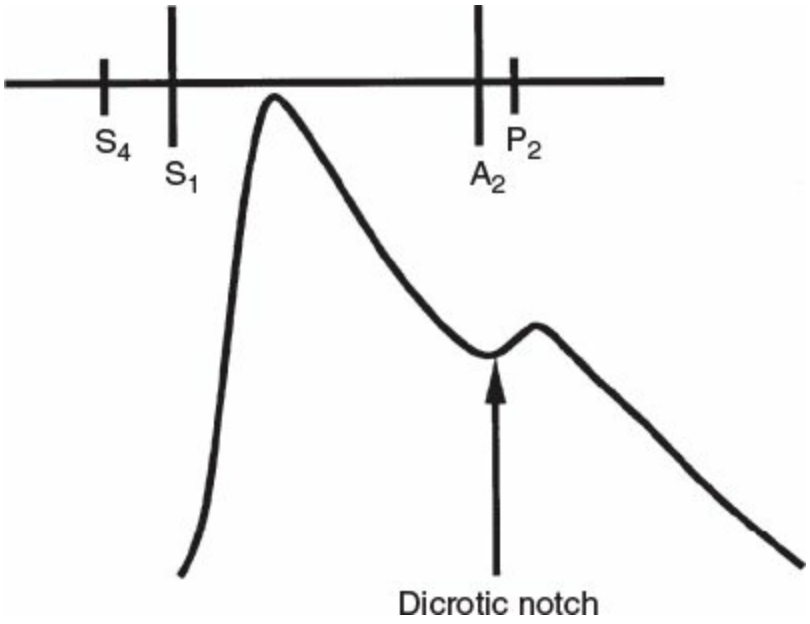

Figure 8.2 (From Chatterjee K. Physical examination. In: Topol EJ, ed. Textbook of Cardiovascular Medicine, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002: Fig. 15.2, with permission.)

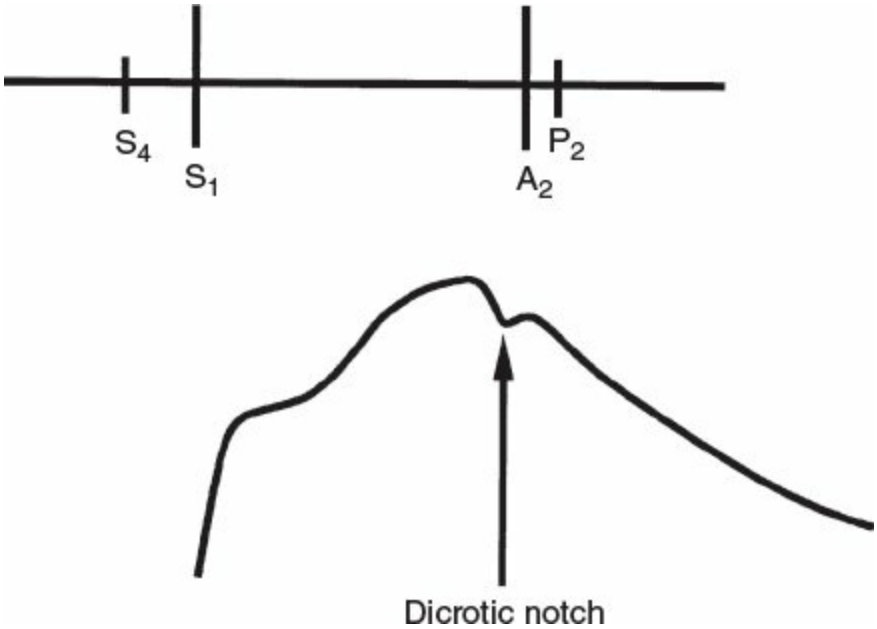

Figure 8.3 (From Chatterjee K. Physical examination. In: Topol EJ, ed. Textbook of Cardiovascular Medicine, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002: Fig. 15.2, with permission.)

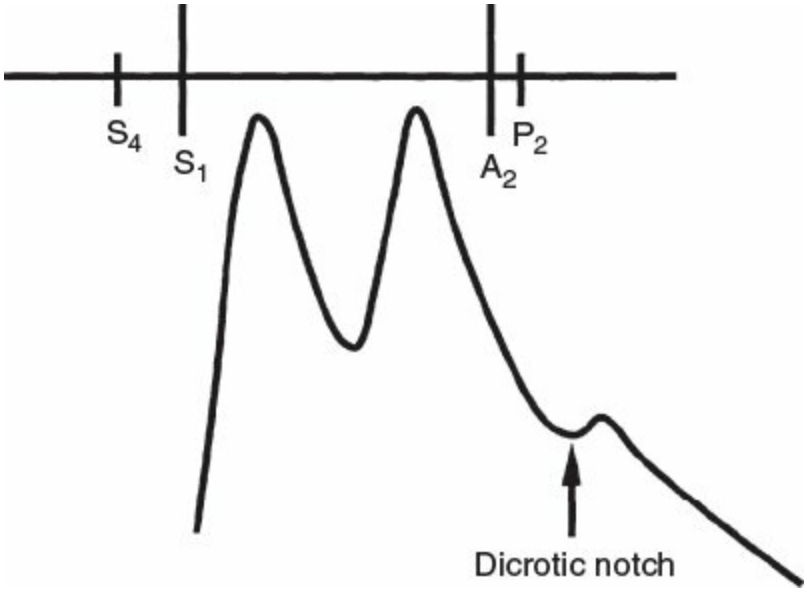

Figure 8.4 (From Chatterjee K. Physical examination. In: Topol EJ, ed. Textbook of Cardiovascular Medicine, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002: Fig. 15.2, with permission.)

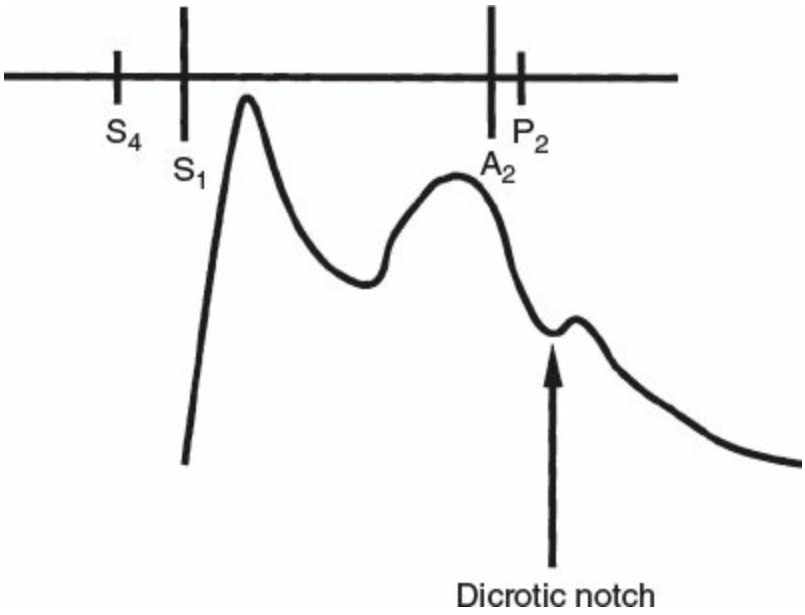

Figure 8.5 (From Chatterjee K. Physical examination. In: Topol EJ, ed. Textbook of Cardiovascular Medicine, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002: Fig. 15.2, with permission.)

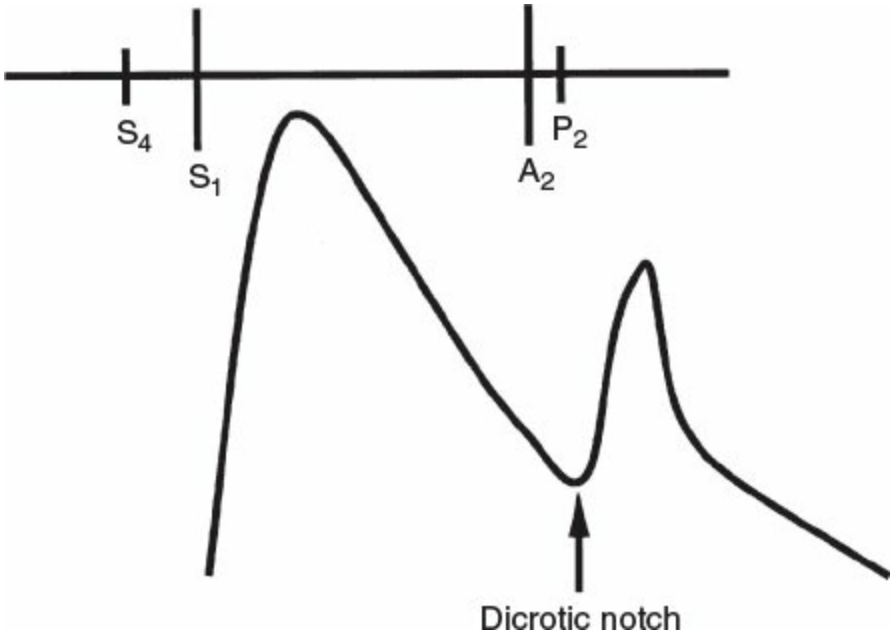

Figure 8.6 (From Chatterjee K. Physical examination. In: Topol EJ, ed. Textbook of Cardiovascular Medicine, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002: Fig. 15.2, with permission.)

44. During physical examination, you notice an elevated systemic venous pressure with sharp y-descent Kussmaul sign and quiet pericardium. What might the patient have?

a. Constrictive pericarditis
b. Restrictive myocardial disorder
c. Tricuspid regurgitation
d. Pulmonary HTN
e. Tamponade

45. During another physical examination, you notice a prominent v wave with a sharp y descent. What condition does the patient have?

a. Constrictive cardiomyopathy
b. Restrictive cardiomyopathy
c. Tricuspid regurgitation
d. Pulmonary HTN
e. Tamponade

46. Again you notice an elevated systemic venous pressure without obvious x or y descent and quiet precordium and pulsus paradoxus. What does the patient have?

a. Constrictive cardiomyopathy
b. Restrictive cardiomyopathy
c. Tricuspid regurgitation
d. Pulmonary HTN

e. Tamponade

ANSWERS

1. **c.** Use of rapamycin as part of the immunosuppressive regimen. Transplant vasculopathy is a possible complication after transplant that is best to be avoided. The recommended intervention is to control cardiovascular risk factors and start every patient on a statin. Once there is vasculopathy, proliferation signal inhibitors (PSIs) such as sirolimus and everolimus can be used (substituted for mycophenolate mofetil or azathioprine).

2. **b.** EF of 20% and dyspnea while doing chores at home (New York Heart Association [NYHA] class II symptoms). Based on the results of Emphasis-HF trial, patients with NYHA class II symptoms and EF <30% are eligible for adding eplerenone to their regimen if they were hospitalized in the last 6 months or had an elevated brain natriuretic peptide. This extended the patients who could be placed on an aldosterone blocker. Previous studies studied the benefit of spironolactone in patients with NYHA class IV symptoms in the last 6 months and EF ≤35% and eplerenone in patients 2 weeks post-MI with EF ≤40% and signs of heart failure. Aldosterone antagonists should not be used in patients with creatinine clearance <30 mL/min/1.73 m^2. EF or QRS alone are not enough to determine patients who would benefit. Functional class assessment is important.

3. **b.** No viability found on dobutamine echo with EF of 15%. The use of surgical revascularization of coronary disease and systolic heart failure is reasonable in patients with acute coronary syndrome and symptomatic angina. Although in the STITCH (Surgical Treatment for Ischemic Heart Failure) trial, a study of medical therapy versus CABG in patients with EF ≤35%, there was no difference in all-cause mortality, there was a suggestion of a trend toward patients with CABG having fewer hospitalizations for heart failure or death from cardiovascular causes. The choice of CABG in a patient with no viability and very low EF is unlikely to be successful in improving morbidity or mortality from heart failure.

4. **c.** Normal tissue Doppler measurement of the left ventricular (LV) lateral and septal walls. Patients with amyloid heart disease usually show restrictive pattern of diastology with low tissue Doppler of the LV myocardium.

5. **b.** Downregulation primarily of β_1-receptors with little change in β_2-receptors. In the cardiac myocyte, there are 3 adrenergic receptors (α_1, β_1, and β_2). In a normal heart

the predominant β receptor is β_1. In a failing heart there is selective down-regulation of β_1 receptors not β_2 receptors.

6. **b.** Hydralazine plus nitrates. In the V-HeFT II trial, although ACE inhibitors improved survival, it was hydralazine in combination with nitrates that had greater improvement in LV function and exercise tolerance.

7. **c.** All of them except losartan. There is no trial evidence that angiotensin II receptor blocker improved mortality in post-MI patients. The Studies of Left Ventricular Dysfunction (SOLVD) prevention used ACE inhibitors in patients with an EF less than 35%.

8. **b.** Digoxin reduces hospitalization. In the large Digitalis Investigation Group study, digitalis only improved hospitalization. It had no effect on survival.

9. **e.** No known treatment. Allograft vasculopathy is the leading cause of long-term morbidity and mortality for cardiac transplant patients. Routine cardiac catheterization has been advocated for these patients but has not shown survival benefit with revascularization. Statin therapy appears to improve long-term survival in these patients and should be used for all heart transplant patients. However, its effect on allograft vasculopathy is unknown.

10. **d.** She should have a positron emission tomography (PET) scan to assess the area of viability before proceeding with CABG or PCI. This patient is at high risk for any type of intervention because of her low EF. However, if there are areas of viability on the PET scan, her EF might improve with complete revascularization. Studies have consistently shown that patients with low EF do better with CABG than with PCI.

11. **b.** Start dopamine. This patient is in cardiogenic shock. She needs BP support before all else. In these patients, dopamine is the first line of choice, followed by norepinephrine. If there is no change with dopamine and norepinephrine, then dobutamine may be added while the patient is being prepared for IABP placement.

12. **c.** Consider LV assist device. This is a relatively young patient with no contraindication to cardiac transplant. However, in the current state, she is not eligible for transplantation. LV assist device as a bridge to transplant has been performed with success.

13. **c.** Acute right ventricular (RV) failure. His hemodynamic pressures are

characteristic of acute RV failure. He needs aggressive fluid resuscitation.

14. **b.** Suggest nitroprusside. This patient is in heart failure and needs to have her BP and SVR lowered. BP is adequate and does not need vasopressor or IABP support. Although nesiritide has been approved for use in acute heart failure, it only mildly lowers the BP.

15. **a.** Place an implantable defibrillator. She fits the criteria of the initial Multicenter Automatic Defibrillator Trial (MADIT). Therefore, based on randomized clinical trial data, she would benefit from an implantable defibrillator. Also, secondary prevention trials such as the Antiarrhythmics Versus Implantable Defibrillators Trial, the Canadian Implantable Defibrillator Study, and the Cardiac Arrest Study Hamburg trial also support an implantable defibrillator in this patient.

16. **d.** β-Blockers should be started in stable CHF patients. They should not be started when the patient is congested. Although nonselective agents with vasodilating effects may be preferred, this is not clear at this time.

17. **e.** Amlodipine proved to be of small benefit in a NYHA class III or IV patient with an EF <30%. This benefit was seen more in dilated cardiomyopathy patients. In the Prospective Randomized Amlodipine Survival Evaluation Trial, in which NYHA class III or IV patients with an EF less than 30% were enrolled, there was a statistically insignificant reduction in the combined mortality and morbidity in the amlodipine group. However, the benefit appeared to be greater in patients with nonischemic cardiomyopathy.

18. **b.** Begin ACE inhibitor and β-blockers. She has well-compensated cardiomyopathy. Only medication that prolongs her life needs to be started. She does not need medication for symptom relief; therefore, ACE inhibitor and β-blockers should be started.

19. **b.** Stop diuretics. This patient has prerenal azotemia caused by aggressive diuresis. His renal function should recover.

20. **c.** Bears little relation to the severity of LV dysfunction. Short-term administration of positive inotropic agents and vasodilators does not improve maximal exercise capacity in patients with CHF. Moreover, ACE inhibitors have failed to show consistent improvement in exercise tolerance. Numerous studies have not shown a correlation between LV function and exercise tolerance.

21. **e.** Enrolling her in an exercise training program. As stated, there is no medication that has consistently shown improvement in exercise tolerance; exercise training is the only method that has shown consistent improvement in these patients.

22. **b.** $\dot{V}_E/\dot{V}O_2$ slope during exercise. This is the best correlate of prognosis. There is a higher ventilation for any given CO_2 production ($\dot{V}_E/\dot{V}O_2$ slope), which reflects the severity of heart failure and prognosis.

23. **a.** Glucagon and milrinone. Milrinone is a second-generation phosphodiesterase inhibitor. It has no β-effect; therefore, it is an ideal vasopressor in the setting of β-blocker overdose. Although a pacer is a good idea and should be placed, giving medication is faster and should be instituted first.

24. **b.** Atenolol. Atenolol is most affected by reduced renal function. Depending on how severe his creatinine clearance is, he should have his medication dose or frequency adjusted.

25. **c.** PCWP is 26 mmHg. Restrictive mitral inflow pattern in the presence of a short E-wave deceleration time has been shown to correlate with high pulmonary capillary pressure, impaired functional class, and bad prognosis in postinfarction patients.

26. **d.** High filling pressure and reduced LV compliance. These conditions are indicated by a restrictive mitral inflow pattern with short E-wave deceleration time.

27. **c.** Abnormal HR recovery predicts mortality in all patients; however, there is no treatment. A delayed decrease in HR after exercise or an abnormal HR recovery predicts all-cause mortality in healthy adults and in patients referred for exercise testing—independent of ischemia. However, at this time, there is no treatment to improve abnormal HR recovery.

28. **c.** CABG. This patient has left main trunk equivalent with low EF. He is a candidate for CABG with left internal mammary artery to the LAD. CABG will prolong his long-term survival compared with PTCA/stent.

29. **d.** She should undergo exercise testing for better assessment. Recurrent peripartum cardiomyopathy occurs in 20% of patients with normal resting LV function but abnormal stress ventricular response. Recurrent peripartum cardiomyopathy with decompensation occurred in 41% of patients with abnormal resting LV function.

30. **d.** Although this has been seen in retrospective trials, it has not been validated in a

randomized trial; therefore, continue the current regimen. In a substudy done by the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico, aspirin did not decrease the mortality benefit of lisinopril after MI or increase the risk of adverse clinical events. There have been some retrospective studies to assess this question that have had conflicting results; therefore, it is best to stay with the current regimen.

31. **b.** Refer the patient for biventricular pacing based on QRS duration. Patients with QRS duration greater than 150 to 160 milliseconds derived the greatest benefit from biventricular pacing.

32. **a.** 20%. There is no role for routine EP study in the asymptomatic hypertrophic cardiomyopathy patient.

33. **c.** Dofetilide was used in patients with an EF less than 35%. The study compared dofetilide with amiodarone. Dofetilide did not increase mortality. It has not been studied against β-blockers or calcium channel blockers in patients with normal EF.

34. **b.** Losartan showed neither mortality benefit nor reduced hospitalization. In the large Evaluation of Losartan in the Elderly II study, losartan did not show mortality benefit or reduced hospitalization. Losartan was better tolerated than captopril. Because the patient has no side effects with enalapril, her prescription should not be changed.

35. **c.** Spironolactone in addition to standard therapy decreases mortality and rehospitalization. In the Randomized Aldactone Evaluation Study, patients with NYHA class III or IV with an EF less than 35% had improvement in mortality, reduction in hospitalization, and improvement in functional class when spironolactone was taken in addition to standard therapy (ACE inhibitor and diuretic).

36. **e.** Cardioversion. This patient has post-MI AFib. He has LV dysfunction and renal insufficiency. Procainamide should be used in patients with normal LV and renal clearance. Amiodarone would take too long to work, and he is already in distress. Lidocaine is not used in AFib. Metoprolol tartrate would exacerbate his heart failure; therefore, cardioversion is the only choice.

37. An LV pressure–volume loop.

a.= 1. Mitral valve opening
b.= 2. End diastole

c.= 3. Aortic valve opening
d.= 4. End systole

38. **c.** Up. The response of the LV to increased afterload is to shift the loop up. Increased preload would shift the loop to the right.

39. **a.** Normal. The initial peak of the carotid puse waveform reflects the ejection of the blood from the LV into the aorta before it goes into the periphery. After the pressure peaks, it begins a decline as ejection slows and blood continues to flow to the periphery. There is a reversal of blood flow from the compliant central arteries back toward the ventricle. With this reversal of flow, the aortic valves close. A notch on the descending limb of the aortic pressure curve is associated with this transient reversal of blood flow. The smaller secondary positive wave is attributed to the elastic recoil of the aorta and aortic valve.

40. **b.** Aortic stenosis. Pulsus parvus et tardus which is characteristic of aortic stenosis. Small and delayed carotid pulse.

41. **c.** Aortic regurgitation. Pulsus bisferiens or bifid arterial pulse.

42. **d.** Hypertrophic cardiomyopathy. This can also be characterized by a bisferiens carotid pulse with rapid fall in first wave with rapid rise of the second.

43. **e.** Severe CHF decompensation. Demonstrates the dicrotic pulse which can occur in diastole in patients with low stroke volume being ejected. This can occur in severe heart failure, cardiac tamponade, and hypovolemic shock.

44. **a.** Constrictive pericarditis. The high initial venous wave (a wave) is characteristic of atrial contraction. The rapid y descent is suggestive of rapid ventricular filling.

45. **c.** Tricuspid regurgitation. The v wave is a reflection of ventricular contraction and the pressure that is transmitted back to the atrium from a tricuspid valve that pushes back into the atrium. In the tricuspid regurgitation, there is increased pressure during ventricular systole.

46. **e.** Tamponade. There is constant pressure from the pericardium that does not allow for atrial relaxation so the y descent is blunted.

Adult Congenital Heart Disease

Luke J. Burchill

Adult Congenital Heart Disease Source Material

Published guidelines for the management of adult congenital heart disease (ACHD) patients provide an excellent overview of ACHD and are a rich source of questions for the cardiology boards.[1–5] The questions in this section relate directly to existing guidelines for the care of ACHD patients, with particular emphasis given to the American Heart Association (AHA) guidelines.

QUESTIONS

1. A 55-year-old woman with a history of unrepaired ventricular septal defect (VSD) and Eisenmenger physiology presents to your clinic. Her most recent hemoglobin measured 17.5 g/dL (11.5 to 15.0), hematocrit 55% (36 to 46), mean corpuscular volume (MCV) 76 (83 to 99), and platelet count 140 × 10^3 cells/μL (150 to 400). She reports New York Heart Association class III limitations with increasing fatigue and infrequent headaches over the last 6 months. Blood pressure (BP) 110/70 mmHg, heart rate (HR) 70 BPM, and regular, O_2 saturation 77% on room air. Cardiac examination reveals peripheral clubbing and cyanosis, a parasternal heave, loud P_2, and a murmur of tricuspid regurgitation (TR). Electrocardiogram (ECG) shows sinus rhythm. She has had repeat phlebotomy for treatment of presumed hyperviscosity syndrome but does not feel any better. What of the following options is the most appropriate next step in management?

   a. Phlebotomy should continue until symptoms improve.
   b. Refer for heart–lung transplantation.
   c. Measure serum erythropoietin.
   d. Commence a pulmonary vasodilator.
   e. Obtain iron studies.

2. A 25-year-old man presents to your clinic with 48-hour history of documented fever and chills. He has a history of a "hole in the heart" and examination reveals a 4/6 systolic murmur heard loudest at the lower left sternal edge. A restrictive muscular VSD is confirmed on echocardiogram. Which of the following is the most appropriate next step?

   a. Oral antibiotics
   b. Intravenous (IV) antibiotics
   c. Blood cultures
   d. Transesophageal echocardiogram
   e. Cardiac surgery consult

3. Blood cultures are positive for Streptococcus viridans and the patient is treated for infective endocarditis (IE). A small mobile echodensity is noted adjacent to the VSD. At clinic review 3 months later he is much improved, repeat blood cultures are negative, and transesophageal echocardiography (TEE) is negative for vegetations. The patient asks whether his VSD should now be closed. What is the best answer?

   a. Closure is indicated in those with a VSD complicated by IE.
   b. VSD closure is NOT indicated in those with a VSD complicated by IE.
   c. VSD closure is only indicated in the presence of a significant shunt (Q_p/Q_s, pulmonary to systemic blood flow ratio ≥ 2.0).
   d. VSD closure is only indicated in the presence of a significant shunt accompanied by symptoms.

4. For which of the following conditions is IE prophylaxis not required prior to extensive dental procedures (more than one option may be correct)?

   a. Ebstein anomaly without prior intervention
   b. 4 weeks following percutaneous closure of a secundum atrial septal defect (ASD)
   c. Mechanical aortic valve replacement (AVR) for bicuspid aortic valve disease
   d. Eisenmenger syndrome
   e. Tetralogy of Fallot (TOF) with residual VSD at the site of prior surgical repair

5. With which of the following adult congenital heart conditions can the following ECG tracing be seen (Fig. 9.1)?

   a. Primum ASD
   b. Congenitally corrected transposition
   c. Ebstein anomaly
   d. VSD

e. Coarctation of the aorta

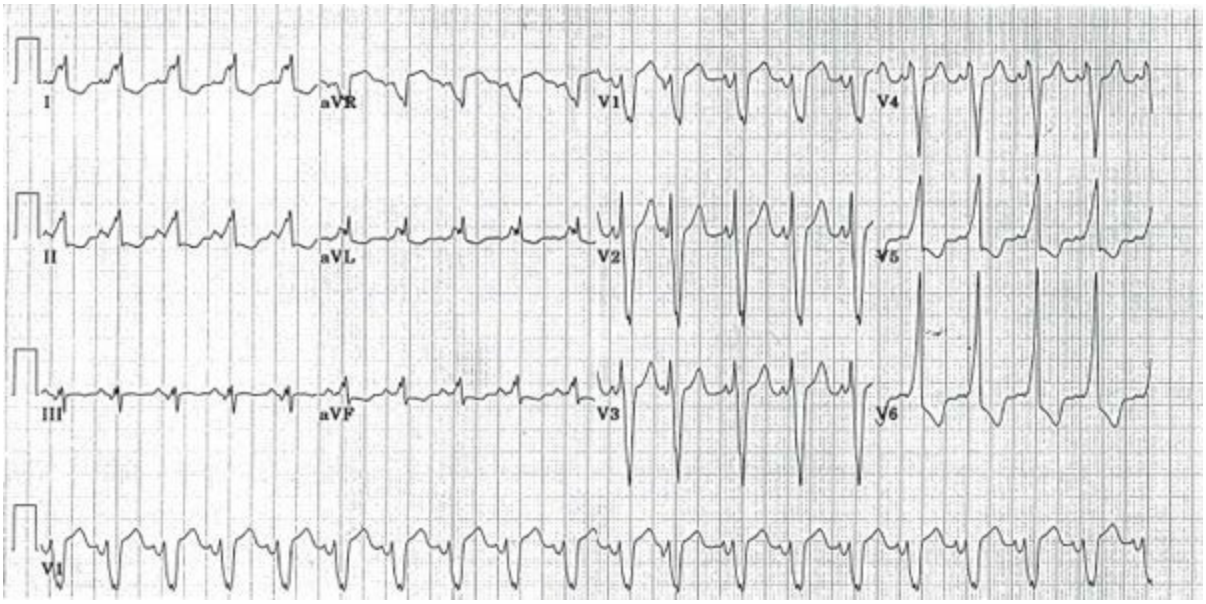

Figure 9.1

6. Which of the following is an absolute contraindication to pregnancy?

   a. Surgically corrected transposition of great arteries
   b. Congenitally corrected transposition of great arteries
   c. Ebstein anomaly
   d. Eisenmenger syndrome
   e. Status post Fontan operation

Questions 7 to 11

Match the following conditions with their corresponding surgical procedures. There may be more than one answer for each question.

7. Pulmonary atresia

8. D-transposition of great vessels

9. Tricuspid atresia

10. Congenitally corrected transposition of the great arteries

11. Aortic stenosis

   a. Ross
   b. Blalock-Taussig
   c. Senning or Mustard

d. Arterial switch
e. Fontan
f. Rashkind
g. None of the above

Questions 12 to 16

Match the following disease conditions with their gender preponderance.

12. VSD

13. ASD

14. Bicuspid aortic valve

15. Coarctation of the aorta

16. Pulmonary atresia with an intact ventricular septum

a. Predominantly male
b. Predominantly female
c. Equal preponderance

Questions 17 to 21

Match the following cardiac catheterization still-frame slides (Figs. 9.2, 9.3, 9.4, 9.5, and 9.6) to their respective diagnoses.

17. Figure 9.2

18. Figure 9.3

19. Figure 9.4

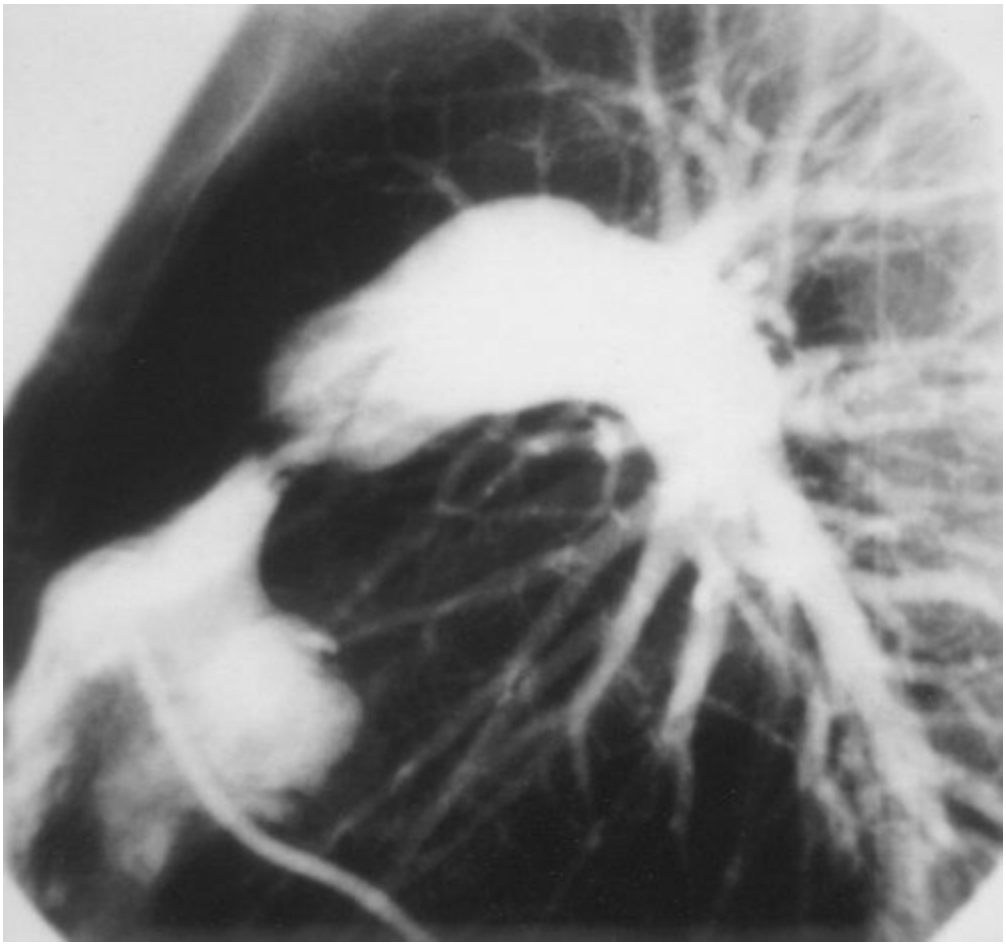

Figure 9.2

Figure 9.3

20. Figure 9.5

21. Figure 9.6

a. Coarctation of the aorta
b. Patent ductus arteriosus (PDA)
c. Hypertrophic cardiomyopathy
d. Pulmonic stenosis
e. VSD

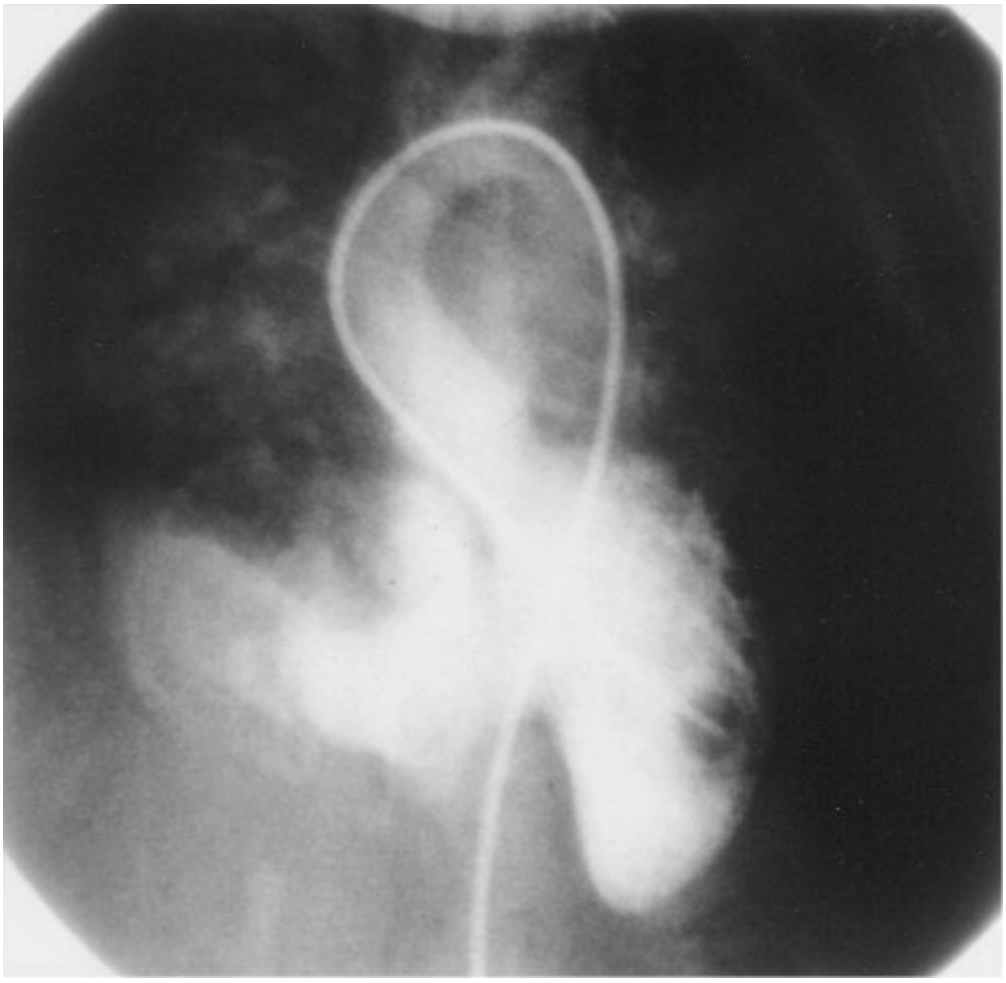

Figure 9.4

Figure 9.5

Questions 22 to 26

Match the physical examination findings with the corresponding adult congenital heart disorder.

22. Right ventricular (RV) lift with a loud systolic ejection murmur along the left sternal border, with a single S_2

23. Systolic ejection click, loud S1, holosystolic murmur, split S2 and hepatomegaly

24. Weak or delayed femoral arterial pulses, harsh systolic ejection murmur in the back, and a systolic ejection click in the aortic area

25. Cyanosis, digital clubbing, loud P_2, and a variable Graham Steell murmur

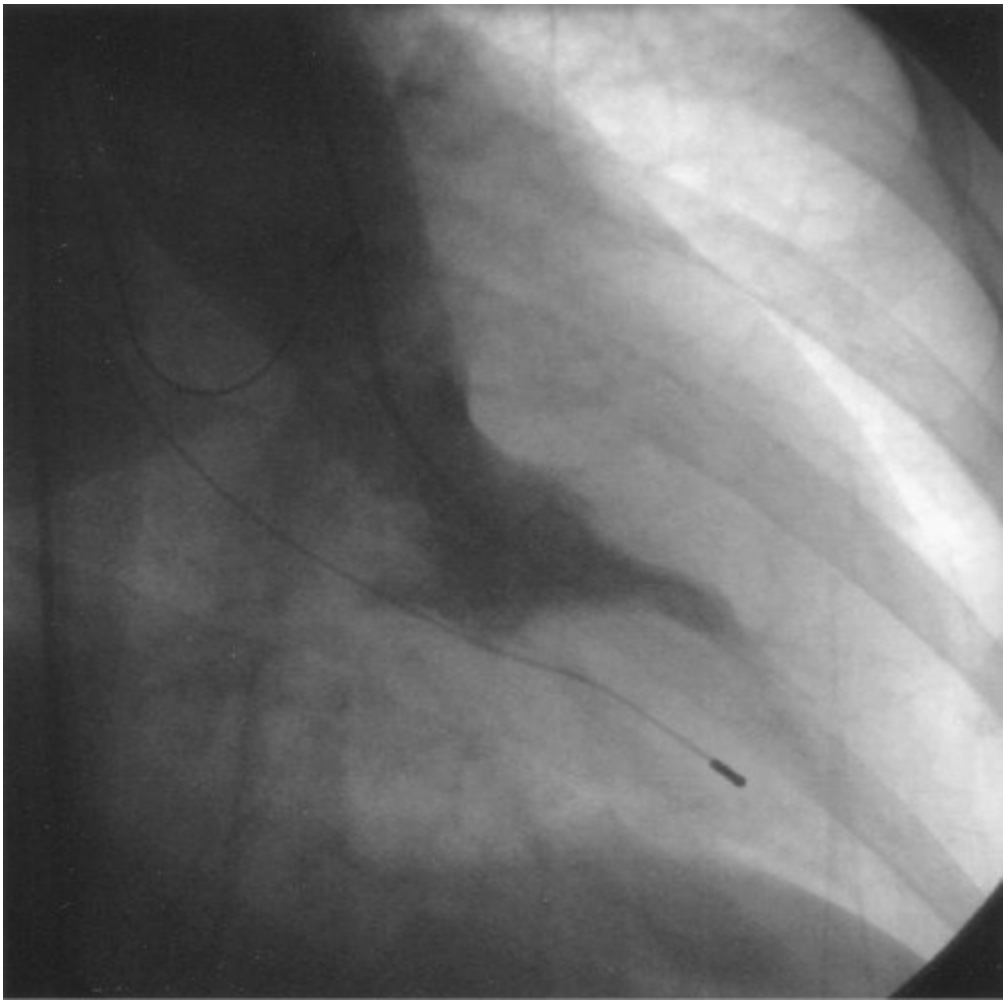

Figure 9.6

26. Wide pulse pressure, prominent left ventricular (LV) impulse, and a continuous machinery murmur enveloping S_2

- **a.** Eisenmenger syndrome
- **b.** Coarctation of the aorta
- **c.** PDA
- **d.** Ebstein anomaly
- **e.** TOF

Questions 27 to 31

Match the following congenital defects with their associated disease conditions. (more than one may apply)

27. Ostium primum ASD

28. Noonan syndrome

29. Coronary sinus ASD

30. Williams syndrome

31. Sinus venosus ASD

a. Supravalvular aortic stenosis
b. Supravalvular pulmonic stenosis
c. Cleft mitral valve
d. Anomalous pulmonary venous drainage
e. Persistent left superior vena cava (SVC)

Questions 32 to 36

Match the characteristic chest radiography findings with the corresponding congenital disorder.

32. Prominent central pulmonary arteries (PAs) (possible calcifications) and peripheral pruning

33. Right aortic arch, RV enlargement, and a "boot-shaped" heart

34. Marked cardiomegaly, severe right atrial (RA) enlargement, and normal lung fields

35. Posterior rib notching and a "reverse E" or "3" sign

36. Pulmonary plethora, prominent ascending aorta, proximal PA dilatation, and opacity at the confluence of the aortic knob and descending aorta

a. Eisenmenger syndrome
b. Coarctation of the aorta
c. PDA
d. Ebstein anomaly
e. TOF

Questions 37 to 41

Match the following congenital cardiac disorder with the characteristic transthoracic echocardiogram (TTE) finding (Figs. 9.7, 9.8, 9.9, 9.10, and 9.11).

37. Bicuspid aortic valve

38. Cor triatriatum

39. Ostium primum ASD

40. Quadricuspid aortic valve

41. Subaortic valve stenosis

    a. Figure 9.7
    b. Figure 9.8
    c. Figure 9.9
    d. Figure 9.10
    e. Figure 9.11

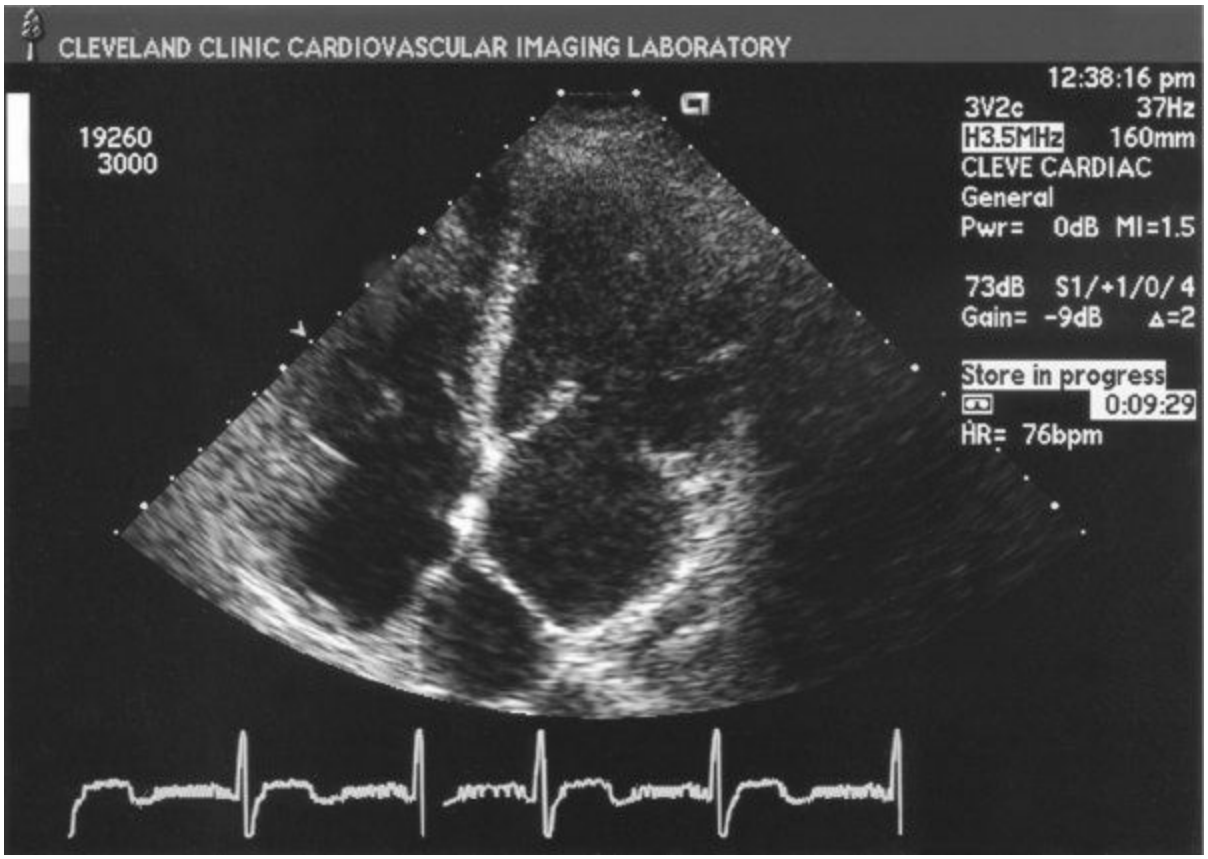

Figure 9.7

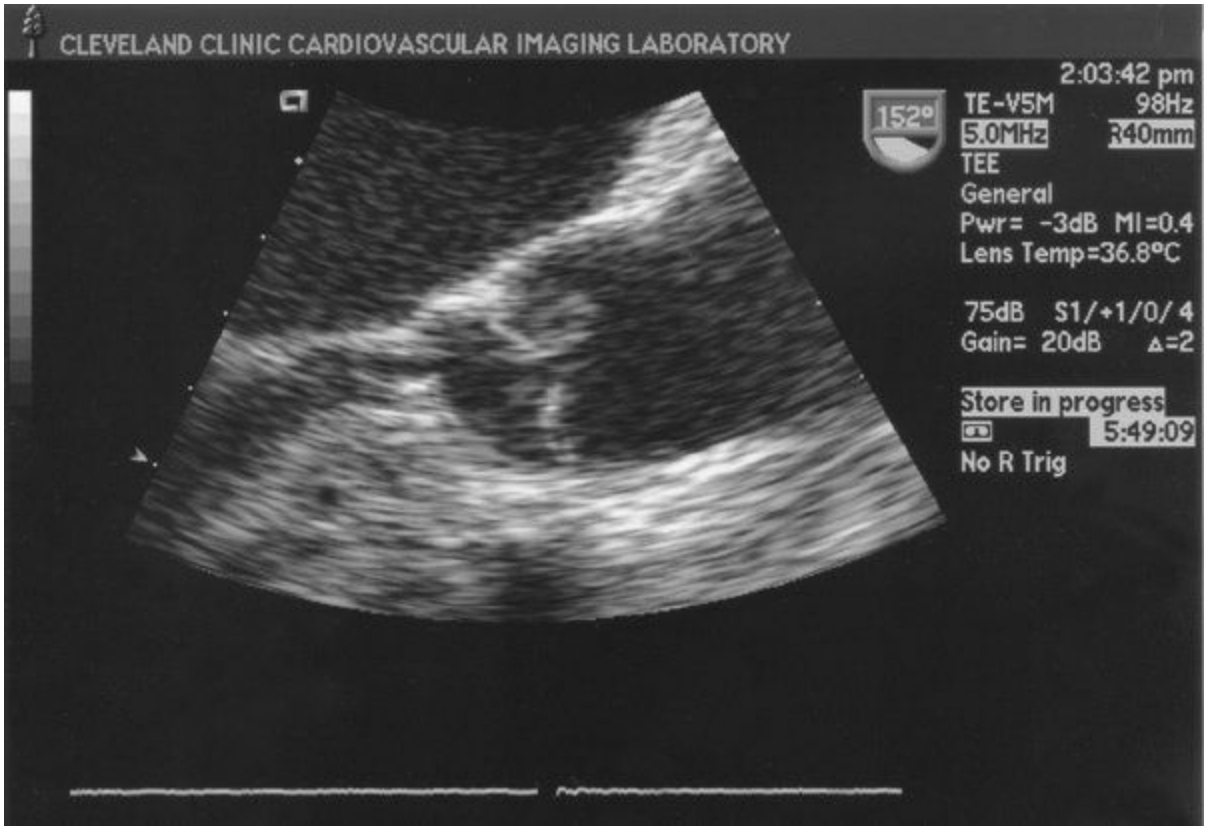

Figure 9.8

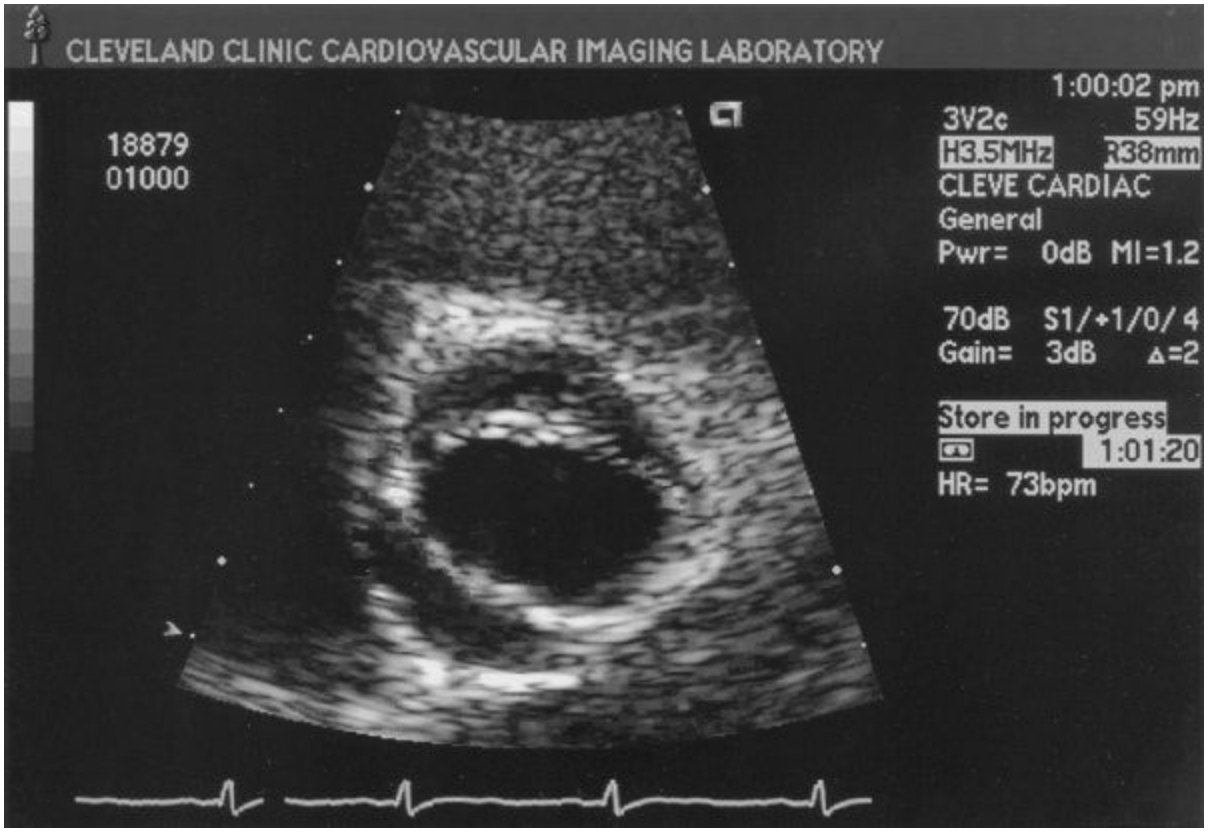

Figure 9.9

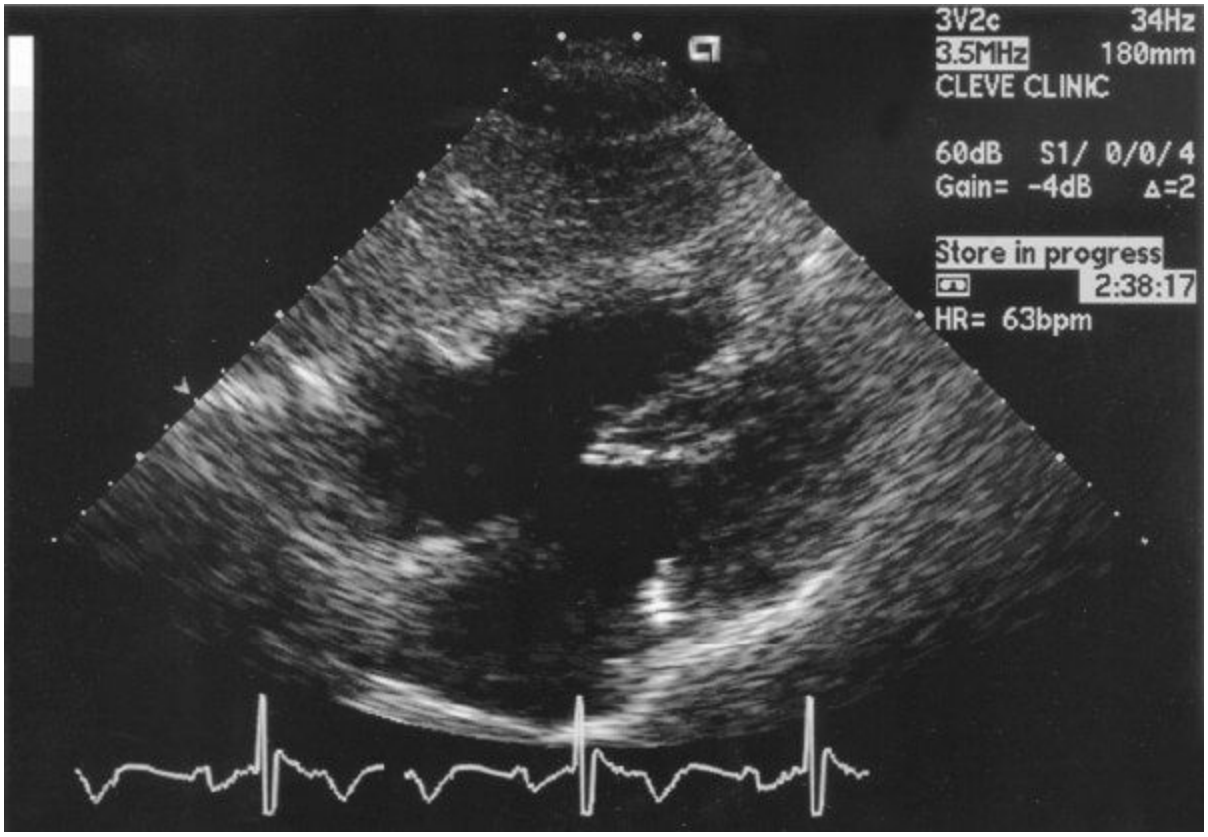

Figure 9.10

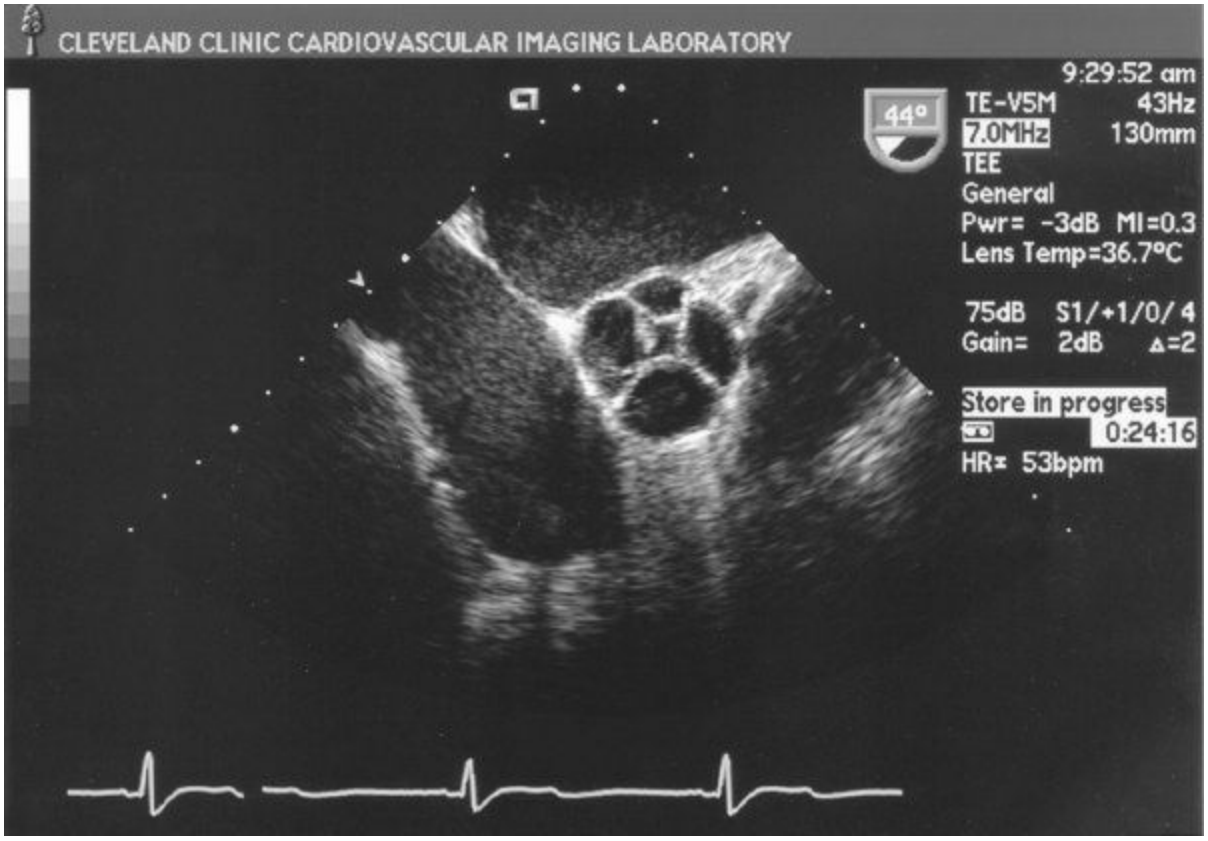

Figure 9.11

Intracardiac Shunts

42. Which of the following are associated with patent foramen ovale (PFO)?

a. Migraine
b. Platypnea-orthodeoxia
c. Decompression sickness
d. Paradoxical embolism & stroke
e. All of the above

43. A 25-year-old man is referred to you for an abnormal heart sound. The patient is asymptomatic and very active. BP is 130/50 mmHg. He has a continuous murmur at the left upper sternal border. A TTE reveals a small PDA with mildly dilated left atrium (LA) and mildly dilated LV but normal RV size and normal pulmonary pressures. How would the patient be best managed?

a. Ligation or percutaneous closure of the PDA
b. Repeat TTE in 1 year
c. Stress echocardiography to determine LV enlargement or dysfunction postexercise
d. Pulmonary vasodilator
e. TEE

44. Which of the following is **most** commonly associated with a sinus venosus ASD?

a. Coarctation of the aorta
b. Bicuspid aortic valve
c. Anomalous right pulmonary venous connection
d. Inlet VSD
e. Persistent left SVC

45. The best echocardiographic scan plane for demonstrating a secundum ASD is

a. apical four-chamber view.
b. parasternal long-axis view.
c. parasternal short-axis view.
d. subcostal four-chamber view.
e. suprasternal long-axis view.

46. Review the image taken at the time of percutaneous closure of an intracardiac shunt in a 25-year-old patient (Fig. 9.12). Which of the following defects was closed in this patient?

a. Primum ASD

b. Secundum ASD
c. Sinus venosus ASD
d. Unroofed coronary sinus
e. Atrioventricular septal defect (AVSD)

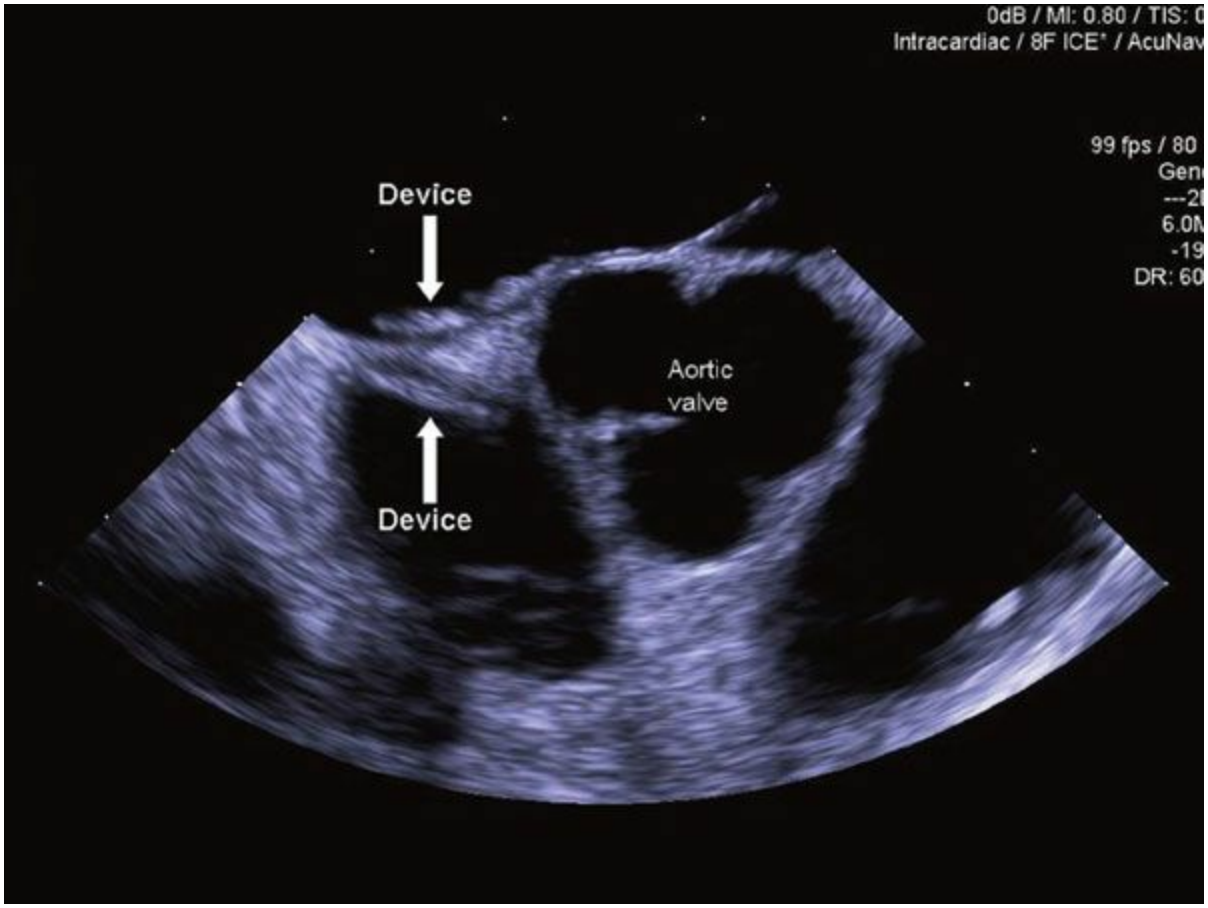

Figure 9.12

47. Secundum ASDs may be associated with

a. pulmonary hypertension.
b. mitral valve prolapse.
c. partial anomalous pulmonary venous connection.
d. pulmonic stenosis.
e. all of the above.

48. Which type of VSD is demonstrated in Figure 9.13?

a. Type 1/supracristal
b. Type 2/perimembranous
c. Type 3/inlet
d. Type 4/muscular

49. Percutaneous VSD closure is approved by the U.S. Food and Drug Administration for which type of VSD?

a. Type 1/supracristal
b. Type 2/perimembranous
c. Type 3/inlet
d. Type 4/muscular
e. None: Surgery is the only approved treatment for VSD closure

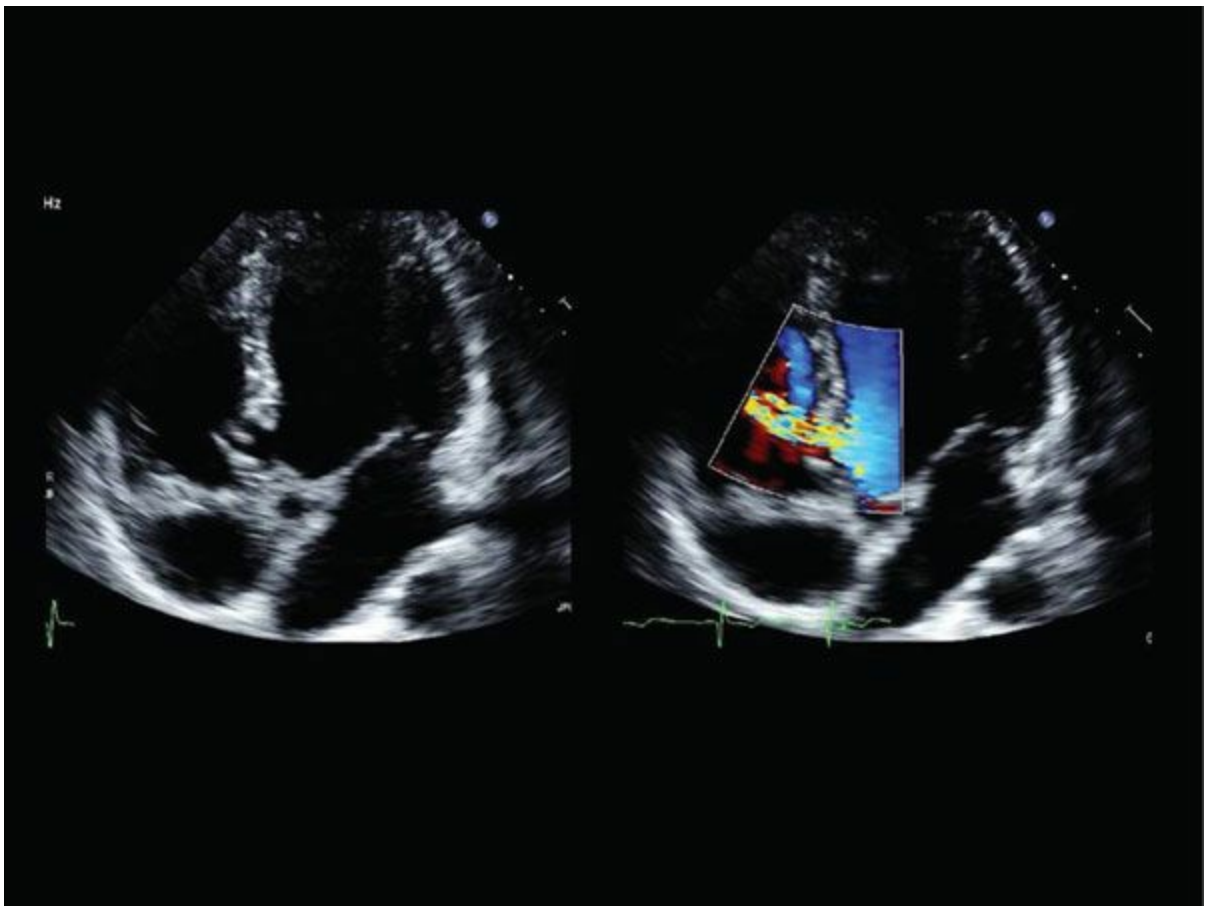

Figure 9.13

Left-Sided Lesions

50. What is the most common coexisting congenital anomaly in patients with coarctation of the aorta?

a. Cleft mitral valve
b. Bicuspid aortic valve
c. Ebstein anomaly
d. VSD
e. PDA

51. A 20-year-old man is referred for further evaluation of hypertension. He has remained hypertensive despite a 12-week trial of β-blocker treatment. Examination reveals a right upper extremity BP of 150/100 mmHg and a right lower extremity BP of 130/90 mmHg. HR is 88 bpm. There is brachial– femoral pulse delay. The rest of the physical and neurologic examinations are within normal limits. A TTE confirmed a diagnosis of coarctation of the aorta, with a maximum gradient of 30 mmHg. He is referred for cardiac catheterization. Intervention for coarctation is recommended when the coarctation gradient is greater than which of the following?

a. 10 mmHg
b. 20 mmHg
c. 40 mmHg
d. 60 mmHg
e. None of the above; indications for intervention in coarctation are determined by symptoms and not the coarctation gradient

52. Which of the following is the most common coronary artery anomaly?

a. Bland-Garland-White syndrome (left main coronary arising from the PA)
b. Coronary arteriovenous fistula
c. Left circumflex artery arising from the right coronary artery
d. Left coronary artery arising from the right sinus of Valsalva
e. Coronary cameral fistula

53. Which of the following statements about coronary arteriovenous fistula is true?

a. The left coronary artery is most commonly involved.
b. The fistula most commonly empties into the LV.
c. Despite the success of surgical closure, the prognosis is still poor.
d. Spontaneous closure rarely occurs.
e. A large right-to-left shunt may cause congestive heart failure (CHF).

54. Which of the following differentiates valvular aortic stenosis from subvalvular aortic stenosis?

a. Male preponderance
b. Surgical risk of repair
c. Dilatation of the ascending aorta
d. Aortic regurgitation
e. Valvular calcification

55. Echocardiography in a 20-year-old asymptomatic man reveals a subaortic membrane with a peak gradient of 20 mmHg. The aortic valve remains mobile, but there is

associated mild to moderate aortic valve insufficiency. LV size is normal ejection fraction is 60%. What should you advise this patient?

a. There is no indication for intervention at this time.
b. Surgical resection of the membrane and debridement of the aortic valve to reduce aortic regurgitation is indicated.
c. Transluminal balloon dilatation is the best treatment option in this case.
d. AVR and membrane resection is indicated.

56. The peak age range for surgical intervention for patients with a bicuspid aortic valve is

a. 10 to 20 years.
b. 20 to 40 years.
c. 40 to 60 years.
d. 60 to 80 years.

Right-Sided Lesions

57. A 45-year-old man with known Ebstein anomaly seeks your advice with regard to optimal management. He is asymptomatic and has an active lifestyle without any limitations. His physical examination is remarkable for the absence of cyanosis. He has a loud holosystolic murmur at the left lower sternal border that is accentuated with respiration. He has no organomegaly or peripheral edema. His TTE reveals moderately severe 3+ TR with an RV systolic pressure of 35 mmHg and normal LV and RV systolic function. There is no evidence of interatrial communication. Which of the following should you recommend?

a. Furosemide and digoxin
b. Tricuspid valve repair
c. Tricuspid valve replacement
d. Dual-chamber pacemaker
e. Regular follow-up with repeat TTE in 6 months

58. The most common problem in adults with surgically repaired TOF is

a. ventricular tachycardia.
b. pulmonary hypertension.
c. pulmonary regurgitation.
d. cyanosis.
e. residual VSD.

59. A 34-year-old gentleman reports a history of TOF, Blalock-Taussig shunt at

10 months, and complete repair at age 3. Although he has been reasonably active for several years, he has noted progressive exercise intolerance in recent months. Examination reveals a III/VI systolic ejection murmur loudest at the second left intercostal space and a II/IV diastolic murmur along the left sternal edge. Jugular venous pulse is not elevated. Lungs are clear and there is no hepatomegaly or peripheral edema. An echocardiogram demonstrates RV dilatation, moderate-to-severe pulmonic regurgitation but no significant TR. The ECG shows sinus rhythm and right bundle branch block with a QRS duration of 160 milliseconds. The most reasonable next step in the evaluation of this patient would be

a. repeat echocardiogram with a saline bubble study.
b. electrophysiologic study for ventricular arrhythmias.
c. cardiac catheterization.
d. cardiac magnetic resonance imaging study.
e. diuretics and digitalis.

60. A 35-year-old man is referred for evaluation of dyspnea and a loud cardiac murmur. Examination reveals an RV lift, a palpable systolic thrill at the second left intercostal space, and a widely split second heart sound. There is a loud and harsh ejection systolic murmur heard loudest at the second left intercostal space. BP is 130/80 mmHg, HR 90 bpm, and regular, oxygen saturation 98% on room air. What is the most likely diagnosis?

a. Unrepaired TOF
b. ASD
c. VSD
d. PDA
e. Pulmonary stenosis

61. Echocardiography confirms doming valvular pulmonary stenosis with a mean Doppler gradient of 40 mmHg. There is no significant pulmonary regurgitation or TR. ECG is normal. The patient undergoes cardiac catheterization (results below):

	Pressure	Saturation
SVC		82
IVC		78
RA	Mean 15	
RV	70/15	
PA	23/15 mean 19	82
PCWP	Mean 6	
Aorta	130/80 mean 90	98

What is the most appropriate management for this patient?

a. Referral to a pulmonary hypertension specialist
b. Repeat cardiac catheterization with vasodilator challenge
c. Balloon valvotomy
d. Surgical repair
e. Diuretics

62. Which complications are seen in adults late after the atriopulmonary Fontan procedure among those born with tricuspid atresia?

a. Protein-losing enteropathy
b. Thromboembolic events
c. Intra-atrial reentrant tachycardia (IART)
d. All of the above

Syndromes

63. Which of the following syndromes is associated with pulmonary arteriovenous fistula?

a. Williams syndrome
b. Weber-Osler-Rendu syndrome
c. Bland-Garland-White syndrome
d. Kartagener syndrome
e. Crouzon syndrome

64. What is the most common cardiac defect seen in patients with Noonan syndrome?

a. AVSD
b. Pulmonary stenosis
c. Coarctation of the aorta

d. Hypertrophic cardiomyopathy
e. Mitral valve prolapse

65. The most common chromosomal abnormality associated with TOF is

a. 22q11.2 microdeletion.
b. 7q11.23 microdeletion.
c. missense mutations in the PTPN11 gene on chromosome 12.
d. Trisomy 21.
e. Monosomy X (45, X).

66. Which of the following is true for Loeys-Dietz syndrome (LDS)?

a. Inheritance is autosomal recessive.
b. FBN1 mutations have been implicated.
c. The risk of aortic dissection is lower than for patients with Marfan syndrome.
d. Patients are characteristically tall with long extremities.
e. Hypertelorism, bifid uvula, and arterial tortuosity are common features.

67. Which of the following syndromes is/are NOT associated with pulmonary stenosis?

a. Noonan syndrome
b. Williams syndrome
c. Shone syndrome
d. Congenital rubella syndrome
e. LEOPARD syndrome

ANSWERS

1. e. Obtain iron studies. Eisenmenger syndrome is the most extreme manifestation of pulmonary arterial hypertension associated with any nonrestrictive congenital heart defect that exposes the pulmonary vascular bed to systemic pressures. The development of pulmonary obstructive arteriopathy and increased pulmonary vascular resistance leads to shunt reversal and cyanosis. Secondary erythrocytosis is a physiologic response to chronic hypoxemia. Eisenmenger syndrome is a multisystem disease that also results in abnormal clotting, impaired renal function, altered uric acid and bilirubin metabolism, and musculoskeletal disease including gout. A common misconception in the management of patients with cyanotic coronary heart disease (CHD) is that an increased hematocrit level alone is an indication for phlebotomy. In fact, therapeutic phlebotomy has a very limited role in patient management and should only be performed if the hemoglobin is more than 20 mg/dL and the hematocrit is greater than 65% with symptoms of hyperviscosity

and no evidence of dehydration. Symptoms of hyperviscosity include headache, fainting/dizziness, altered mentation, altered vision, tinnitus, myalgias, and restless legs. Hyperviscosity symptoms should disappear after adequate phlebotomy.

Eisenmenger patients with a history of repeat phlebotomies are at increased risk for iron deficiency anemia, which itself is associated with increased stroke risk.[6] The patient's history of phlebotomies, persistent fatigue, low MCV, and low hemoglobin (relative to oxygen saturation) are all suggestive of iron deficiency anemia. Iron studies are the most appropriate next investigation in this context. Pulmonary vasodilator therapy has been shown to improve 6-minute walk distance in patients with Eisenmenger physiology[7]; however, further investigations are generally indicated prior to commencement (e.g., pulmonary function tests with volumes and CO_2 diffusion, computed tomography for exclusion of pulmonary emboli, cardiac catheterization with vasodilator challenge). Heart–lung transplantation may be considered in Eisenmenger patients with severe limitations; however, long-term survival after heart–lung transplantation is often inferior to continuing conservative management in this population.

2. **c.** Blood cultures. The incidence of IE in young adults with CHD is almost 35-fold that of the general population.[8] Hence, a high index of suspicion for IE is required in these patients. ACHD patients who present with fever and potential IE should have blood cultures drawn before antibiotic therapy is initiated to avoid subsequent false-negative blood cultures and, in the instance of positive blood cultures, to guide antibiotic treatment. In this case, blood cultures should be taken as the first step in the patient's management and prior to commencement of antibiotic therapy. Since the sensitivity of TTE is too low to exclude IE, TEE should be performed after multiple sets of blood cultures are taken. Surgery for IE is indicated in patients with recurrent emboli, medically uncontrolled infection, prosthetic material infection, CHF, and development of heart block.

3. **a.** Closure is indicated in patients with a VSD complicated by IE (AHA guidelines, class I recommendation, level of evidence C[1]). VSD closure is also indicated in the following circumstances:

   - Patients with attributable symptoms; LV volume overload; deteriorating ventricular function due to volume (LV) or pressure (RV) overload; and/or a Q_p/Q_s (pulmonary-to-systemic blood flow ratio) $\geq$1.5:1 in the absence of advanced pulmonary vascular disease
   - Significant RV outflow tract (RVOT) obstruction (catheter gradient > 50 mmHg)
   - VSD closure may also be considered in patients with a perimembranous or

subarterial VSD and more than mild or progressive aortic regurgitation[3]

- In deciding whether to close a defect, TTE ± TEE is essential to define the size and location of the defect and to identify coexisting septal defects as more than one muscular defect is common.

4. **a.** Ebstein anomaly without prior intervention. Current AHA guidelines for ACHD patients recommend antibiotic prophylaxis before dental procedures in the following patient subgroups[1]:
   - Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
   - Prior IE
   - Unrepaired and palliated cyanotic congenital heart disease, including surgically palliated constructed palliative shunts and conduits
   - Completely repaired CHD with prosthetic materials, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
   - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device that inhibits endothelialization

5. **c.** Ebstein anomaly. The ECG demonstrates a short PR interval, presence of delta waves, and wide QRS interval that are all consistent with preexcitation and Wolff-Parkinson-White syndrome. Wolff-Parkinson-White syndrome is commonly associated with Ebstein anomaly. Catheter ablation can be beneficial for treatment of recurrent supraventricular tachycardia in some patients, although recurrence is common due to the presence of multiple accessory pathways.[9] (see also question 57).

6. **d.** Eisenmenger syndrome. Eisenmenger syndrome is one of few conditions that pose an absolute contraindication to pregnancy[1–3] due to very high maternal mortality and fetal loss.

7. **b, e.** Blalock-Taussig and Fontan (see also Table 9.1).

8. **c, d, f.** Senning or Mustard, arterial switch, and Rashkind.

9. **e, f.** Fontan and Rashkind.

10. **g.** None of the above.

11. **a.** Ross. Please refer to Table 9.1, which provides a complete overview of common

surgical procedures for congenital heart disease.

12. **c.** Equal preponderance.

13. **b.** Predominantly female.

14. **a.** Predominantly male.

15. **a.** Predominantly male.

16. **c.** Equal preponderance.

17. **Figure 9.2, d.** Pulmonic stenosis. A left lateral right ventriculogram demonstrates pulmonic stenosis with dilatation of the proximal main PA.

18. **Figure 9.3, a.** Coarctation of the aorta. Left lateral view of the LV and aorta. The catheter was advanced from the femoral vein and crossed a large patent foramen ovale to reach the left side of the heart. A discrete area of narrowing (coarctation) is seen in the upper descending aorta.

19. **Figure 9.4, e.** VSD. A left ventriculogram obtained in the left anterior oblique view allows optimal visualization of the interventricular septum and demonstrates a large VSD with significant left-to-right shunt of contrast.

TABLE 9-1 Common Surgical Procedures for Congenital Heart Disease

Procedure	Description	Intent	Result
Blalock-Taussig	Subclavian artery to PA anastomosis	PAL	Increases PBF
Central shunt	Conduit or anastomosis between the aorta and PA	PAL	Increases PBF
Fontan	Anastomosis or conduit between the right atrium and PA	PAL	Increases PBF in cases of univentricular heart or tricuspid atresia
Hemi-Fontan	SVC to PA anastomosis with baffle placed in the right atrium so that inferior vena cava blood flow goes across ASD to left heart	PAL	Increases PBF and sets the stage for Fontan completion
Glenn (bidirectional Glenn)	SVC to PA anastomosis	PAL	Increases PBF
Jatene arterial switch	Transection of the aorta and PA with reimplantation onto the proper ventricles, coronary arteries reimplanted	COR	Creates normal relationship between the ventricles and great arteries in d-TGA
Konno	Replacement of aortic valve with aortic valve annular enlargement	COR	Alleviates subaortic obstruction and replaces abnormal aortic valve
Mustard/Senning	Atrial switch with intra-atrial baffle made of pericardium (Mustard) or atrial wall flaps (Senning)	COR	Reestablishes proper flow sequence to PA and aorta in d-TGA
Norwood (first stage)	PA anastomosis to aorta, conduit from the aorta to main PA	PAL	Increases flow to aorta for subaortic obstruction with single ventricle
PA band	Constrictive band around main PA	PAL	Decreases PBF
Potts	Descending aorta-to-PA shunt	PAL	Increases PBF (rarely done anymore)
Rashkind	Atrial septostomy with catheter balloon	PAL	Increases mixing of blood for d-TGA or tricuspid atresia
Rastelli	Closure of VSD + valved conduit from RV to PA	COR	Increases PBF, may reestablish proper sequence of flow to aorta and PA
Ross	Pulmonary autograft to aorta, pulmonary homograft	COR	Correction for aortic stenosis; avoids mechanical and bioprosthetic valves
Waterston	Ascending aorta to right pulmonary anastomosis	PAL	Increases PBF (rarely done anymore)

ASD, atrial septal defect; COR, total correction; d-TGA, D-transposition of the great arteries; PA, pulmonary artery; PAL, palliation; PBF, pulmonary blood flow; RV, right ventricle; SVC, superior vena cava.

From *ACC Current Journal Review.* March/April 1996:46, with permission.

20. **Figure 9.5, b.** Patent ductus arteriosus (PDA). An aortogram in straight lateral view. There is a large abnormal communication between the upper descending aorta and the main PA, confirming the diagnosis of PDA.

21. **Figure 9.6, c.** Hypertrophic cardiomyopathy. A left ventriculogram in right anterior oblique projection demonstrates a small ventricle with marked ventricular hypertrophy and narrow left ventricular outfl ow tract (LVOT).

22. **e.** TOF. On cardiac palpation and auscultation, patients with TOF demonstrate RV lift (RV hypertrophy) and a systolic ejection murmur over the pulmonic region caused by RVOT obstruction. A soft, short systolic ejection murmur suggests severe obstruction. The intensity and severity of the ejection murmur are inversely related to the severity of RV obstruction. P_2 is absent, and only the aortic component of S_2

is audible.

23. **d.** Ebstein anomaly. Patients with Ebstein anomaly have a widely split S_1 (reflecting delayed closure of the anterior tricuspid leaflet) and split S_2 (delayed closure of the pulmonary valve due to associated right bundle branch block). The "sail sound" contributes to a loud S_1 and reflects increased tension in the large mobile anterior leaflet as it reaches the limits of its systolic excursion. The systolic murmur of TR is typically grade 2/6 to 3/6 and heard loudest overlying the tricuspid area. Ejection clicks, opening snaps, and diastolic murmurs may be heard. Hepatomegaly caused by passive congestion and elevated RA pressure may be present.

24. **b.** Coarctation of the aorta. Patients with coarctation of the aorta have systolic hypertension and higher BP in their arms than in their legs, resulting in delayed femoral arterial pulses. Because many patients also have bicuspid aortic valve, a systolic ejection click is frequently present, and the aortic component of S_2 is accentuated. A harsh systolic ejection murmur is audible along the left sternal border and radiates to the back, especially over the point of discrete coarctation.

25. **a.** Eisenmenger syndrome. Patients with Eisenmenger syndrome demonstrate cyanosis and digital clubbing, the severity of which depends on the magnitude of right-to-left shunting. An RV lift and loud P_2 caused by pulmonary hypertension are usually present. The murmur caused by ASD, VSD, or PDA is no longer present when Eisenmenger syndrome develops because left- and right-sided pressures have equalized. Many patients will have a tricuspid or pulmonary regurgitation murmur, or both.

26. **c.** PDA. Patients with PDA exhibit hyperdynamic LV impulse with wide pulse pressure. A continuous machinery murmur, heard best in the pulmonic region, is a characteristic finding.

27. **c.** Cleft mitral valve. (see also question 45).

28. **b.** Supravalvular pulmonic stenosis.

29. **e.** Persistent left SVC. (see also question 45).

30. **a.** Supravalvar aortic stenosis and b. Supravalvar pulmonary stenosis

31. **d.** Anomalous pulmonary venous drainage. (see also question 44).

32. **a.** Eisenmenger syndrome.

33. **e.** TOF.

34. **d.** Ebstein anomaly.

35. **b.** Coarctation of the aorta.

36. **c.** PDA.

37. **c.** Figure 9.9. This is a parasternal short-axis view at the aortic valve level using TTE. Two leaflets showing a "fish-mouth" opening during systole are seen instead of three leaflets.

38. **a.** Figure 9.7. This is an apical four-chamber view using TTE. There is a membrane separating the LA into a posterior chamber, usually where the pulmonary veins empty, and an anterior chamber that contains the mitral valve.

39. **d.** Figure 9.10. Subcostal TTE view showing the ASD in the lower atrial septum, with downward displacement of the atrioventricular (AV) valve. (see also question 45).

40. **e.** Figure 9.11. This is a parasternal short-axis view at the aortic valve level, using TTE. There are four visible leaflets.

41. **b.** Figure 9.8. A magnified TEE long-axis view of the LVOT, aortic valve, and ascending aorta. There is a membrane visible in the LVOT, consistent with a subaortic membrane.

42. **e.** All of the above. The foramen ovale is the interface between the septum primum and septum secundum and in utero provides an important route for blood as it bypasses the collapsed fetal lungs (oxygenation being achieved via the placenta). In about 25% of humans the flap of tissue making up the foramen ovale does not fuse after birth and results in a PFO. Stroke patients with PFO and atrial septal aneurysm (ASA) have an average annual risk of recurrent stroke of 4.4%.[10] PFO is also associated with decompression sickness, platypnea-orthodeoxia, and migraine. Factors associated with a greater risk of paradoxical embolism are large PFO size and the presence of an ASA. Though several management strategies exist for patients with cryptogenic stroke and PFO, including anticoagulation, antiplatelet therapy, and closure via percutaneous or surgical means, no clear consensus

regarding therapy exists.

43. **a.** Ligation or percutaneous closure of the PDA. PDA is the persistence after birth of an in utero communication between the aorta and the left PA, which, along with the foramen ovale, is designed to bypass blood away from the collapsed fetal lungs. It is the third most common congenital heart defect in adults and is generally found in isolation in the adult. Frequently, this lesion is discovered by the unusual quality of a continuous "machinery" murmur at the left upper sternal border. Because a patent ductus is an aortopulmonary communication, the pulse pressure frequently is widened and the pulses are brisk to bounding.

Closure of a PDA either percutaneously or surgically is indicated for LA and/or LV enlargement or in patients with prior endarteritis.[1] It is reasonable to close a small asymptomatic PDA by catheter device so as to decrease the future risk of endarteritis (0.45% per year after the second decade of life); however, this is somewhat controversial. Surgical repair is recommended in those who meet indications and with PDAs too large for device closure or distorted ductal anatomy. Pulmonary vasodilators are not indicated in this patient due to the absence of pulmonary hypertension. By lowering pulmonary vascular resistance, pulmonary vasodilators could conceivably increase left-to-right shunting in those with moderate-to-large PDAs. Endocarditis prophylaxis is recommended for ACHD patients with a residual shunt including PDA.

44. **c.** Anomalous right pulmonary venous connection. Sinus venosus ASDs constitute 2% to 3% of interatrial communications. Strictly speaking, this defect lies outside the true atrial septum and is an abnormality of the venous connections. These defects are located on the right side of the upper or posterior atrial septum, most commonly at the SVC/RA junction and less commonly at the level of the inferior vena cava (IVC). Because of their superior location, sinus venosus defects are easily missed on TTE. Partial anomalous venous return of the right upper pulmonary vein is a common association (seen in up to 85% of patients). A bicaval view on TEE or demonstration by CT/MRI is diagnostic.

45. **d.** Subcostal four-chamber view. ASDs and anomalous pulmonary venous return should be suspected in patients with unexplained RV dilatation and volume/pressure overload (Fig. 9.14).

A secundum ASD is the common type of ASD and is located centrally in the interatrial septum at the site of the fossa ovalis. The defect may be single, multiple, or fenestrated. This defect is best viewed by transthoracic echocardiography in the subcostal view (due to ultrasound waves being better reflected off the interatrial septum in this view). Coexisting partial anomalous pulmonary venous drainage is

seen in 5% of patients with a secundum ASD. The atrial septal defect occurs when the interatrial septum is deficient at the crux of the heart/level of the atrioventricular valves.

A primum ASD occurs as part of the spectrum of AVSD. Partial AVSD commonly describes a primum ASD in combination with a so-called cleft mitral valve, more correctly described as a trileaflet left-sided AV valve. Primum ASDs are often well demonstrated from the apical four-chamber view (± subcostal) in association with mitral regurgitation from a trileaflet left-sided AV valve (Fig. 9.15).

A coronary sinus defect is located in the wall that separates the coronary sinus from the LA. It may be fenestrated or completely absent. There is an associated left-sided SVC contributing to dilatation of the coronary sinus seen best on parasternal long-axis views. A coronary sinus defect should be suspected in a patient who has evidence of RV volume or pressure overload but no suggestion of a defect in the central portion of the atrial septum. Injection of agitated saline into the left arm leads to contrast in the coronary sinus, then the RA and finally the RV. An unroofed coronary sinus contains fenestrations such that bubbles travel from the left sided SVC and into the left atrium.

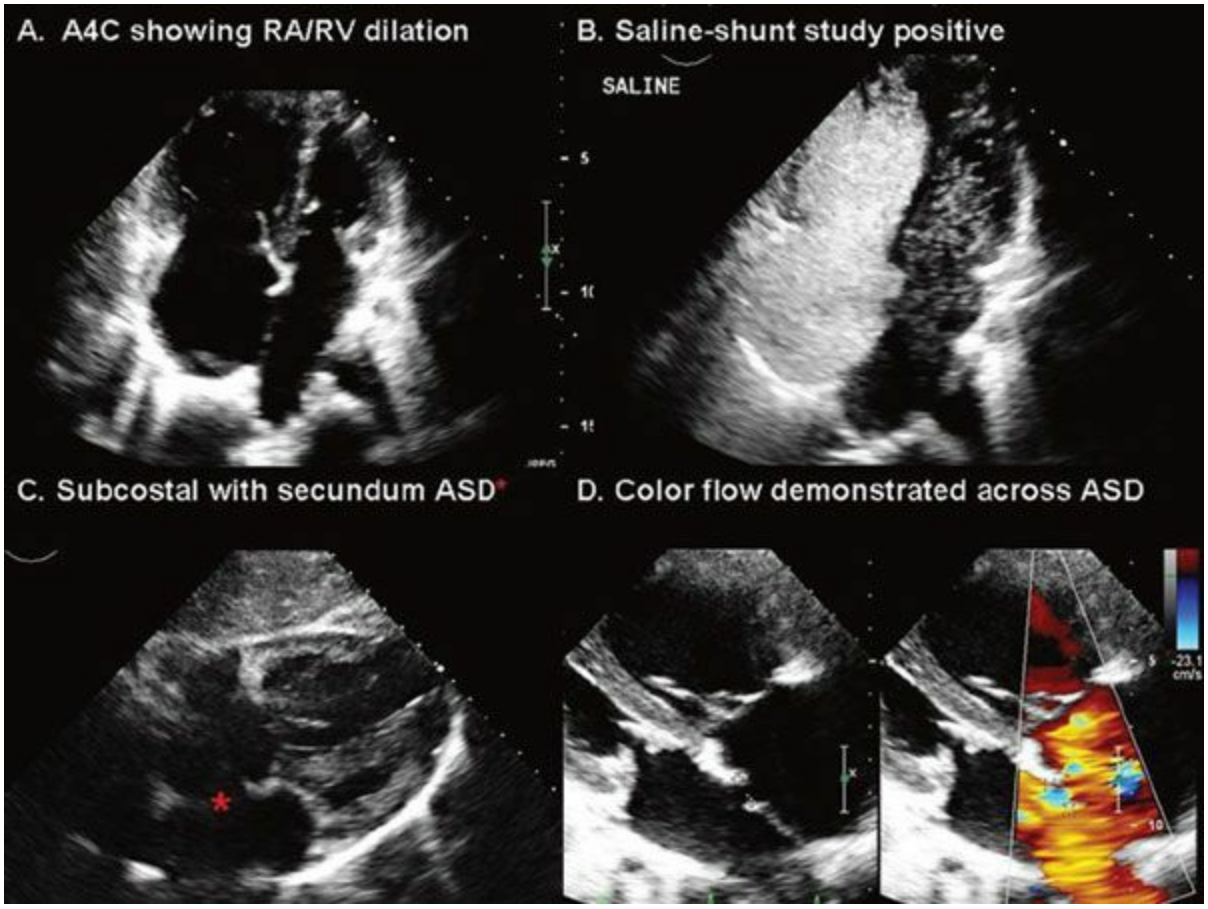

Figure 9.14 The findings of RA and RV dilatation in the apical four-chamber (A4C) view (**A**) and significant

right-to-left shunting of agitated saline (**B**) are highly suggestive of an ASD ± anomalous pulmonary venous return. A secundum ASD is confirmed as a defect in the mid-portion of the interatrial septum, best seen in subcostal scan plane (**C**) and with color flow Doppler (**D**). ASD, atrial septal defect; RA, right atrium; RV, right ventricle.

46. **b.** Secundum ASD. The majority of secundum ASDs can be closed with a percutaneous catheter technique. ASD closure is indicated for RA and RV enlargement with or without symptoms. Small ASDs (<5 mm) with no evidence of volume overload do not require closure unless associated with cryptogenic paradoxical embolism. Sinus venous, coronary sinus, and primum defects are not amenable to device closure (Fig. 9.16; see also Question 3).

47. **e.** All of the above. Large ASDs can lead to RV volume overload, excessive blood flow to the pulmonary circulation, and pulmonary hypertension. Associated lesions are listed in Table 9.2 for each ASD type.

48. **b.** Type 2/perimembranous. See Table 9.3.

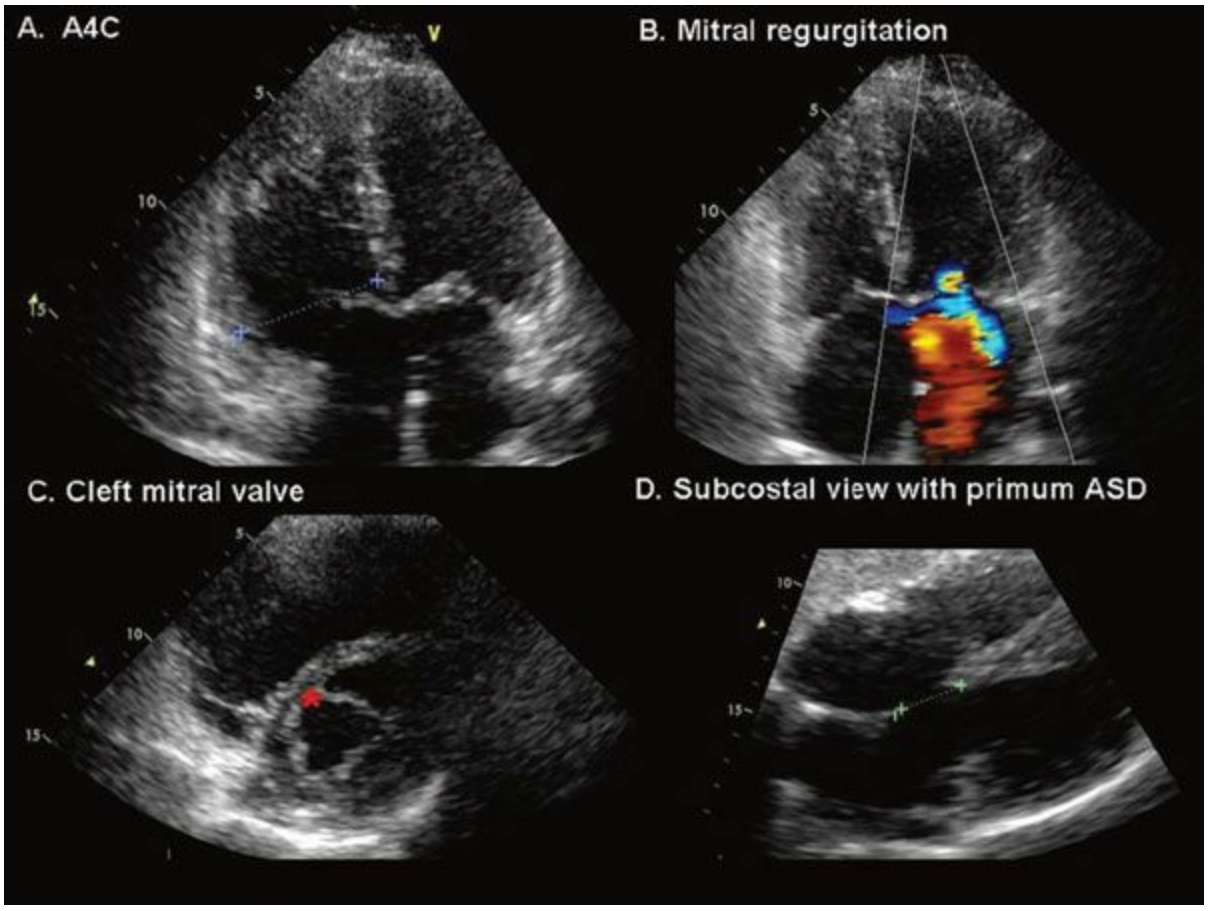

Figure 9.15 Primum ASD and its associated features. Note that the septal leaflet of the tricuspid valve is on the same plane as the mitral valve (**A**). Normally the septal leaflet of the tricuspid leaflet is apically displaced compared with the mitral valve. Mitral regurgitation frequently coexists with primum (**B**). (**C**) Short-axis views of the mitral valve show a “cleft” pointing toward the septum (*). (**D**) The cleft is more accurately

characterized as a commissure between the superior and inferior bridging leaflets of the common AV canal. Additional echocardiographic features of AVSD (not demonstrated here) include elongation of the LV outflow tract (gooseneck deformity) ± LVOT obstruction. A4C, apical 4 chamber; ASD, atrial septal defect.

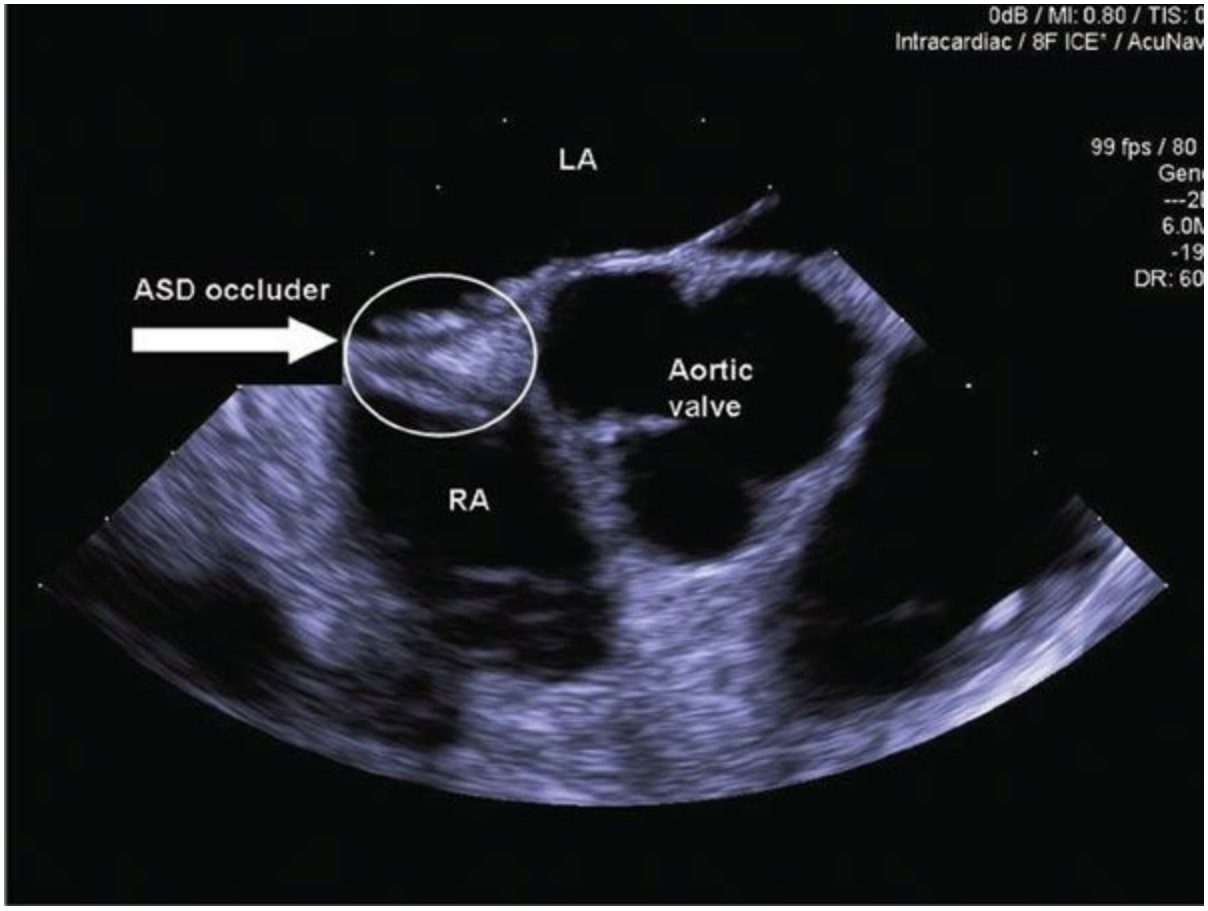

Figure 9.16 An atrial septal defect (ASD) occlusion device is seen positioned across a secundum ASD. The image was acquired using intracardiac echocardiography and consists of a short-axis view of the heart demonstrating the aortic valve and the interatrial septum dividing the left atrium (LA) and right atrium (RA).

TABLE 9-2 Atrial Septal Defects and Associated Lesions

Type of Atrial Septal Defect	Associated Lesions
Secundum	Pulmonic stenosis Mitral valve prolapse Partial anomalous pulmonary venous connection (5%)
Primum	Trileaflet left-sided AV valve aka "cleft" mitral valve LVOT obstruction / RVOT obstruction Pulmonary vascular disease risk highest in Trisomy 21[11]
Sinus venosus	Partial anomalous pulmonary venous connection (right upper pulmonary vein in 80%)
Coronary sinus	Persistent left-sided SVC Partial anomalous pulmonary venous connection

AV, atrioventricular; LVOT, left ventricular outflow tract; RVOT, right ventricular outflow tract; SVC, superior vena cava.

Modified from Warnes et al.[1]

TABLE 9-3 Classification of Ventricular Septal Defects

VSD Type	Synonyms	Location	Echocardiographic Views and Associated Features
Type 1	Conal Supracristal Subarterial Doubly committed juxta-arterial	Below the aortic and pulmonary valves in the conal/outlet septum	Short-axis view VSD flow in the RVOT and just below the aortic valve annulus Aortic valve prolapse is most common in this group due to progressive prolapse of the aortic valve
Type 2	Perimembranous Paramembranous Membranous	Involves the membranous septum and is bordered by an AV valve (commonly the aortic valve)	Parasternal long-axis Aortic valve prolapse may be present Aneurysm formation involving the septal leaflet of the tricuspid valve can accompany complete or partial closure of the VSD
Type 3	Inlet AV canal type	In the inlet portion of the RV septum inferior to the AV valve apparatus	Apical four-chamber/subcostal Left- and right-sided AV valves on the same level Primum ASD + "cleft" mitral valve with mitral regurgitation Gooseneck deformity (elongation) of the LVOT ± LVOT obstruction
Type 4	Muscular	A VSD completely surrounded by muscle Single or multiple Apical, posterior, or anterior	Apical four-chamber/subcostal/PLAX VSDs may occur in association with left-sided obstructive lesions such as bicuspid aortic valve, subaortic stenosis, aortic coarctation

Small VSDs ≤25% of the aortic annulus diameter/main PA <20 mmHg/Q_p:Q_s < 1.2:1. Usually restrictive and do not cause pulmonary arterial, left atrial, or LV dilatation.

Moderate VSDs 25–75% of the aortic annulus diameter/main PA = 35 mmHg/Q_p:Q_s > 1.2:1. Moderately restrictive but can lead to mild-to-moderate pulmonary/LA/LV dilatation.

Large VSDs ≥75% of the aortic diameter are usually nonrestrictive and the LV pressure is directly transmitted to the RV and pulmonary vascular bed. Significantly elevated pulmonary pressures. The majority of patients with large VSDs will develop irreversible pulmonary vascular disease in the first 1–2 y of life.

ASD, atrial septal defect; AV, atrioventricular; LA, left atrium; LV, left ventricle; LVOT, left ventricular outflow tract; PA, pulmonary artery; RV, right ventricle; RVOT, right ventricular outflow tract; VSD, ventricular septal defect.

49. d. Type 4/muscular. When indicated (see also Question 9), percutaneous device closure of a muscular VSD may be performed in VSDs remote (>4 mm) from the tricuspid and aortic valves. Percutaneous VSD closure is NOT approved by the U.S. Food and Drug Administration in the presence of the following:

- High pulmonary vascular resistance and/or irreversible pulmonary vascular disease
- Perimembranous or post-infarction VSDs
- Sepsis or an active bacterial infection
- Contraindications to antiplatelet therapy
- Weight < 5.2 kg

50. b. Bicuspid aortic valve. Aortic coarctation is a common congenital defect that

usually occurs in the region of the ligamentum arteriosus. It is most often discrete but may be associated with diffuse hypoplasia of the aortic arch and isthmus. Bicuspid aortic valve is the most common coexisting anomaly. However, the presence of VSD, PDA, and malformations of the mitral valve apparatus is well documented. Intracranial aneurysms have been reported in 3% to 10% of patients with coarctation of the aorta.[12] There is no association between aortic coarctation and Ebstein anomaly (the latter being associated with right-sided lesions).

51. **b.** 20 mmHg. Intervention for coarctation is recommended in those with a peak-to-peak coarctation gradient greater than or equal to 20 mmHg.[1,4] In the presence of significant collateral vessel blood flow, catheter-based and Doppler systolic gradients may underestimate the degree of obstruction and intervention may be considered with gradients <20 mmHg in this setting.

    The most appropriate intervention for adults with native coarctation of the aorta remains controversial and either surgical or percutaneous intervention may be considered according to anatomy, comorbidities, center outcomes, and patient preference. In most ACHD centers, stenting has replaced balloon dilatation as the percutaneous intervention of choice, although this is not recommended in those with long segments of coarctation, vessel tortuosity, and transverse arch hypoplasia. Early mortality is usually less than 1% for primary operation in aortic coarctation.

52. **d.** Left coronary artery arising from the right sinus of Valsalva.

53. **d.** Spontaneous closure rarely occurs. Coronary fistulae rarely close spontaneously. The most common origin of coronary arteriovenous fistula is the right coronary artery, with a fistulous communication into the RV, RA, or coronary sinus (appearance on echocardiography demonstrated on the next page). Less commonly, it empties into the LV, LA, or PA. Complications may include CHF from left-to-right shunt, bacterial endocarditis, coronary ischemia, and rupture or thrombosis of the fistula. Surgical closure is associated with a good outcome (Fig. 9.17).

54. **e.** Valvular calcification. Both valvular and subvalvular aortic stenoses have male preponderance and may be associated with dilatation of the ascending aorta. The indications and risk of operation are similar. Although aortic regurgitation is more common in subvalvular aortic stenosis, it may also occur in valvular aortic stenosis. Valvular calcification is usually not observed in subvalvular aortic valve stenosis.

55. **c.** Transluminal balloon dilatation is the best treatment option in this case. Subaortic valve stenosis involves the presence of a membranous diaphragm in the LVOT that

creates a turbulent flow across the LVOT. This frequently causes damage to the aortic valve and may cause aortic valve insufficiency. Surgical intervention is recommended for patients with subaortic stenosis and a peak instantaneous gradient of 50 mmHg or mean gradient of 30 mmHg on echo Doppler.[1] Elective surgical resection is also indicated with lesser gradients <30 mmHg in the presence of progressive aortic regurgitation, LV systolic dysfunction (<55%), or dilatation (end-systolic diameter >50 mm). Although recurrences occur, surgical resection is frequently curative. Patients with aortic regurgitation may undergo valve repair at the time of subaortic stenosis resection. AVR would best be avoided unless the valve is severely damaged as it would involve the patient having to have further surgery if a biologic valve or be on long-term anticoagulation if a mechanical valve.

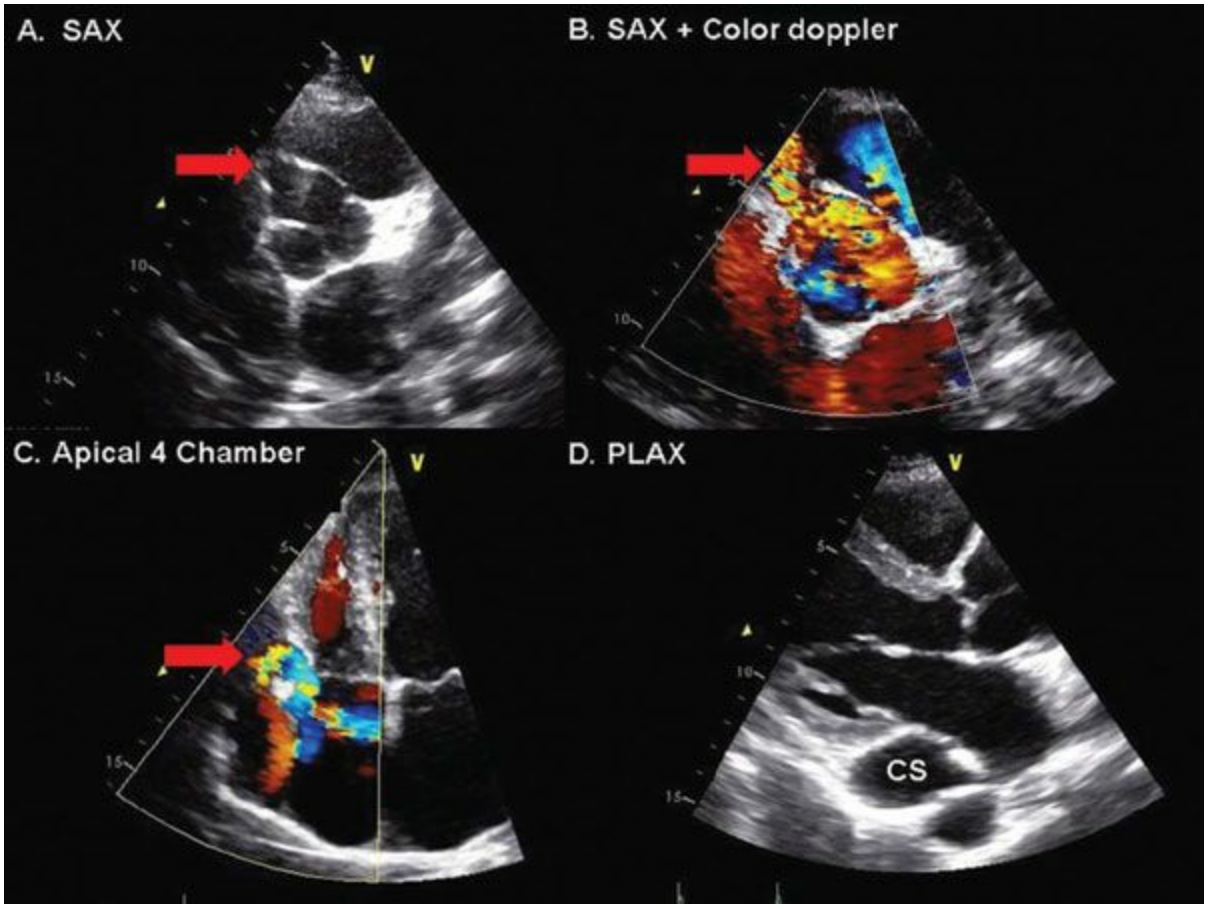

Figure 9.17 The right coronary artery fistula (red arrow) is seen in transthoracic short- axis (SAX) views arising from the right coronary cusp of the aortic valve (**A**) confirmed with color flow Doppler (**B**). In this case, the right coronary fistula drained into the right atrium (**C**) via a dilated coronary sinus (**D**). PLAX, parasternal long axis.

56. **d.** 60 to 80 years. Bicuspid aortic valve is the most common congenital cardiac anomaly with an incidence of 1% to 2% and a male predominance (4:1 sex ratio). Bicuspid aortic valve is sometimes inherited as an autosomal dominant trait with

variable penetrance. Three morphologic types are recognized on the basis of commissural fusion: fusion of the left and right coronary cusps (most common), fusion of the right and non-coronary cusps, and fusion of the left and non- coronary cusps (least common). Sclerosis of the bicuspid aortic valve begins in the second decade and calcification may appear as early as the fourth decade.[13] The peak age range for surgical intervention is between 60 and 80 years.[14] Bicuspid aortic valve disease is associated with intrinsic abnormalities of the aortic media that predisposes to aortic root dilatation/aneurysm/rupture, and/or dissection. Other left-sided lesions associated with bicuspid aortic valve include coarctation of the aorta, subaortic stenosis, parachute mitral valve, VSD, and PDA.

57. e. Regular follow-up with repeat TTE in 6 months. Ebstein anomaly is characterized by apical displacement of the septal tricuspid leaflet of >8 mm/m^2 and the presence of an elongated anterior tricuspid leaflet. The clinical presentation of Ebstein anomaly is influenced by numerous factors including the extent of tricuspid leaflet distortion and regurgitation, the degree of pulmonary stenosis, RA pressure, right heart size, and the presence of a right-to-left shunt. More than 50% of patients have a shunt at the atrial level with either a PFO or secundum ASD. Tricuspid valve repair or replacement is recommended by the AHA for the following indications[1]:

- Symptoms or deteriorating exercise capacity
- Cyanosis (saturations < 90%) due to right-to-left shunting
- Paradoxical embolism
- Progressive RV dilatation or reduction in RV systolic function
- The patient has moderately severe TR with preserved RV systolic function. He has no symptoms and no evidence of CHF. There is no indication for intervention at this time.

58. c. Pulmonary regurgitation. TOF comprises (1) RVOT obstruction, (2) a VSD, (3) an aorta that overrides the VSD, and (4) RV hypertrophy. Primary repair in the first year of life consists of VSD closure and relief of RVOT obstruction, the latter achieved by increasing the RVOT diameter through patch augmentation or placement of a transannular patch. The integrity of the pulmonary valve is frequently disrupted at the time of repair and predisposes patients to pulmonary regurgitation, the most common residual abnormality seen in adults with repaired TOF.

Although less common than pulmonary regurgitation, ventricular tachycardia is an important cause of late mortality in adults with repaired TOF. TOF patients at highest risk for ventricular tachycardia and sudden death include those with

significant residual pulmonary regurgitation/RVOT obstruction, reduced RV or LV function, QRS duration >180 milliseconds, high-grade ectopy on Holter monitoring, and inducible ventricular tachycardia.[15–17]

59. **d.** Cardiac magnetic resonance imaging study. Pulmonary valve replacement is recommended in adults with repaired TOF, severe pulmonary regurgitation, and any of the following[1]:

- Moderate-to-severe RV dysfunction
- Moderate-to-severe RV enlargement (generally defined as >160 to 170 mL/m^2)
- Development of symptomatic or sustained atrial and/or ventricular arrhythmias
- Moderate-to-severe TR

Surgery in adults with repaired TOF may also be considered for residual RVOT obstruction (peak gradient >50 mmHg), residual VSD with shunt greater than 1.5:1, and severe aortic regurgitation with associated symptoms or more than mild LV dysfunction.

Due to the complex geometry of the RV and limitations of echocardiography, cardiac magnetic resonance imaging is the gold standard investigation for assessment of RV dimensions and function in repaired TOF. Further evaluation of pulmonary regurgitation is also possible.

A positive bubble study would be helpful in confirming the presence of an ASD but would not help in deciding timing of pulmonary valve replacement. An ASD is unlikely to explain the degree of RV dilatation seen in this patient, particularly in the presence of a clear etiology (severe pulmonary regurgitation). Formal electrophysiologic testing is not indicated in TOF patients without a history of presyncope or palpitations. Invasive hemodynamics would not provide additional diagnostic or prognostic information. Since there is no evidence of volume overload, the initiation of diuretics and digoxin would not be recommended.

60. **e.** Pulmonary stenosis. The clinical findings (RV lift, a palpable systolic thrill at the second left intercostal space, a widely split second heart sound, and harsh ejection systolic murmur heard loudest at the second left intercostal space) are consistent with significant pulmonary stenosis. The RV lift is evidence of a pressure-loaded RV. The second heart sound is split due to delayed closure of the pulmonary valve. Pulmonary valve stenosis is heard loudest at the second left intercostal space and may be associated with a palpable thrill.

61. **c.** Balloon valvotomy. Echocardiography (TTE ± TEE) generally provides a definitive diagnosis in most patients with pulmonary stenosis. Doppler gradients

from echo are adequate for deciding on the timing of intervention. Cardiac catheterization may be used to confirm the diagnosis of pulmonary stenosis and to exclude pulmonary hypertension in cases where this is a concern.

The cardiac catheterization results confirm RV hypertension (RV systolic pressure 70 mmHg) with a slightly elevated end-diastolic RV pressure (15 mmHg). RV hypertension should be differentiated from pulmonary hypertension: The finding of normal main PA pressures distal to the site of valvar stenosis (+ normal transpulmonary gradient) excludes pulmonary hypertension in this patient. Hence, vasodilator challenge and referral to a pulmonary hypertension are not indicated.

For patients with domed valvular pulmonary stenosis, balloon valvotomy is the treatment of choice. Balloon valvotomy is recommended in patients with a peak instantaneous Doppler gradient greater than 60 mmHg or a mean gradient greater than 40 mmHg (assuming less than moderate pulmonary regurgitation).[1] There is no role for medical therapy in valvular pulmonary stenosis patients who meet criteria for intervention.

62. **d.** All of the above. Protein-losing enteropathy is a condition diagnosed in <5% of Fontan patients,[18] in which protein is lost via the gut resulting in ascites, peripheral edema, and pleural and pericardial effusions. The precise cause of protein-losing enteropathy is unknown, although elevated systemic venous pressures appear to play a role. The diagnosis is made by measuring increased a1-antitrypsin in the stool.

Thromboembolic complications occur in up to 20% of patients with the slow passive flow in the Fontan circuit and the coagulation abnormalities consequent on liver congestion both playing a role.

Atrial tachyarrhythmias are very common in adults after the Fontan operation,[19] the most common type being an atypical form of atrial flutter called "intra-atrial reentrant tachycardia" or IART. IART arises from macroreentrant circuits around surgical scars and patches and tends to be slower than typical flutter. Early recognition and treatment of IART is important for preventing complications such as thromboembolism, hemodynamic instability, syncope, and death. Unfortunately, recurrence of IART is common even in the setting of chronic antiarrhythmic medications and catheter-based ablation.

63. **b.** Weber-Osler-Rendu syndrome. Pulmonary arteriovenous fistula involves direct communication between pulmonary arteries and veins. Most patients have associated Weber-Osler-Rendu syndrome, a condition associated with the presence of multiple telangiectasias. Williams syndrome is associated with mental retardation, elfin facies, and supravalvular aortic and pulmonic stenosis. Bland-Garland-White syndrome involves the anomalous origin of the left coronary artery

from the PA. Kartagener syndrome is associated with situs inversus, sinusitis, and bronchiectasis. Crouzon syndrome is associated with PDA and aortic coarctation (see also Table 9.4).

64. **b.** Pulmonary stenosis. Pulmonary stenosis is the most common cardiac abnormality (40%) seen in patients with Noonan syndrome. Other associations include AVSDs (13.8%), coarctation of the aorta (12.5%), and hypertrophic cardiomyopathy (8.8%).[20] Although less common in Noonan syndrome patients, LVOT obstruction may be due to asymmetric hypertrophy and valvular or supravalvar aortic stenosis.[21]

65. **a.** 22q11.2 microdeletion. See Table 9.4.

TABLE 9-4 Common Chromosomal Abnormalities Seen in Adult Congenital Heart Disease

Chromosomal Abnormality	Syndrome	Cardiac Defects	Extracardiac Manifestations
22q11.2 microdeletion Autosomal dominant	22q11.2 microdeletion syndrome Previously called DiGeorge/CATCH-22	Conotruncal defects Tetralogy of Fallot Truncus arteriosus Interrupted aortic arch Double outlet right ventricle	C–Cardiac defects A–Abnormal facies* T–Thymic hypoplasia C–Cleft palate H–Hypocalcemia + Psychiatric conditions (schizophrenia)
7q11.23 microdeletion Autosomal dominant Defects involving the elastin gene	William syndrome	Pulmonary artery stenosis Supravalvar LVOTO	Elfin facies (small chin, patulous lips, upturned nose, broad forehead), infantile hypercalcemia Short stature "Cocktail" personality
Chromosome 12/PTPN11 gene Autosomal dominant	Noonan syndrome	Dysplastic pulmonary valve stenosis Pulmonary artery stenosis TOF ASD Hypertrophic cardiomyopathy	Short stature, ptosis, hypertelorism, webbed neck, flat chest, pectus deformity, lymphedema, inguinal hernia, undescended/cryptorchid testes Intellectual impairment in 1/3
Trisomy 21	Down syndrome	AVSD VSD Mitral valve prolapse Aortic regurgitation Pulmonary HT	Short stature, characteristic facial appearance Intellectual impairment Atlantoaxial instability Thyroid disorders White blood cell disorders
Monosomy X (45, X) 45 XO karyotype in 50% 45XO/XX mosaics and other X-chromosome abnormalities in the remainder	Turner syndrome	Coarctation of the aorta (postductal) Left-sided obstructive lesions PAPVR without ASD Aortic dissection/rupture Systemic HT	Short stature, webbing of the neck, wide set nipples, small chin, prominent ears, absent pubic hair Intellectual function is grossly intact

ASD, atrial septal defect; AVSD, atrioventricular septal defect; HT, hypertension; LVOTO, LV outflow tract obstruction; PAPVR, partial anomalous pulmonary venous return; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

*hypertelorism, low set ears, micrognathia, small mouth, malformed nose, and down-slanting palpebral fissures

66. **e.** Hypertelorism, bifid uvula, and arterial tortuosity are common features. LDS is an autosomal dominant syndrome caused by transforming growth factor-fl receptor gene mutations and characterized by the triad of (a) arterial tortuosity and aneurysms, (b) hypertelorism, and (c) bifid uvula or cleft palate.[22] Almost all patients with LDS will develop aortic root dilatation that requires early surgical intervention due to the increased risk of dissection and rupture in these patients. Surgical intervention is recommended once the aortic root (or other aortic segments) is >4.0 cm or rapidly expanding (>0.5 cm over 1 year).[23] Other aortic segments and branch vessels may also be involved. While there is overlap in the skeletal manifestations of Marfan syndrome and LDS (both demonstrate joint hyperlaxity, arachnodactyly, pectus deformity, and scoliosis), long limbs and tall stature are not characteristic of LDS.

67. **c.** Shone syndrome. The key learning point is that Shone syndrome/complex describes left-sided obstructive lesions and is therefore not implicated in pulmonary stenosis (Table 9.5).

TABLE 9-5 Adult Congenital Heart Disease Syndromes Associated with Pulmonary Stenosis

Syndrome	Cardiac Defects
Noonan syndrome	Dysplastic pulmonary valve stenosis, pulmonary artery stenosis
	Tetralogy of Fallot, atrial septal defect, hypertrophic cardiomyopathy[21]
Williams syndrome	Pulmonary artery stenosis
	Supravalvar aortic stenosis[24,25]
Shone syndrome	Multilevel obstruction of left ventricular inflow and outflow
	Mitral stenosis (parachute mitral valve, supramitral ring)
	Subvalvular left ventricular outflow tract obstruction
	Valvular outflow tract obstruction
	Coarctation of the aorta[26]
	May be familial
Congenital rubella syndrome	Pulmonary artery stenosis, peripheral pulmonary artery stenosis
	Patent ductus arteriosus
	Non-cardiac: Cataracts, retinopathy, deafness, intellectual impairment[27]
LEOPARD syndrome	Pulmonary stenosis
	Non-cardiac: Café-au-lait spots and multiple lentigines[28]

Physiology/Biochemistry

Amar Krishnaswamy

QUESTIONS

1. At the level of the endothelium, nitric oxide (NO) causes the following:
   a. Promotes smooth muscle relaxation
   b. Reduced leukocyte adhesion
   c. Increased smooth muscle proliferation
   d. Downregulation of oxidative enzymes

2. The following cells are considered most important to the process of atherosclerosis:
   a. Monocyte/macrophage lineage
   b. Platelets
   c. Red blood cells
   d. B cells

3. The following are characteristics of a vulnerable plaque except
   a. high concentration of macrophages.
   b. high concentration of collagen.
   c. neovascularization.
   d. large necrotic core.

4. Arterial thrombosis after plaque rupture is initiated by
   a. tissue plasminogen activator.
   b. factor XIII.
   c. protein C.
   d. activated protein C.
   e. tissue factor.

5. Low levels of gene expression can be detected by

   a. Northern blot.
   b. Western blot.
   c. reverse transcriptase-polymerase chain reaction (RT-PCR).
   d. Southern blot.
   e. gene transfer.

6. The final common pathway of platelet aggregation is mediated through

   a. adenosine diphosphate (ADP) binding.
   b. collagen.
   c. thrombin.
   d. $\alpha_v\beta_3$ receptor.
   e. glycoprotein (GP) IIb/IIIa receptor.

7. Inducers of smooth muscle cell proliferation include the following except

   a. platelet-derived growth factor-β.
   b. basic fibroblast growth factor (bFGF).
   c. transforming growth factor-β (TGF-β).
   d. thrombin.
   e. oxidized low-density lipoprotein (LDL).

8. Inhibitors of cardiac myocyte apoptosis include

   a. insulin-like growth factor-1β.
   b. dobutamine.
   c. ischemia.
   d. caspase 3.
   e. Bid cleavage.

9. The following are endothelium-independent vasodilators except

   a. nitroglycerin.
   b. papaverine.
   c. adenosine.
   d. acetylcholine (ACh).
   e. verapamil.

ANSWERS

1. **C.** Increased smooth muscle proliferation. NO has important effects on the

endothelium to produce vasodilation, reduced leukocyte adhesion and platelet reactivity, and downregulation of oxidative enzymes. Consistent with these beneficial effects, NO results in a reduction in smooth muscle proliferation, not an increase.

2. **b.** Monocyte/macrophage lineage. These cells bind oxidized LDL to form foam cells, which then release proinflammatory cytokines to perpetuate the atherosclerotic process.

3. **b.** High concentration of collagen. It is in fact the low concentration of collagen (due to low levels of smooth muscle cells) that results in the collagen-poor thin cap of vulnerable plaques. These plaques display high concentrations of macrophages (foam cells) and T-lymphocytes (producing interferon-γ), as well as significant neovascularization and a large necrotic core that is vulnerable to rupture and propagate thrombosis. In fact, saphenous vein graft (SVG) lesions tend to have a larger necrotic core than native coronary lesions, which is one factor that contributes to greater plaque friability and worse outcomes with SVG stenting.

4. **e.** Tissue factor. Tissue factor binding to factor VII is the initiating event for the extrinsic blood coagulation cascade. The complex can also cleave factor IX and contribute to activation of the intrinsic cascade as well. Tissue factor is normally not expressed in the vasculature, but, in atherosclerotic vessels, tissue factor is expressed by macrophages and smooth muscle cells. Tissue factor expression is increased in the lesions of patients who present with unstable angina. On plaque rupture, the exposure of tissue factor to blood-borne coagulation factors leads to thrombus formation.

5. **c.** Reverse transcriptase-polymerase chain reaction (RT-PCR). RT-PCR is capable of finding a single copy of RNA. Northern blot analysis requires at least 5 to 10 μg of total RNA. Western blot analysis is for determining protein levels. Southern blot analysis is for genotyping and requires multiple copies of DNA. Gene transfer is not a detection method.

6. **e.** Glycoprotein (GP) IIb/IIIa receptor. ADP, collagen, and thrombin bind independently, leading to platelet activation and, ultimately, to expression of the GP IIb/IIIa receptor. GP IIb/IIIa receptor expression leads to platelet clumping by binding to surrounding activated platelets. The $\alpha_v\beta_3$ receptor does not lead to platelet aggregation.

7. **c.** Transforming growth factor-β (TGF-β). Platelet-derived growth factor-β, bFGF,

and thrombin are all smooth muscle mitogens. Oxidized LDL causes smooth muscle cell proliferation through the autocrine release of bFGF. TGF-β alters the smooth muscle cell phenotype from a proliferative to a synthetic state and, thus, is antiproliferative.

8. **a.** Insulin-like growth factor-1β. Insulin-like growth factor-1β overexpression has been shown to be cardioprotective because of decreased apoptosis in the setting of myocardial ischemia. Dobutamine has been shown to induce cardiomyocyte apoptosis. Caspase 3 and Bid cleavage are cytoplasmic markers of apoptosis, but do not directly influence apoptosis itself.

9. **d.** Acetylcholine (ACh). ACh, acting through muscarinic receptors, exerts its effect on the endothelium by promoting the conversion of L-arginine to NO. This in turn produces smooth muscle cell relaxation and consequent vasodilation. ACh is therefore an endothelium-dependent vasodilator. In patients with endothelial dysfunction, this effect is lost, and the direct action of ACh on smooth muscle cells producing vasoconstriction is more pronounced. The other agents listed are all endothelium-independent vasodilators.

Hypertension

Amanda R. Vest • Leslie S. Cho

QUESTIONS

1. A 35-year-old woman at 24 weeks of pregnancy is found to have several blood pressure readings in the range of 145 to 158 mmHg systolic, 80 to 92 mmHg diastolic. This is her first pregnancy and she has no prior history of hypertension. She reports bilateral mild ankle swelling and nausea, but no right upper quadrant pain, visual changes, headaches, or dyspnea. A 24-hour urine collection shows 360 g protein. The hemoglobin is 8.0 g/dL and the platelet count is 43,000 cells/mm^3. Which of the following is the correct diagnosis?

   a. Chronic hypertension
   b. Gestational hypertension
   c. Preeclampsia
   d. Eclampsia

2. A 42-year-old woman presents for post hospitalization follow-up. She was recently admitted to hospital for 3 days due to sudden-onset dyspnea. Her blood pressure on presentation was 164/98 mmHg. Her examination and chest radiograph were consistent with pulmonary edema. She responded well to intravenous diuretics and was discharged on lisinopril. She has no family history of hypertension. On examination during the clinic visit, her blood pressure is 158/90 mmHg. She is normal in weight and has a normal cardiovascular examination except for a right-sided carotid bruit. Her blood tests are notable for a rise in creatinine from 0.9 to 1.8 mg/dL since hospital discharge. What is the most appropriate follow-up investigation?

   a. Coronary angiogram
   b. Duplex ultrasonography of the renal arteries
   c. Urinary catecholamines

d. 24-Hour urinary-free cortisol

3. An 83-year-old woman presents to cardiology clinic for follow-up of her hypertension and coronary artery disease. Her only current symptom is dizziness on standing from a sitting position. The dizziness caused her to lose balance and fall on two occasions. Her current resting blood pressure is 144/90 mmHg with pulse 60 beats per minute (bpm). Her medications include hydrochlorothiazide 25 mg daily, doxazosin 2 mg daily, metoprolol XL 50 mg daily, simvastatin 40 mg daily, and aspirin 81 mg daily. What changes in medication therapy would you recommend?

   a. Discontinue hydrochlorothiazide and start lisinopril 20 mg daily.
   b. Discontinue atenolol and increase hydrochlorothiazide to 50 mg daily.
   c. Discontinue doxazosin and initiate clonidine 0.4 mg twice daily.
   d. Discontinue doxazosin and start lisinopril 5 mg daily.
   e. Discontinue doxazosin and increase metoprolol to 100 mg daily.

4. A 64-year-old woman with hypertension, stage III chronic kidney disease (CKD), and diabetes is not yet at blood pressure goal on the following antihypertensives: lisinopril 40 mg, hydrochlorothiazide 25 mg, and metoprolol XL150 mg. Which of the following additional agents is contraindicated?

   a. Aliskiren
   b. Hydrochlorothiazide
   c. Amlodipine
   d. Methyldopa

5. A 57-year-old woman with multidrug-resistant hypertension presents to her primary care doctor with multiple complaints. Her antihypertensive regimen consists of valsartan, hydralazine, amlodipine, captopril, and hydrochlorothiazide. Which of the following pairings of medication and side effect are most likely to be correct?

   a. Valsartan and cough
   b. Hydralazine and ankle edema
   c. Amlodipine and insomnia
   d. Captopril and constipation

6. A 19-year-old young man presents with an aortic root diameter of 4.4 cm and a strong family history of aortic dissection. His father died of a type A dissection at age 42, and his older brother recently underwent aortic root repair for an aneurysm measuring 5.6 cm in diameter. Both brothers have the fibrillin-1 gene mutation. The patient currently receives metoprolol 50 mg daily, with a pulse of 55 bpm and

blood pressure measurements in the range of 115 to 125/65 to 75 mmHg. Which additional medication should be added?

a. No additional medications
b. Amlodipine
c. Ramipril
d. Losartan

7. A 62-year-old man with type 1 diabetes mellitus receives intermittent hemodialysis for his end-stage renal disease. His blood pressure has become elevated over the past year and has not reached goal levels despite initiation of three antihypertensive medications. He takes several medications for comorbid conditions, several of which may be exacerbating his elevated blood pressure. Medications for which of the following conditions would not be expected to have a side effect of hypertension?

a. Diabetes
b. Anemia
c. Hyperparathyroidism
d. Glaucoma
e. Osteoarthritis

8. A 58-year-old man with resistant hypertension returns for outpatient follow-up. His blood pressure is 168/79 mmHg and pulse 70 bpm, despite 25 mg hydrochlorothiazide daily, 200 mg metoprolol XL daily, 320 mg valsartan daily, 10 mg amlodipine daily, and a 0.1 mg/24 hour clonidine patch. He is considering entering a sympathetic denervation trial and has some questions about the procedure. Which of the following is the most accurate brief description of the denervation procedure?

a. Access through a femoral vein, cryoablation of a unilateral renal artery
b. Access through a femoral artery, radiofrequency ablation of a unilateral renal artery
c. Access through a femoral vein, radiofrequency ablation of bilateral renal arteries
d. Access through a femoral artery, alcohol ablation of bilateral renal arteries
e. Access through a femoral artery, radiofrequency ablation of bilateral renal arteries
f. At this time renal denervation cannot be recommended for this patient population

9. Which of the following patient characteristics is a risk factor for development of angiotensin-converting enzyme inhibitor (ACEI)-induced angioedema?

a. Diabetes

b. Female gender
c. Age <45 years
d. Age >65 years

10. A 76-year-old man with hypertension has inadequate blood pressure control on chlorthalidone 25 mg daily. His primary care doctor is choosing a second antihypertensive agent. Which of the following comorbidities would be an evidence-based indication for choosing ramipril over amlodipine as the second agent?

a. Heart failure with preserved ejection fraction (HFPEF)
b. Peripheral arterial disease
c. Sleep apnea
d. Aortic aneurysm

11. A 30-year-old man with no past medical history presents to his primary care physician complaining of new-onset morning headaches that have been ongoing for the past few weeks. His blood pressure is noted to be 220/100 mmHg with a gradient between his brachial and popliteal arteries. On auscultation, there is a II/VI systolic crescendo–decrescendo murmur heard across the precordium. His electrocardiogram is significant for left ventricular hypertrophy. A chest X-ray shows cardiomegaly with evidence of rib notching. The patient most likely has what valvular abnormality?

a. Bicuspid aortic valve
b. Mitral regurgitation
c. Tricuspid regurgitation
d. Pulmonary stenosis

12. A 55-year-old man with diabetes mellitus presents to his cardiologist with a blood pressure of 165/95 mmHg. According to the JNC (Joint National Committee) 8 guidelines, what is his target blood pressure measurement?

a. Prehypertension, 140/90 mmHg
b. Stage 2, 130/80 mmHg
c. Stage 1, 140/90 mmHg
d. Stage 2, 110/70 mmHg

13. What is the mechanism of action of the antihypertensive medication aliskiren?

a. ACEI
b. Nonselective β-blockade
c. Angiotensin receptor blocker (ARB)

d. Direct renin inhibitor

14. A 35-year-old woman with no past medical history, not receiving oral contraceptives, and with a family history of hypertension presents with a gradual increase in blood pressure over the past few years. Today in clinic her blood pressure is 155/95 mmHg. What is the most appropriate next step?

a. Patient has essential hypertension; start thiazide diuretic
b. She is asymptomatic; therefore, observe patient and have her follow-up in 1 year
c. Have her follow-up in a few weeks for repeat blood pressure measurements
d. Renal magnetic resonance imaging (MRI)

15. A 68-year-old man with coronary artery disease, hypertension, diabetes mellitus, and stage II hypertension presents for routine follow-up in the cardiology clinic. His blood pressure is 180/100 mmHg. He is compliant with all his medications and is currently on hydrochlorothiazide, lisinopril, metoprolol, amlodipine, and isosorbide mononitrate. He recently has had two episodes of noncardiogenic pulmonary edema in the setting of an ejection fraction of 55% with no evidence of diastolic dysfunction. What is the most appropriate next step in the management of his hypertension?

a. Addition of minoxidil
b. Renal MRI
c. Discussion of medical adherence
d. Addition of hydralazine

16. A 44-year-old woman had a blood pressure of 115/75 mmHg a few years ago. She now has a blood pressure of 155/75 mmHg, which was confirmed on a repeat visit. How much has her risk for cardiovascular disease increased?

a. No change
b. Twofold
c. Fourfold
d. Tenfold

17. Which of the following antihypertensive agents is a known cause of autoimmune hemolytic anemia?

a. Metoprolol
b. Methyldopa
c. Captopril
d. Losartan

18. A patient is initiated on an ACEI. What is the recommended cutoff for rise in creatinine before stopping the medication?

a. 10% increase in creatinine
b. 20% increase in creatinine
c. 35% increase in creatinine
d. 50% increase in creatinine

19. A 68-year-old man with hypertension and history of a stroke presents for further management of his hypertension. He is currently prescribed a thiazide diuretic; however, his blood pressure remains elevated. From the standpoint of decreasing his future risk of stroke, which of the following drug classes would be most beneficial?

a. Calcium channel blocker
b. ACEI
c. ARB
d. β-Blocker

20. A 56-year-old woman presents to your clinic for physical examination. She has no significant past medical history and is asymptomatic. Her vital signs are significant for a blood pressure of 145/95 mmHg. What are the next steps in her evaluation for hypertension?

a. She should return in 1 year for her yearly physical examination.
b. She should have a repeat blood pressure measurement at a later time point during her visit and return in a few weeks to obtain repeat testing if that measurement is elevated.
c. Start patient on thiazide diuretic at the initial clinic visit.
d. Begin evaluation for secondary causes of hypertension.

21. A 45-year-old woman with no significant past medical history is noted to have a blood pressure of 145/90 mmHg in the outpatient clinic. This is confirmed on repeat visits. Which of the following tests would not be indicated at this time?

a. Electrocardiogram
b. Urinalysis
c. Creatinine
d. Urine metanephrines

22. A 26-year-old man with no significant history presents to his primary care physician with complaints of episodic palpitations, morning headaches, and diaphoresis. He denies any illicit drug use. His physical examination is notable for a blood pressure

of 230/120 mmHg. His ophthalmologic examination is significant for AV nicking. What is the most appropriate next step?

a. Toxicology screen
b. Urine metanephrines
c. MRI thorax
d. Start thiazide diuretic with follow-up in 1 month

23. A 65-year-old man with a history of hypertension and dyslipidemia is admitted to the coronary care unit with a diagnosis of a myocardial infarction. He undergoes an emergent cardiac catheterization with insertion of a drug-eluting stent to his left circumflex coronary artery. His vital signs show a blood pressure of 170/90 mmHg with a heart rate of 85 bpm and no evidence of heart failure on examination. Which of the following medications would be most appropriate to treat this patient's hypertension?

a. Amlodipine
b. Verapamil
c. Metoprolol
d. Nitroprusside

24. Which of the following antihypertensive drug classes is most effective at reducing carotid intimal thickness?

a. Calcium channel blocker
b. β-Blocker
c. ACEI
d. Thiazide diuretic

25. What is the long-term antihypertensive mechanism of action for thiazide diuretics?

a. Decreased plasma volume
b. Natriuresis
c. Decreased cardiac output
d. Decreased peripheral resistance

26. A 46-year-old woman, status post orthotopic heart transplantation, is currently taking mycophenolate, prednisone, and tacrolimus as an immunosuppressive regimen. On routine laboratory evaluation, she is found to have leukopenia. Mycophenolate levels have not been elevated in the past few months. Which of the following antihypertensive agents is the most likely culprit?

a. Hydrochlorothiazide

b. Metoprolol
c. Captopril
d. Clonidine

27. A 34-year-old man with isolated essential hypertension presents to clinic and is found to have a blood pressure of 180/100 mmHg after intensive lifestyle modifications. What is the most appropriate next step?

a. Start hydrochlorothiazide.
b. Start hydrochlorothiazide and lisinopril.
c. Repeat blood pressure in 4 weeks.
d. Start amlodipine.

28. A 62-year-old man with isolated essential hypertension, currently taking hydrochlorothiazide 25 mg PO daily, comes to you for his first clinic visit. He notes that his blood pressure at home is always less than 140/80 mmHg, but in clinic it is always at least 155/95 mmHg. What is the next step?

a. Increase dose of thiazide
b. Addition of second antihypertensive medication
c. Do nothing as he has white coat hypertension
d. Evaluate for secondary causes of hypertension

29. A 48-year-old man with diabetes mellitus, hypertension, and hyperlipidemia presents to the emergency room with hypertensive emergency. His mean arterial pressure is 150 mmHg, pulse 58 bpm. The electrocardiogram is notable for sinus bradycardia with PR prolongation (260 milliseconds) and no ST deviations or T-wave abnormalities. Which medications would be the most appropriate therapy for this patient?

a. Intravenous nitroprusside
b. Sublingual nifedipine
c. Intravenous labetalol
d. Intravenous nitroglycerin

30. A 48-year-old obese man with hypertension, dyslipidemia, and diabetes mellitus presents to the outpatient clinic for his yearly physical. He has refused medications in the past, but now is willing to consider treatment. His blood pressure is 145/95 mmHg with a heart rate of 80 bpm. His laboratory data are significant for a creatinine of 1.3 mg/dL with the presence of microalbuminuria. Which of the following mediations would be most appropriate?

a. Carvedilol

b. Lisinopril
c. Chlorthalidone
d. Terazosin

31. A 34-year-old woman with essential hypertension is considering becoming pregnant. Which of the following medications would be absolutely contraindicated to control her blood pressure during pregnancy?

a. Methyldopa
b. Labetolol
c. Captopril
d. Nifedipine

32. A 48-year-old Caucasian man with impaired fasting glucose presents to his physician for a follow-up visit after he was noted to have a blood pressure of 150/95 mmHg. On repeat evaluation his blood pressure is 155/95 mmHg. Which of the following medications would be the least favored?

a. Hydrochlorothiazide 25 mg PO daily
b. Lisinopril 10 mg PO daily
c. Atenolol 25 mg PO daily
d. Chlorthalidone 25 mg PO daily

33. A 65-year-old African American man with isolated hypertension presents to clinic for his yearly physical examination. He is noted to have a blood pressure of 170/95 mmHg. He is currently prescribed lisinopril and metoprolol. Which of the following medication changes would be most appropriate?

a. Continue current medications at increased doses
b. Conversion of patient to a calcium channel blocker and thiazide diuretic
c. Addition of clonidine
d. Stopping lisinopril because of concern for renal artery stenosis

34. A 42-year-old woman with a new diagnosis of diabetes mellitus presents for management of hypertension. She was previously an avid athlete, but over the past few years has noted increased weight gain, a radial fracture after a minor fall, and increasing hirsutism. She is currently on hydrochlorothiazide, amlodipine, and lisinopril. What is the most appropriate next step in the management of this patient's hypertension?

a. Referral to nutrition specialist to assist her with weight loss
b. Addition of clonidine
c. 24-Hour urine cortisol test

d. MRI of the brain

35. A 69-year-old woman with diabetes mellitus and hyperlipidemia and no history of hypertension is noted at her yearly clinic visit to have new-onset hypertension with a blood pressure of 180/110 mmHg. She undergoes screening for secondary causes of hypertension and is found to have a pheochromocytoma. What of the following medications is contraindicated as monotherapy?

a. Metoprolol
b. Lisinopril
c. Phentolamine
d. Hydrochlorothiazide

36. A 42-year-old man presents for a routine physical examination. He is noted to have a body mass index of 30 kg/m^2, impaired fasting glucose, and a blood pressure of 135/85 mmHg. What is the best treatment plan for this individual?

a. Aggressive lifestyle modification
b. Institute thiazide diuretic regimen
c. No treatment at this time
d. Initiate ACEI

37. A 50-year-old man with CKD and hypertension has a blood pressure of 165/110 mmHg. What is this patient's target blood pressure according to the JNC 8 guidelines?

a. 140/90 mmHg
b. 130/80 mmHg
c. 120/80 mmHg
d. 110/70 mmHg

38. A 36-year-old patient, status post heart transplantation, is found to have hypertension. He is currently taking prednisone, mycophenolate, and cyclosporine. Which of the following antihypertensive medications would increase cyclosporine levels?

a. Lisinopril
b. Hydrochlorothiazide
c. Diltiazem
d. Metoprolol

39. A 56-year-old man with resistant hypertension begins to take a new antihypertensive agent. Within the next few weeks he is diagnosed with pericarditis. Which of the

following agents is most likely responsible?

a. Carvedilol
b. Minoxidil
c. Amlodipine
d. Captopril

40. A 27-year-old woman presents to the cardiology clinic for evaluation of uncontrolled hypertension. She was diagnosed 2 years ago and is currently taking hydrochlorothiazide, lisinopril, and amlodipine. She denies nonadherence and has a blood pressure of 170/100 mmHg that is equal in both arms. On routine laboratory examination, she has a potassium level of 2.9 mEq/L with a sodium level of 148 mEq/L. What is the most appropriate diagnostic test?

a. Renal MRI/magnetic resonance angiography
b. Morning renin and aldosterone concentrations
c. Adrenal vein sampling
d. 24-Hour urine cortisol concentration

41. A 58-year-old obese man with hypertension, diabetes mellitus, hyperlipidemia, and recent myocardial infarction presents for his annual physical examination. He is currently prescribed atenolol, hydrochlorothiazide, amlodipine, and quinapril. His blood pressure is at target values. His HbA1c is at goal. However, he has noted increasing lower extremity edema over the past few months and had a near-fatal car accident after falling asleep while driving. His echocardiogram reveals an ejection fraction of 65% with no evidence of diastolic dysfunction. Which of the following management decisions would be most appropriate at this time?

a. Discontinue calcium channel blocker
b. Polysomnography
c. Addition of loop diuretic
d. Maintain current regimen with advisement that his symptoms are typical with aging

42. A 56-year-old man on hydralazine, hydrochlorothiazide, lisinopril, and metoprolol begins to develop a malar rash and arthralgias. Which of the above antihypertensive agents is known to cause drug-induced lupus?

a. Hydralazine
b. Hydrochlorothiazide
c. Lisinopril
d. Metoprolol

43. A 47-year-old man with coronary artery disease, diabetes mellitus, and hypertension is currently taking clonidine. He is found to have a blood pressure of 170/90 mmHg after forgetting to take his medication for 48 hours. What is the best strategy to control his blood pressure?

a. Restart clonidine.
b. Start nitroprusside.
c. Start esmolol.
d. Add thiazide diuretic.

ANSWERS

1. **c.** Preeclampsia. Chronic hypertension is characterized by blood pressure ≤140/90 mmHg present before pregnancy, before the 20th week of gestation, or persisting beyond the 42nd postpartum day. Conversely, gestational hypertension develops beyond 20 weeks of gestation and usually resolves within 42 days postpartum. Preeclampsia is characterized by hypertension presenting beyond 20 weeks of gestation with >300 mg protein in a 24-hour urine collection or >30 mg/mmol in a spot urine sample, although in rare cases hypertension or proteinuria can be absent. Thrombocytopenia in this patient is very concerning for HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets), a life-threatening condition showing significant overlap with preeclampsia. Eclampsia is the occurrence of seizures in a pregnant woman with preeclampsia. Edema is no longer considered to be part of the diagnostic criteria for preeclampsia because it occurs in more than half of normal pregnancies.

2. **b.** Duplex ultrasonography of the renal arteries. This young woman likely has hypertension secondary to fibromuscular dysplasia (FMD). FMD is a noninflammatory, nonatherosclerotic vascular condition typically affecting young women. It most frequently presents with hypertension, transient ischemic attack, stroke, or an asymptomatic cervical bruit. Sudden onset of pulmonary edema and a significant rise in creatinine after ACEI/ARB initiation are also common manifestations and reflect the presence of renal artery stenosis. About 60% to 75% of cases of FMD involve the renal arteries. Duplex ultrasonography is a noninvasive investigation that is highly specific and sensitive for renal artery stenosis, whether the stenosis is caused by atherosclerosis or FMD, and therefore is often the first test for diagnosis of this condition. Duplex ultrasonography of the carotids would also have been a good choice in this patient given the presence of a carotid bruit. The classic "string-of-beads" appearance of the arteries may be seen on angiography. The clinical history is not suggestive of pheochromocytoma

(Answer c) or Cushing syndrome (Answer d).

3. **d.** Discontinue doxazosin and start lisinopril 5 mg daily. The likely culprit of this patient's postural dizziness and falls is doxazosin. Elderly patients are more susceptible to drug side effects and management of hypertension should take into account such symptoms. Doxazosin demonstrated less effective blood pressure lowering than a thiazide in the antihypertensive and lipid lowering treatment to prevent heart attack trial (ALLHAT) study and was associated with excess cardiovascular events and incident heart failure. It would therefore be appropriate to discontinue doxazosin. There is minimal additional efficacy increasing from 25 to 50 mg of hydrochlorothiazide. The β-blocker should be continued due to the coronary artery disease history, but increasing to 100 mg metoprolol risks bradycardia. Clonidine 0.4 mg twice daily would also lower the heart rate and would be an excessive dose for initiation in an elderly patient who is already near blood pressure goal. The JNC recommendation of a "start low, go slow" approach in the elderly is intended to limit drug side effects, including hypotension. The discontinuation of doxazosin and initiation of 5 mg lisinopril is therefore the most appropriate option.

4. **a.** Aliskiren. The U.S. Food and Drug Administration issued a black box warning in 2012 that aliskiren should not be used with ACEIs or ARBs in patients with diabetes, because of the risk of renal impairment. There is also a warning to avoid the use of aliskiren with ACEIs or ARBs in patients with a glomerular filtration rate <60 mL/min. Conversely, methyldopa usually does not reduce glomerular filtration rate, renal blood flow, or filtration fraction. Normal or elevated plasma renin activity may decrease during methyldopa therapy. Hydrochlorothiazide may be a useful addition in stage III CKD but is unlikely to be effective in patients with a glomerular filtration rate <30 mL/min. Amlodipine is also a reasonable add-on medication to consider in this scenario.

5. **b.** Hydralazine and ankle edema. Vasodilatory lower extremity edema is most commonly seen with direct arteriolar dilators such as hydralazine and minoxidil. Dihydropyridine calcium antagonists, such as amlodipine, and α-adrenergic antagonists, such as doxazosin, are also associated with extremity edema. ACEIs are associated with an approximate 20% incidence of cough, which is purported to be bradykinin mediated. Angiotensin receptor antagonists, such as valsartan, do not directly inhibit angiotensin-converting enzyme activity or inhibit the breakdown of bradykinin. However, there are reports of angiotensin receptor antagonist-associated cough, but the incidence, severity, and frequency of dry cough in patients receiving valsartan or losartan are equivalent to those receiving placebo. Sleep

disturbance is a side effect of β-blockers, especially those that cross the blood-brain barrier (e.g., propranolol and metoprolol). Constipation is a frequent side effect of verapamil.

6. **d.** Losartan. Both brothers carry the gene mutation for Marfan syndrome; presumably their father's fatal aortic dissection was also a result of this connective tissue disease. Recent data suggest that the ARB losartan may slow the progression of aortic root dilatation in Marfan syndrome. Initially promising animal model studies demonstrating the benefits of transforming growth factor-beta pathway blockade by losartan have now translated into human clinical trials demonstrating benefit for patients with Marfan syndrome. In a randomized controlled trial of 233 Marfan patients, aortic root dilatation rate per MRI was significantly lower in the losartan group, when compared with controls, at a mean of 3-year follow-up.

7. **a.** Diabetes. There are no established links between hypertension and oral or subcutaneous therapies for diabetes. However, all four other conditions can be treated with medications that may be iatrogenic causes or contributors to hypertension. Approximately 20% to 30% of patients who receive erythropoietin intravenously for anemia of CKD develop an elevation in diastolic pressure of 10 mmHg or more. Secondary hyperparathyroidism is common in CKD patients, and cinacalcet can lower parathyroid hormone levels by increasing the sensitivity of the calcium-sensing receptor to extracellular calcium. However, hypertension is an adverse effect in approximately 7% of patients. Systemic absorption of ophthalmic drops is limited, but α-adrenergic agonists such as brimonidine may raise the pulse and blood pressure. Nonsteroidal anti-inflammatory medications such as ibuprofen are a common cause of fluid retention and hypertension exacerbation, especially for patients with renal dysfunction.

8. **e.** Access through a femoral artery, radiofrequency ablation of bilateral renal arteries. Current renal denervation catheters are introduced via standard femoral artery access. These catheters have a radiofrequency energy electrode tip that delivers a series of 2-minute ablations along the lumen of each renal artery to disrupt the sympathetic nerve fibers. Symplicity HTN-2 was a randomized, controlled trial comparing 54 patients receiving standard medical therapy for resistant hypertension with 52 patients who underwent percutaneous renal sympathetic denervation. The denervation group demonstrated a mean 32/12 mmHg blood pressure reduction at 6 months, compared with a 1/0 mmHg reduction in controls. However, the larger Symplicity 2 study did not show any difference. Thus, at this time, renal denervation cannot be recommended as therapy.

9. **b.** Female gender. ACEIs are the leading cause of drug-induced angioedema in the United States because they are so widely prescribed, accounting for 20% to 40% of all emergency room visits for angioedema. ACEIs induce angioedema in approximately 0.2% of recipients and the risk appears equivalent between the different ACEI medications. Severe reactions can be observed many months or even years after initiation of ACEI therapy. One large Veteran's Affairs study by Miller et al. documented an almost fourfold higher rate of ACEI angioedema in blacks compared with whites, a 50% higher rate in women and a 12% lower rate in patients with diabetes. Patient age quartiles were unassociated with angioedema risk.

10. **b.** Peripheral arterial disease. There is now evidence to support the specific use of ramipril in patients with peripheral arterial disease and intermittent claudication. Ramipril has been associated with a significant increase in pain-free and maximum treadmill walking times at 6 months, as compared with placebo. Relative to placebo, ramipril also significantly improved the physical functioning component of a quality of life score. Although blood pressure control is an important management component for hypertensive patients with HFPEF, there is no compelling evidence for superiority of one medication over another in this setting. There is also no strong evidence to guide a specific antihypertensive choice for a patient with sleep apnea, although the presence of increased sympathetic nerve activity and a nocturnal diuresis in sleep apnea patients may explain reports that β-blockers tend to lower blood pressure more than thiazide diuretics in this setting. β-Blockers and ACEIs or ARBs are commonly used for blood pressure control in patients with aortic aneurysms.

11. **a.** Bicuspid aortic valve. This young man has a classic presentation of coarctation of the aorta. This secondary cause of hypertension is the result of stenosis of the aorta, usually at the embryonic site of the ligamentum arteriosum and is typically distal to the origin of the left subclavian artery. The presentation in adulthood is varied and is twice as common in men. Symptoms of hypertension or congestive heart failure are common. The electrocardiogram is characterized by left ventricular hypertrophy. Right ventricular hypertrophy is common if a concomitant ventricular septal defect is present. The most common associated valvular abnormality is a bicuspid aortic valve seen in 22% to 42% of cases. Intracranial aneurysms are seen in up to 10% of cases. Patients will often have a characteristic systolic precordial murmur secondary to the development of collateral arteries. Long-term management involves surgical or transcatheter correction. Patients will often continue to have systemic hypertension after repair and should be treated accordingly.

12. **b.** Stage 2, 130/80 mmHg. The most recent JNC 8 guidelines recommend that patients with diabetes have blood pressure goal of less than 140/90 mmHg based on the large ACCORD-BP (Action to Control Cardiovascular Risk in Diabetes — Blood–Pressure-lowering arm) study. The new guideline makes no distinction between patients with CKD or diabetes mellitus with no or with otherwise uncomplicated hypertension in patients less than 60 years of age. The most controversial aspect of the new guideline involves patients >60 years whose treatment goal is now <150/90 mmHg if they have no CKD or diabetes mellitus.

13. **d.** Direct renin inhibitor. Aliskiren is a direct renin inhibitor. The renin enzyme controls the rate-limiting step in the generation of angiotensin II. Aliskiren reaches peak concentration in 2 to 4 hours with a half-life of 24 to 36 hours. It is 50% protein bound. Diarrhea is the most common side effect occurring in up to 9.5% of patients. A dose of 150 mg daily will decrease systolic blood pressure on average 12.5 mmHg with a further 2.7 mmHg decrease when the dose is increased to 300 mg PO daily as compared with placebo. Aliskiren has been shown to have similar blood pressure-lowering effects when compared with thiazide diuretics as well as ACEIs. However, to date there are limited data on the effect of aliskiren on hypertension-induced end-organ damage and clinical outcomes.

14. **a.** Patient has essential hypertension; start thiazide diuretic. The patient likely has essential hypertension. The age of onset is typically between the early 20s to the late 50s. The presence of a family history of hypertension, the mild elevation in blood pressure, and the gradual onset make the diagnosis of essential hypertension more likely. First-line therapy in this individual, assuming she is not trying to become pregnant, is the use of a thiazide diuretic. Reevaluation in 1 year would not be appropriate, given the long-term complications associated with uncontrolled hypertension. A repeat evaluation in a few weeks is not necessary, given the documented hypertension over the past few years. The presence of unilateral renal artery stenosis from vascular hyperplasia is a possibility; however, the clinical history is most consistent with essential hypertension.

15. **b.** Renal MRI. The distinction between essential hypertension and secondary causes is critical in the management of a patient with long-standing hypertension that is difficult to control. In this scenario, the inability to control the patient's blood pressure with multiple medications increases the pretest probability of a secondary etiology. In this individual, the presence of multiple cardiac risk factors, along with repeat episodes of noncardiogenic pulmonary edema, suggests the diagnosis of bilateral renal artery stenosis. Addition of further antihypertensive medications would be indicated, but not prior to initiating a workup for renal artery stenosis. A

renal MRI would be the most appropriate of the mentioned answers.

16. **b.** Twofold. Increasing blood pressure beginning at 115/75 mmHg is noted to be a risk factor for stroke, heart failure, and myocardial infarction. For every 20 mmHg increase in systolic blood pressure and for every 10 mmHg in diastolic blood pressure, there is a twofold increase in the risk of cardiovascular disease. For the above patient, her risk of cardiovascular disease has increased by twofold.

17. **b.** Methyldopa. The central α-agonist methyldopa is known to cause an autoimmune hemolytic anemia in up to 20% of patients taking the medication. Other common side effects include sedation, insulin resistance, and galactorrhea. Methyldopa is not a first-line agent for treatment of hypertension and is usually reserved for pregnant patients and those with resistant hypertension.

18. **c.** 35% increase in creatinine. According to the JNC 7 guidelines, patients initiated on an ACEI should be continued on that medication unless the creatinine increases by more than 35% or another indication for discontinuation presents itself.

19. **a.** Calcium channel blocker. The Blood Pressure Lowering Treatment Trialist Collaboration Study found that calcium channel blockers provided a greater benefit in the reduction of stroke when compared with other antihypertensive agents. However, there was no difference in cardiovascular mortality or overall cardiovascular events.

20. **b.** She should have a repeat blood pressure measurement at a later time point during her visit and return in a few weeks to obtain repeat testing if that measurement is elevated. The JNC 7 guidelines suggest that the diagnosis of hypertension requires at least two separate blood pressure measurements during a clinic visit. The patient should be resting in a chair for at least 5 minutes and should have her arm supported at heart level when the blood pressure is measured. Blood pressure measurements should be evaluated in the contralateral arm and while standing as well. Elevations in blood pressure should be confirmed in a timely manner on a repeat visit, the timing of which is dependent on the level of hypertension and the presence of comorbid conditions. The patient in this vignette has mild isolated hypertension and should return in a few weeks (6 to 8 weeks). Those with more elevated blood pressure should return sooner. Antihypertensive medications should not be initiated on this initial visit as diurnal variations in blood pressure are common and she may not have hypertension. Ambulatory monitoring of blood pressure should be attempted. An evaluation for secondary cause is premature as the diagnosis of hypertension is not confirmed. Waiting to reevaluate the patient in

1-year time is unacceptable, as hypertension, if left untreated, increases the risk of stroke, myocardial infarction, heart failure, and renal insufficiency.

21. **d.** Urine metanephrines. The initial assessment of any patient with a new diagnosis of hypertension requires evaluation for evidence of hypertension-induced end-organ damage. All patients with a new diagnosis of hypertension should have the following testing: serum hematocrit, blood urea nitrogen, serum creatinine, serum potassium, serum calcium, blood glucose, an electrocardiogram, an ophthalmologic examination, a fasting lipid panel, and a urinalysis. Evaluation for secondary causes of hypertension should be limited to those with uncontrolled hypertension after treatment.

22. **b.** Urine metanephrines. This patient's medical history is consistent with a diagnosis of pheochromocytoma. Pheochromocytomas arise from chromaffin cells. These tumors are most commonly found in the adrenal glands, but may be present anywhere there are sympathetic nerves. Classic symptoms are episodic palpitations, headaches, and diaphoresis. Rarely, patients may present with orthostatic hypotension. Initial diagnostic testing would involve the evaluation of a urine specimen for urine metanephrines. A toxicology screen is not indicated given his clinical history. An MRI of the abdomen would be helpful to evaluate for intra-abdominal masses, but an MRI of the thorax would be of limited benefit. Starting a thiazide diuretic would be beneficial, but ultimately the patient requires surgical therapy for correction of his hypertension.

23. **c.** Metoprolol. The initial choice of antihypertensive medication in this patient should be a β-blocker. Multiple studies have shown the benefit of β-blockers in the post-myocardial infarction period. The morphine in acute myocardial infarction (MIAMI-1) and International Study of Infarct Survival (ISIS-1) trials in the fibrinolytic era both showed trends toward a decrease in mortality with the use of intravenous β-blockers. The clopidogrel and metoprolol in myocardial infarction (COMMIT) trial found decreases in the rate of reinfarction and ventricular fibrillation with intravenous metoprolol followed by oral metoprolol; however, there was a 30% increase in the risk of cardiogenic shock. A meta-analysis of the post-myocardial infarction use of β-blockers has shown up to a 40% decrease in cardiovascular mortality. The American Heart Association 2013 ST-segment elevation myocardial infarction (STEMI) guidelines recommend initiation of oral β-blockers in the first 24 hours, providing that heart failure signs, evidence of a low-output state, risk factors for cardiogenic shock, or other contraindications to β-blockers are absent. However, intravenous β-blockers carry a class IIa indication in STEMI, given the concern for possible complications.

24. **a.** Calcium channel blocker. Calcium channel blockers are the most effective of the antihypertensive regimens at reducing carotid atherosclerosis. Studies comparing various calcium channel blockers with thiazide diuretics, ACEIs, and β-blockers have shown that calcium channel blockers have greater ability to decrease carotid intimal thickness.

25. **d.** Decreased peripheral resistance. The initial mechanism of action for lowering blood pressure is a decrease in plasma volume secondary to natriuresis. This triggers an increase in the activity of the rennin-angiotensin system, resulting in a return of plasma volume to normal. However, there is a long-term decrease in peripheral resistance that produces the chronic antihypertensive effects of thiazide diuretics.

26. **c.** Captopril. Aside from mycophenolate, the ACEI captopril is the most likely cause of this patient's leukopenia. When immunosuppressive therapy is combined with ACEIs, there are reports of the development of anemia, neutropenia, leukopenia, and agranulocytosis. The best treatment strategy in this patient would be to use an alternative antihypertensive agent and monitor blood counts closely.

27. **b.** Start hydrochlorothiazide and lisinopril. The most appropriate initial step in the management of the patient in this clinical vignette is the initiation of two antihypertensive medications as recommended in the JNC 7 guidelines. In general, if patients have a blood pressure of greater than 20/10 mmHg above goal, they should be initiated on two antihypertensive agents because monotherapy will typically be ineffective in achieving target blood pressure. Most patients should be started on a thiazide diuretic when commencing treatment of hypertension, as confirmed by the results of the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack trial. Care should be taken in patients at risk for hypotension, specifically elderly patients, those with diabetes, and those with autonomic dysfunction.

28. **c.** Do nothing as he has white coat hypertension. The patient in the above clinical vignette has a diagnosis of white coat hypertension. It is defined as a clinic blood pressure of >140/80 mmHg in at least three clinic settings, with blood pressure measurements of <140/80 mmHg in at least two nonclinic settings, and with absence of end-organ damage. Multiple studies have been undertaken to evaluate if isolated elevations in blood pressure in the medical setting are associated with increased cardiovascular events. A 10-year follow-up study comparing cardiovascular events between patients with white coat hypertension and those with sustained hypertension found worse outcomes in those with sustained hypertension.

The risk of myocardial infarction was two times greater and the risk of a cerebral vascular event was four times greater in the sustained hypertension group. Comparison of normotensive patients with those with white coat hypertension has noted a greater prevalence of left ventricular hypertrophy in the white coat hypertension group. However, there are no clear data that white coat hypertension increases long-term cardiovascular events. Treatment of white coat hypertension is associated with decreases in clinic blood pressure with no significant decrease in ambulatory blood pressure. Patients with white coat hypertension should be monitored closely for development of sustained hypertension, but do not need to be initiated on antihypertensive therapy.

29. **a.** Intravenous nitroprusside. Treatment of hypertensive emergency requires the use of intravenous medications to decrease the mean arterial blood pressure by 25% in the first few hours. Lower target blood pressure goals increase the risk of inducing a cerebral vascular event from decreased cerebral perfusion. Sublingual nifedipine is no longer used for hypertensive emergencies due to its dramatic and unpredictable blood pressure–lowering effects and the associated adverse clinical outcomes. Nitroprusside, labetalol, and nitroglycerin are all reasonable options. However, given the rapid onset and offset of nitroprusside, and the evidence of conduction delay that may limit labetalol use, nitroprusside would be the most appropriate medication for rapid and safe titration of blood pressure.

30. **b.** Lisinopril. The patient in the vignette has a target blood pressure of 130/80 mmHg according to the JNC 7 guidelines. The correct choice of initial blood pressure medication in this patient would be an ACEI. The ALLHAT study suggested that patients with diabetes mellitus have better long-term outcomes when using a thiazide diuretic compared with an ACEI. However, the patient in this vignette has evidence of protein in his urine. JNC 7 recommends that a thiazide diuretic should be first-line therapy, unless there is a specific indication. In this patient, the presence of proteinuria and diabetes mellitus makes the choice of an ACEI a better option than the thiazide. α-Blockers are not considered first-line therapy in hypertensive patients. In the ALLHAT study, there was an increased incidence of heart failure when comparing the α-blocker group (doxazosin) with the thiazide group.

31. **c.** Captopril. ACEIs and ARBs are contraindicated during pregnancy, because of the increased risk of congenital malformations. Methyldopa is the medication most commonly used to control blood pressure in pregnancy. There is significant evidence that it does not produce any harmful outcomes to the fetus. β-Blockers have been used in pregnancy with what appear to be safe results. However, the data

are contradictory. There is some evidence that β-blockers, especially when used early in pregnancy, may increase the risk of fetal bradycardia, hypoglycemia, small placental weight, and a small-for-gestational-age fetus. Calcium channel blockers have been used in pregnancy without deleterious results, but the number of published cases is small. In general, methyldopa is the safest antihypertensive during pregnancy. β-Blockers and calcium channel blockers may be used with caution. ACEIs and ARBs are absolutely contraindicated due to teratogenic effects including renal dysplasia and intrauterine growth restriction.

32. **c.** Atenolol 25 mg PO daily. The least effective option is atenolol. The ALLHAT study showed that the use of thiazide diuretics as first-line therapy for treatment of uncomplicated hypertension was as effective as, if not superior to, amlodipine and lisinopril in preventing fatal coronary artery disease and nonfatal myocardial infarction. The choice of an ACEI would be reasonable, given the presence of glucose intolerance. β-Blockers would not be indicated as first-line therapy in this patient. Multiple meta-analysis comparing β-blockers with placebo or other antihypertensive agents have shown no statistically significant decreases in mortality, myocardial infarction, and stroke. The Anglo Scandinavian Cardiac Outcomes Trial (ASCOT) trial comparing atenolol with amlodipine found a 23% greater risk of stroke in the atenolol group versus the amlodipine-based regimen.

33. **b.** Conversion of patient to a calcium channel blocker and thiazide diuretic. Analysis of the clinical trials in hypertension has noted that there are differences in the effectiveness of antihypertensive medications between different ethnic groups. African Americans are more responsive to calcium channel blockers and thiazide diuretics than other antihypertensive agents. This patient is on an ACEI and a β-blocker. Altering his regimen to include more effective antihypertensive agents would be indicated rather than increasing his medications, adding additional medications, or evaluating him for secondary causes of hypertension. The new JNC 8 guidelines make recommendation of medication based on the race of the patient.

34. **c.** 24-Hour urine cortisol test. This patient's medical history is consistent with a secondary cause of hypertension, in particular, Cushing syndrome. This syndrome is characterized by an excess of cortisol. It may be secondary to a pituitary tumor/hyperplasia (Cushing disease), an adrenal tumor, or ectopic adrenocorticotropic production. Clinical manifestations include diabetes mellitus, hypertension, obesity, hypokalemia, osteoporosis, and fungal infections. The initial step in diagnosis is a 24-hour urine free cortisol test. Treatment is surgical.

35. **a.** Metoprolol. Pheochromocytoma is a rare cause of hypertension. Treatment

ultimately requires surgical removal. The use of β-blocker monotherapy is contraindicated as part of the medical management of pheochromocytomas. The catecholamines secreted by these tumors activate both peripheral α- and β-receptors. Blockage of these peripheral β-receptors results in unopposed α-activation. This can result in severe hypertension. Typical medical management of pheochromocytomas involves the use of antihypertensives with α-blocking capability. For example, prazosin or phenoxybenzamine may be used. Only once α-blockade is established should the use of a β-blocker be entertained.

36. **a.** Aggressive lifestyle modification. Patients with prehypertension are at increased risk for cardiovascular events compared with normotensive individuals; therefore, care of these patients should be focused on aggressive control of all cardiovascular risk factors. Analysis of the Women's Health Initiative compared cardiovascular outcomes in prehypertension patients with normotensive patients and found that the prehypertension patients had hazard ratios indicating a 1.58 (95% confidence interval [CI], 1.12 to 2.21) greater risk for cardiovascular death; 1.76 (95% CI, 1.40 to 2.22) greater risk for myocardial infarction; 1.93 (95% CI, 1.49 to 2.50) greater risk for stroke; 1.36 (95% CI, 1.05 to 1.77) greater risk for hospitalized heart failure; and a 1.66 (95% CI, 1.44 to 1.92) greater risk for any cardiovascular event. Not only are these patients at increased risk for cardiovascular events, but they also have a high incidence of hypertension development. In the Trial of Preventing Hypertension (TROPHY) trial, patients with prehypertension were randomized to candesartan or placebo. Over a period of 4 years, 67% of the untreated group developed hypertension as defined by the JNC 7 guidelines. These data suggest that patients with prehypertension are a high-risk population and should be treated aggressively. According to the JNC 7 guidelines, these individuals should increase their activity level, modify their diet, avoid excessive alcohol, and attempt weight loss. Initiation of antihypertensive medications should be reserved for those who progress to evident hypertension.

37. **a.** 140/90 mmHg. JNC 8 guidelines recommend that in patients with CKD or diabetes mellitus, the target blood pressure should be <140/90 mmHg.

38. **c.** Diltiazem. Patients who have undergone heart transplantation often have preexisting hypertension or develop hypertension subsequent to the heart transplant. This is a unique patient population as many of the immunosuppressive medications used after transplantation have multiple drug interactions. With respect to antihypertensive agents, most if not all calcium channel blockers have been shown to increase cyclosporine levels. Diltiazem and verapamil, in particular, are potent inhibitors of protein P-glycoprotein and CYP3A4. These enzymes are critical for

the metabolism of diltiazem, and their inhibition can increase cyclosporine levels up to sixfold. It is recommended that patients who require diltiazem and are on cyclosporine have their cyclosporine dose decreased by 25% to 50%. Diltiazem can also increase tacrolimus levels.

39. **b.** Minoxidil. Pericarditis is a known complication of the direct vasodilator minoxidil often accompanied by a pericardial effusion. Its other major side effect is hirsutism. Prompt withdrawal of the medication once the diagnosis of a pericardial effusion or pericarditis is made is recommended. Minoxidil is a potent peripheral vasodilator and is typically reserved for patients with severe or difficult-to-control hypertension.

40. **b.** Morning renin and aldosterone concentrations. The patient in this vignette has secondary hypertension from Conn syndrome. This is primary hyperaldosteronism from uncontrolled secretion of aldosterone. Classic laboratory findings include hypokalemia and mild hypernatremia. The initial diagnostic test of choice is an aldosterone-renin ratio. A ratio of >20 is considered diagnostic. In this patient, the presence of lisinopril complicates the testing. ACEIs are known to decrease renin levels, and ideally the test should be done in the early morning after withdrawal of ACEI therapy. Adrenal vein sampling would be helpful in the diagnosis of primary hyperaldosteronism; however, it is not the initial test of choice. A 24-hour urine test would be more appropriate if Cushing syndrome were suspected. The patient's clinical description is not consistent with this diagnosis. The presence of FMD should be suspected in any young woman with suspected secondary hypertension. However, the laboratory abnormalities are more suggestive of Conn syndrome than renal artery stenosis.

41. **b.** Polysomnography. The patient's clinical history is consistent with the presence of obstructive sleep apnea; therefore, polysomnography (an overnight sleep study) would be the best option. Multiple studies have found evidence for increased risk of hypertension in patients with obstructive sleep apnea. There is no definitive evidence that treating patients with sleep apnea can lower blood pressure; however, there is an increasing hypertension risk as the number of overnight apneic episodes increases. Patients with >30 apnea or hypopnea episodes per hour have an odds ratio of 1.37 of developing hypertension versus those patients with <1.5 apnea or hypopnea episodes per hour.

42. **a.** Hydralazine. Hydralazine is known to cause a lupus-like syndrome in 5% to 20% of patients taking the medication. This syndrome is characterized by arthralgias, myalgias, pericarditis, fever, and rash. Lisinopril, metoprolol, and

hydrochlorothiazide are not known to induce lupus. Other side effects of hydralazine include nausea, vomiting, tachycardia, anorexia, flushing, and diarrhea. Treatment of hydralazine-induced lupus involves withdrawal of the medication.

43. a. Restart clonidine. Rebound hypertension is a known complication of clonidine. Immediate treatment of clonidine withdrawal involves reinstitution of therapy with a slow taper. The mechanism of action is thought to be an increase in sympathetic nervous system activity.

Hyperlipidemia

Michael B. Rocco

QUESTIONS

1. Familial hypercholesterolemia (FH) is a common autosomal dominant disorder resulting from mutations leading to impaired hepatic clearance of low-density lipoprotein (LDL) from the circulation. All of the following statements are true regarding heterozygous FH except that

   a. it occurs in 1 in 5,000 persons.
   b. it is associated with serum low-density lipoprotein cholesterol (LDL-C) two to three times above the average.
   c. it is associated with four- to sixfold increased risk of premature coronary heart disease (CHD).
   d. without treatment, the average age for development of symptomatic CHD is 45 years in men and 55 years in women.
   e. ninety percent of FH heterozygotes exhibit detectable xanthomas on the extensor tendons of the hands or on the Achilles tendons by the age of 39.

2. Phenotypic presentation of FH has been demonstrated to be caused by various mutations associated with all but one of the following:

   a. Defects in the hepatic LDL receptor (LDL-R)
   b. Defects in apolipoprotein B (apoB)
   c. Loss-of-function mutation of PCSK9
   d. Loss-of-function mutation of LDLRAP1

3. A 31-year-old man is referred to you for hyperlipidemia assessment. He has no previous cardiovascular history himself and denies any first-degree relatives with a history of CHD although his father and paternal uncle are treated for elevated

cholesterol and triglycerides (TGs). He reports that two uncles and a cousin have had heart attacks at young ages. His physical examination reveals a body mass index (BMI) of 32, arcus cornea and xanthelasmas but no xanthomas, and a blood pressure (BP) of 150/80 mmHg. His fasting lipid profile is as follows: total cholesterol (TC) 300 mg/dL, TGs 430 mg/dL, high-density lipoprotein cholesterol (HDL-C) 50 mg/dL, direct LDL-C 202 mg/dL. Fasting blood glucose is 112 mg/dL. Which primary dyslipidemia is this patient most likely to have?

a. Polygenic hypercholesterolemia
b. Heterozygous FH
c. Familial combined hyperlipidemia
d. Hyperapobetalipoproteinemia
e. Familial endogenous hypertriglyceridemia

4. Which of the following statements regarding FH is NOT true?

a. The Food and Drug Administration (FDA) indications for LDL apheresis after maximal tolerated pharmacologic therapy include (a) homozygous FH patients and (b) heterozygous FH in the absence of CHD when LDL-C ≥300 mg/dL and in the presence of CHD when LDL-C ≥200 mg/dL.
b. Mipomersen (which inhibits the translation of apoB100 mRNA, thus blocking the production of apoB100 and formation of very low-density lipoprotein [VLDL] and LDL particles) lowers LDL-C by 28% to 36% in individuals with homozygous and heterozygous FH.
c. TC levels are generally >600 mg/dL with LDL-C levels 6- to eightfold higher than average in individuals with homozygous FH.
d. Lomitapide has been approved to treat homozygous and heterozygous FH.
e. Simon Broome Register Group criteria for definite FH requires (a) TC >290 mg/dL in adults or TC >260 mg/dL in children under 16 years OR LDL-C >190 mg/dL in adults or >155 mg/dL in children PLUS (b) tendon xanthomas in the patient, or first- or second-degree relative OR DNA-based evidence of mutations such as LDL-R mutation or familial defective apoB100.

5. Recent statistics from the American Heart Association (AHA) Statistical Update in 2014 report that all of the following regarding dyslipidemia in the United States are true EXCEPT that

a. 98,900,000 U.S. adults over 20 years of age have elevated TC >200 mg/dL (43.4%).
b. 35.8% of adults have LDL >130 mg/dL (71 million adults).
c. 48.7 million adults (21.8%) have HDL <40 mg/dL.
d. National Health and Nutrition Examination Survey (NHANES) data through

2006 reported that 10.3% of adolescents (12 to 19 years) have abnormal lipid levels.

e. inadequate control of dyslipidemia is responsible for 4 million yearly deaths worldwide and 350,000 in the United States.

f. 68.2% of adults and 31.8% of children/adolescents are overweight or obese.

6. Many randomized clinical trials (RCTs) and meta-analyses have contributed to the lipid management guidelines over the past two decades. Which of the following statements is NOT correct?

   a. PROVE-IT/TIMI-22 showed that individuals post myocardial infarction (MI) treated with the more potent statin atorvastatin versus pravastatin had a 16% relative risk reduction.

   b. The JUPITER trial demonstrated that in individuals without documented cardiovascular disease (CVD) and median LDL-C of 108 mg/dL, aggressive statin therapy with rosuvastatin offered greater benefit in individuals with ultrasensitive C-reactive protein (usCRP) >2 versus <2 mg/L.

   c. Primary prevention hypertensive patients in the ASCOT-LLA trial showed reductions in nonfatal MI, CHD death but not all-cause mortality when patients with average lipids and hypertension were treated with atorvastatin 10 mg daily for an average of 3.3 years.

   d. WOSCOPS and AFCAPS/TexCAPS were both primary CHD prevention studies, which showed significant clinical benefits for statin therapy, with similar percentage reductions in LDL-C. The main difference between these trials was that subjects in AFCAPS/TexCAPS had considerably lower baseline LDL-C levels than those in WOSCOPS.

   e. Scandinavian Simvastatin Survival Study (4S), Cholesterol and Recurrent Events (CARE), and Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID) all involved secondary prevention of CHD.

   f. Meta-analyses have demonstrated a >20% reduction in CHD events for every 1 mmol/L reduction in LDL-C with similar proportional reductions in diabetics versus nondiabetics. Similar percent reductions were seen even in lower-risk groups with <5% 5-year risk for CVD.

7. The Framingham Risk Score (FRS) was popularized in the National Cholesterol Education Project: Adult Treatment Panel (NCEP ATP) III guidelines. Potential limitations of the FRS include the following:

   1. Does not take family history into account

   2. May overestimate lifetime risk in individuals ≤50 years of age with ≥1 NCEP risk factor

3. May not accurately calculate risk in certain ethnic groups because original Framingham population was almost entirely of European origin
4. Incorporates risk due to insulin-resistant conditions such as metabolic syndrome
5. Does not include emerging risk factors such as CRP, lipoprotein(a), and apoB

a. All of the above
b. 1, 3, and 5
c. 1, 3, 4, and 5
d. None of the above

8. Based on the definition proposed by the NCEP ATP III guidelines, metabolic syndrome would be present if three or more of five criteria were present. Which of the following is NOT one of the criteria?

a. BP ≥130/≥85 or on treatment for hypertension
b. TGs ≥150 mg/dL
c. HDL-C of <40 mg/dL in men and women
d. Fasting glucose =100 mg/dL
e. Waist circumference of >40 inches in men and >35 inches in women

9. NCEP ATP III was published in 2001. Modifications to NCEP ATP III published in 2004 include all of the following except that

a. LDL-C goal <70 mg/dL is a therapeutic option for very high-risk patients.
b. LDL-C goal <70 mg/dL extends to patients at very high risk even with baseline LDL-C <100 mg/dL.
c. factors that favor the optional goal of <70 mg/dL include CVD plus multiple major risk factors (especially diabetes), severe and poorly controlled risk factors (especially smoking), metabolic syndrome, and acute coronary syndromes.
d. for moderately high-risk patients, LDL-C <100 mg/dL is an option with consideration of initiation of therapy with statins for LDL-C between 100 and 130 mg/dL.
e. both higher-dose statins and addition of fibrates and niacin to achieve non–HDL-C goals should be considered to achieve secondary targets and to further reduce cardiovascular event rate.

10. A 53-year-old obese, sedentary woman undergoes lipid screening, revealing TC of 310, TG of 720, HDL-C of 41. LDL-C was not calculated due to elevated TG. HbA1c is 5.9 and thyroid-stimulating hormone (TSH) is normal. NCEP ATP III guideline recommendations for TGs and HDL-C management include all but which of the following:

a. If TGs are ≥500 mg/dL, then TG is the primary target with use of therapeutic options to prevent pancreatitis including fibrates or niacin before LDL-lowering therapy, than treat LDL-C to goal.
b. In patients attaining LDL-C goals, those with TG ≥200 mg/dL have an increased cholesterol content of TG-rich, atherogenic lipoprotein particles. Non–HDL-C takes into account cholesterol in these and LDL particles and is a secondary target for therapy.
c. Therapeutic goal for TG is <150 mg/dL and for HDL-C is >40 in men and >50 in women.
d. HDL-C <40 mg/dL is defined as low and is a risk factor for CVD.
e. Non–HDL-C goal equals the LDL-C goal +30 mg/dL.
f. Combining a fibrate or nicotinic acid with an LDL-C-lowering drug can be considered.

11. Guidelines for management of dyslipidemia emphasize the importance of weight management, dietary choices, and exercise. TLC or Therapeutic Life Style Therapies for primary prevention of CVD include all of the following except

a. diet to reduce intake of saturated fats and dietary cholesterol with total fat range of 25% to 30% of total calories, saturated fat <7% of calories, and low intake of transfatty acids and <200 mg/day of cholesterol.
b. increased intake of plant stanols/sterols up to 2 g/day as a therapeutic option to reduce LDL-C.
c. increased intake of viscous (soluble) fiber to at least 5 to 10 g/day.
d. omega-3 polyunsaturated fatty acid supplements of 800 to 1,000 mg a day.
e. regular physical activity: >30 minutes five to seven times per week or enough moderate activity to expend at least 200 kcal/day.
f. weight loss to maintain BMI <25 kg/m^2.

12. Secondary causes of dyslipidemia include all EXCEPT which of the following?

a. Hyperthyroidism
b. Obstructive liver disease/biliary cirrhosis
c. Renal disorders including nephrotic syndrome and chronic renal failure
d. Drugs including estrogen/progestins, protease inhibitors, anabolic steroids, corticosteroids, isotretinoin (Accutane®), and cyclosporine
e. Metabolic syndrome or diabetes mellitus (DM)
f. Pregnancy

13. According to NCEP ATP III, CHD risk equivalent defines high-risk individuals who would benefit from more intensive lipid-modifying therapies and include

individuals with all of the following except

a. diabetes and additional cardiovascular risk factors.
b. FRS indicating a 10-year risk of MI or coronary death of >10%.
c. claudication with an ankle brachial index of 0.78.
d. individual status post aortic aneurysm endograft.
e. history of transient ischemic attack (TIA) followed by carotid endarterectomy.

Questions 14 to 16

You see a 52-year-old man with a history of type 2 DM on metformin. He has a history of hypertension controlled on amlodipine and an angiotensin-converting enzyme inhibitor. His BMI is 31.7 and waste circumference is 41 inches. His father had a coronary stent at the age of 54. He has the following fasting laboratory values:

Total C: 212 mg/dL
LDL-C: 120 mg/dL
HDL-C: 36 mg/dL
TG: 278 mg/dL
Non–HDL-C: 176 mg/dL
Glucose: 156 mg/dL
HbA1c: 7.6%
TSH: 1.2 mU/L
LFTs (liver function tests): WNL (within normal limits)

14. Based on NCEP ATP III and American Diabetes Association (ADA) guidelines, the most appropriate lipid goals for therapy in this patient are

a. LDL <70 mg/dL and non-HDL <100.
b. LDL <100 mg/dL and non-HDL <130.
c. LDL <70 mg/dL and non-HDL <130.
d. LDL <130 mg/dL and non-HDL <160.

15. Additional secondary goals for therapy in this patient based on these guidelines include

a. apoB <80 mg/dL.
b. apoB <90 mg/dL.
c. LDL particle number (LDL-P) <1,200.
d. LDL-P <1,000.
e. usCRP <2.
f. Answers a and d.
g. Answers a and e.

16. The best initial treatment for this patient's dyslipidemia would be

a. atorvastatin 40 mg/day.
b. fenofibrate 148 mg/day.
c. extended release niacin 2,000 mg/day.
d. simvastatin 20 mg/day.
e. ezetimibe 10 mg/day.
f. omega-3 fish oil 4,000 mg/day.

17. The patient above was started on rosuvastatin 20 mg/day, metformin dose was increased, an aerobic exercise program was recommended, and he was referred for dietary advice. Repeat laboratory values in 4 months are as follows:

	Baseline	4 Months
Total C	212	150 mg/dL
LDL-C	120	66 mg/dL
HDL-C	36	38 mg/dL
TG	278	229 mg/dL
Non–HDL-C	176	126 mg/dL
Glucose	156	112 mg/dL
A1C	7.6	6.8%
LFT	WNL	WNL

The most appropriate additional therapies recommended by NCEP ATP II at this time would include all but

a. nicotinic acid.
b. fenofibrate.
c. ezetimibe.
d. intensification of diet, exercise, and weight loss program.
e. intensification of statin therapy, increase rosuvastatin to 40 mg/day.
f. all of the above.
g. none of the above.

18. Patients such as the one above with diabetes are considered at high risk for CVD events. Which of the following statements is not true in regard to patients with diabetes?

a. Atherosclerosis accounts for approximately 65% to 75% of all diabetic mortality with 75% of these deaths due to coronary atherosclerosis.

b. A diabetic patient without a clinical history of prior MI or coronary artery disease (CHD) has a mortality rate from CHD and MI rate equal to a nondiabetic who has had a previous MI.
c. NHANES data from 2010 indicate that although goals of HbA1c <7 mg/dL, systolic BP <130 mmHg, and LDL-C <100 mg/dL are recommended for diabetics, only 32% of diabetics in the survey currently achieve all three of these goals.
d. Risk for atherosclerotic events is two- to fourfold greater in diabetics than in nondiabetics.
e. Atherosclerosis begins years to decades prior to diagnosis of type DM2 and >50% already have clinical CHD at the time of the diagnosis of DM.

19. Additional markers beyond standard risk factors have been shown to help reclassify risk assessment particularly in individuals in an intermediate-risk category (e.g., FRS of 10% to 20% or American College of Cardiology [ACC]/AHA guideline risk score of 5% to 7.5%). All but one of the following may be useful in hyperlipidemia treatment decisions:

a. usCRP
b. LDL-P
c. Coronary artery calcification score (CACS)
d. HDL particle size and number
e. Lipoprotein(a)

20. Major differences in the ACC/AHA hyperlipidemia treatment guidelines of 2013 compared with NCEP ATP III recommendations include all of the following except

1. elimination of LDL-C and non–HDL-C targets for therapy.
2. a focus on risk reduction targeting therapy to four major groups demonstrated to benefit from statin therapy based on RCT data rather than targeted to risk category and LDL-C level.
3. replacing the FRS with a newly developed risk calculator that includes ethnicity and family history and broadens the outcome events to include stroke.
4. that since the absolute benefit in CVD risk reduction is proportional to the baseline risk of the individual and to the intensity of statin therapy, treatment is focused on intensity of statin treatment and does not recommend use of low-dose statin therapies.
5. that decreasing statin dose is reasonable if LDL-C on therapy is <40 mg/dL.

a. None, all are true
b. 1, 3, and 5

c. 3 and 5
d. All are not true
e. 3, 4, and 5

21. The ACC/AHA hyperlipidemia guidelines of 2013 identify four groups shown to benefit from high-intensity and moderate-intensity statin therapy for use in secondary and primary prevention of CVD. High-risk individuals who would be a candidate for high-intensity statin therapy for LDL-C lowering would include all except

a. those with clinical atherosclerotic cardiovascular disease (ASCVD).
b. primary elevations of LDL-C ≥160 mg/dL.
c. individuals with diabetes aged 40 to 75 years with LDL-C 70 to 189 mg/dL without clinical ASCVD and with ASCVD risk ≥7.5%.
d. without clinical ASCVD or diabetes with LDL-C 70 to 189 mg/dL and estimated 10-year ASCVD risk ≥7.5%.

22. The American Academy of Pediatrics (AAP) 2008 lipid management recommendations for children and teenagers include all of the following except

a. screening as early as 2 years of age in setting of family history of CVD or hyperlipidemia.
b. lower LDL cut points for initiation of treatment dependent on risk level.
c. bile acid sequestrants as initial therapy in younger patients under 16 years of age.
d. considering initiation of therapy as early as 8 years of age in high-risk children.
e. emphasis on overweight, high TG, and low HDL managed with lifestyle interventions and weight management.
f. fiber up to 20 g/day and use of dietary plant stanols/sterols.

23. In decisions regarding screening for and treating hyperlipidemia in children and adolescents, it is important to remember that all of the following are true except that

1. cholesterol is lowest intrauterine and at birth.
2. concentrations are similar to young adult levels by 2 years of age with strongest relation to adult levels at 5 to 10 years and 17 to 19 years.
3. cholesterol levels decrease from 10% to 20% during pre-pubertal and pubertal development.
4. low-fat diets should not be implemented until after age 5 years.
5. statins have not been shown to have an adverse effect on sexual or physical maturation.
6. impact on the atherosclerotic process and clinical outcomes has been

demonstrated with statin treatment in children and adolescents.

a. None of the above
b. 2, 4, and 6
c. 4 and 6
d. 3, 5, and 6
e. All of the above

24. Although statin therapy and LDL-C reduction is the main thrust of pharmacologic therapies, there has been an interest in treating beyond LDL-C with other therapies directed toward HDL-C and TG to further reduce CVD events. This concept is supported by the following observations except that

a. cardiovascular events occur in individuals with treated LDL-C even after aggressive LDL lowering with statins.
b. patients with diabetes studied in clinical trials on statins have CVD event rates higher than the CVD event rates of those patients without diabetes on placebo.
c. intravascular ultrasound (IVUS) studies have shown LDL-C <70 to 80 mg/dL to be associated with plaque regression but the 20% of individuals that progress on therapy often have DM, less increase in HDL, and less decrease in apoB on treatment.
d. the action to control cardiovascular risk in diabetes clinical trial (ACCORD) trial demonstrated a benefit of fenofibrate when added to baseline simvastatin therapy in diabetic patients.
e. observational studies have noted an impact of low/abnormally functioning HDL, VLDL remnants, elevated TG small dense LDL, LDL-P, and apoB/apoA ratios on adverse outcomes.
f. epidemic of obesity, diabetes, and metabolic syndrome associated with dyslipidemia is marked by only modest elevations in LDL-C but increases in HDL-C and TG.

25. In the setting of strong observational and epidemiologic data supporting HDL-C's relationship to CVD risk, the limitations of current therapies, and the increase in incidence of diabetes/metabolic syndrome, there remains a strong interest in focusing on other therapeutic interventions in addition to LDL-C lowering, particularly HDL modulation. HDL is more than a simple carrier of cholesterol. Which of the following statements regarding HDL-C metabolism and function is not true?

a. In addition to reverse cholesterol transport, HDL may have beneficial effects due to antioxidant and anti-inflammatory effects.
b. ATP-binding cassette transporter 1 (ABCA1) and ABCG1 both facilitate free

cholesterol efflux to lipid-poor pre-β1-HDL.

c. Cholesteryl ester transfer protein (CETP) enables exchange of cholesterol esters for TGs between HDL and apoB-containing lipoproteins (LDL and VLDL).

d. HDL can deliver cholesterol to the liver via both direct and indirect reverse cholesterol transport.

26. Since most lipid-lowering guidelines emphasize the use of statin therapy and at potent doses in the highest-risk individuals, it is important to recognize side effects. Clinically significant adverse effects of statins include all of the following except

a. muscle-related adverse events.
b. liver-related adverse events.
c. renal insufficiency.
d. headaches.
e. dyspepsia.

27. You see a 68-year-old woman recently started on a statin for a calculated FRS of 18% 10-year risk and elevated usCRP. She returns in 6 weeks complaining of left lower extremity aching, which she had not experienced before. Regarding muscle-related side effects with statin drugs, all of the following statements are true except that

a. myopathy occurs in approximately 0.1% to 0.5% of patients on statin monotherapy and is dose dependent.
b. the incidence of statin-associated rhabdomyolysis across large, randomized, controlled statin trials is <0.1% and the reported incidence of fatal rhabdomyolysis with statins is extremely rare with 0.15 death per 1 million prescriptions.
c. a review of five large-scale controlled clinical trials of statin safety reported a rate of myopathy ranged from 0.1% to 0.6% and rate of rhabdomyolysis ranged from 0.03% to 0.05%.
d. myalgia symptoms reported in prescribing information range from 5% to 10%.
e. identifying factors that may contribute to myopathy should lead to statin dose reduction.

28. For the patient in Question 27, you obtain a creatine phosphokinase (CPK) which is 282 (upper normal in laboratory of 220 U/L). No baseline CPK is available for comparison. She has no reproducible pain or weakness on examination. She denies darkening of the urine. Should you stop the statin?

a. Yes
b. No

29. You see a 49-year-old obese, sedentary woman with type 2 DM, hypertension, and family history of coronary stent in her father at age 53. LDL-C was 173 mg/dL. Based on NCEP ATP III and 2013 ACC/AHA guidelines she is a candidate for intensive statin therapy. Laboratory values obtained 3 months after treatment with 40 mg of atorvastatin revealed alanine transaminase (ALT)/aspartate transaminase (AST) of 102/96 (upper normal in laboratory of 50/42 U/L). Which of the following regarding liver abnormalities with statin use is not true?

a. Reversal of transaminase elevation is frequently noted with continuation of statins or a reduction in statin dose.
b. Elevations do not often recur with either readministration or selection of another statin.
c. Statins have been shown to worsen the outcome in persons with chronic transaminase elevations due to hepatitis B or C.
d. In this patient review other drugs and supplements, continue the current dose, and repeat in 6 to 12 weeks.
e. Baseline measurement of ALT should be performed before starting therapy.

30. Later that afternoon you are referred a 58-year-old man with waist circumference of 42 inches, fasting glucose of 112 mg/dL, hypertension, current smoker with brother with MI at age 54. LDL-C is 163 mg/dL, TG 275 mg/dL, and HDL-C 47 mg/dL. When first seen prior to initiation of any therapy, he had LFTs similar to those reported for the patient in the previous question (approximately two times upper limit of normal [ULN]). The patient is very worried about taking statins due to concerns of liver failure. Which of the following can you tell him? 10 year risk by Framingham Risk Score is >30% and ACC/AHA calculator score is 21.2.

a. Statin use has not been investigated in patients with baseline LFT abnormalities but should be used due to his high risk.
b. Statins have been studied in patients with baseline elevations and have been shown to further increase the LFTs.
c. Elevations of LFTs greater than two times ULN is a contraindication to starting statins.
d. Statin therapy may lower the LFTs in patients with fatty liver infiltration.
e. Progression to liver failure has never been reported.

31. In 2012, the FDA issued an alert reporting a relationship between statin use and increase in blood glucose and new incidence of diabetes. Which of the following statements is TRUE?

1. A large meta-analysis has reported an approximate 18% increase in relative risk of developing diabetes on statin therapy.

2. This observation appears to be dose dependent with a meta-analysis of high- versus moderate-dose trials reporting an absolute increase in rate of 0.4%.
3. Increase in blood glucose with statins does not attenuate the CVD reduction benefit of statins.
4. Development of diabetes on statin therapy is independent of risk factors for diabetes.
5. Reducing the dose of statin should be utilized to avoid diabetes development in those at risk, for example, metabolic syndrome, obesity, and impaired fasting glucose.

a. All of the above
b. 1, 3, and 5
c. 2 and 3
d. 2, 3, and 5
e. None of the above

32. Your patient is a 51-year-old man with heterozygous FH with predrug therapy LDL-C of 202 mg/dL who had been tried on atorvastatin, simvastatin, and lovastatin in the past but stopped all three due to complaints of muscle aching, had gastrointestinal complaints with resins, and refused further treatment. He recently had an ST-segment elevation MI treated with direct stenting. He was given a prescription to start atorvastatin again but was hesitant to have it filled and comes to you for advice. He has increased his frequency of aerobic exercise and has been following a low-saturated fat diet. LDL-C measured 2 months after the MI was 188 mg/dL. Appropriate options to consider in managing this patient include

1. trial of rosuvastatin beginning at 5 mg two to three times a week followed by slow titration.
2. pretreatment with coenzyme Q10 followed by rechallenge with a different statin or lower dose of previously used statin.
3. niacin titrated to highest tolerated dose in combination with ezetimibe.
4. LDL-C apheresis.
5. emphasis on aggressive lifestyle intervention including very low saturated fat to vegetarian diet, plant sterols/stanols, and high dietary and supplementary fiber.
6. mipomersen.

a. All of the above
b. 1, 2, 3, and 5
c. 1, 2, 3, 4, and 5
d. 1, 3, and 5

e. None of the above

33. Statements regarding fibrates include all of the following except that

a. side effects include gastrointestinal complaints, gallstones, and increase in need for cholecystectomy and elevated hepatic transaminase levels.
b. monotherapy trials have not uniformly demonstrated reductions in CVD risk but subanalysis of groups with a metabolic pattern (elevated TG and low HDL) have been more strongly associated with CVD event reduction.
c. although difficult to demonstrate in individual studies, meta-analysis of fibrate trials has demonstrated reduction in cardiovascular mortality on therapy.
d. myopathy has been reported with both monotherapy and combination therapy with statin.
e. increase in creatinine is more common with gemfibrozil compared with fenofibrate.

34. The following statements regarding use of niacin are true except that

a. possible concerns with niacin use include risk of gout, worsening glucose control, and flushing.
b. combination therapy of statins with niacin has been shown to exert favorable effect on some surrogate markers for CVD outcomes.
c. the Coronary Drug Project in the pre-statin era demonstrated a beneficial effect on MI and mortality in secondary prevention patients with coronary disease treated with high-dose niacin.
d. niacin can raise HDL-C from 20% to 25% and lower TGs from 30% to 50% depending on dose and pretreatment TG levels but has little effect on LDL-C.
e. to reduce adverse event severity, start niacin at low dose and titrate over weeks, take with a light snack, and take aspirin 30 minutes prior.

ANSWERS

1. **a.** It occurs in 1 in 5,000 persons. Homozygous FH occurs in 1 in 1 million individuals while heterozygous FH in 1 in 500 individuals. The other statements are true.

2. **d.** LDLRAP1 mediates internalization of LDL-C via clathrin-coated pits, and loss-of-function mutations would decrease LDL-C clearance. Defects in apolipoprotein B (apoB). The LDL-R on the hepatocyte binds to apoB (acts as ligand, binding LDL particle to receptor) on the LDL particle inducing internalization via clathrin-coated pits (mediated by LDLRAP1) and endocytosis of the complex. Defects in the

receptor itself or the apoB molecule may reduce LDL-C clearance. The protein PCSK9 can bind to the LDL/LDL-R complex and when internalized prevents recycling of the LDL-R to the hepatocyte surface. A gain in function mutation of PCSK9 (by further reducing recycling of LDL-Rs) has been shown to be associated with increase in LDL-C and CVD.

3. **c.** Familial combined hyperlipidemia. Familial combined hyperlipidemia is a common dyslipidemia (1 in 33 to 1 in 100 individuals) characterized by complex inheritance. Xanthomas are rarely present (unlike in heterozygous FH), but xanthelasmas and arcus cornea can be seen. They are generally overweight, are hypertensive, and have insulin resistance or diabetes. Affected individuals generally exhibit a TC of 250 to 350 mg/dL, LDL-C of 200 to 300 mg/dL, and TG of >140 mg/dL (two-thirds of patients have TG of 200 to 500 mg/dL). Patients with polygenic hypercholesterolemia (1 in 20 to 1 in 100 individuals) have alterations in the function or expression of several key proteins involved in LDL metabolism including defective LDL-R and apoB100, and the presence of the apoE4 allele (which has a higher affinity for the LDL-R than the other apoE isoforms leading to downregulation of LDL-R). They have similar elevations in LDL-C as familial combined hyperlipidemia except they do not generally have elevated TG. Hyperapobetalipoproteinemia is associated with increased apoB synthesis. TG may be normal or elevated and arcus cornea and xanthelasmas may be present. However, LDL-C is typical below 160 mg/dL. Familial endogenous hypertriglyceridemia is associated with increased hepatic VLDL formation and TG of 200 to 500 mg/dL but without significant elevations in LDL-C and is not consistently linked with increased CVD risk.

4. **d.** Lomitapide has been approved to treat homozygous and heterozygous FH. Homozygous FH occurs in 1 in 1 million individuals. TC levels are generally >600 mg/dL, with LDL-C levels six- to eightfold higher than average. Without treatment, death from MI occurs in the first or second decades of life. In addition to the xanthomas observed in heterozygotes, FH homozygotes are commonly affected by interdigital xanthomas; tuberous xanthomas on the hands, elbows, buttocks, and feet; and planar xanthomas on the posterior thighs, buttocks, and knees. The mainstay of therapy for FH homozygotes is LDL apheresis and has been associated with stabilization or regression of atherosclerotic lesions and improvement in symptoms. Since immediate reductions in LDL-C of 50% to 80% rebound quickly, the process is performed every 2 to 4 weeks to keep intrapheresis LDL-C ≤120 mg/dL.

   Both mipomersen and lomitapide were FDA approved in 2013 as orphan drugs for management of patients with homozygous FH only. Mipomersen is a subcutaneously injectable RNA antisense oligonucleotide. Lomitapide blocks microsomal TG

transport protein (a key protein in assembly and secretion of apoB-containing lipoproteins in the liver and intestines) reducing hepatic secretion of VLDL. These therapies have a small target population, require risk evaluation and mitigation strategy limiting use to specialized centers, and have concerns with liver toxicity and hepatic steatosis due to accumulation of TGs not secreted into VLDL.

Several clinical diagnostic criteria for FH exist, with the 15-year Simon Broome Register Group being the most commonly used. Definite FH is as defined above. Possible FH by this criteria is defined as (a) above PLUS and (b) MI before age 50 in second-degree relative, or before 60 in first-degree relative or elevated cholesterol in first-degree relative, or >290 mg/dL in second-degree relative.

5. **d.** National Health and Nutrition Examination Survey (NHANES) data through 2006 reported that 10.3% of adolescents (12 to 19 years) have abnormal lipid levels. In adolescents between the ages of 12 and 19, the number of individuals with one or more abnormal lipid level is higher at 20.3% and increases further to 42.9% in association with obesity. All the other facts noted are true. The AHA has established TC <170 mg/dL in children and <200 mg/dL in adults as one of seven goals for ideal cardiovascular health. In one survey in 2010, 38.1% of children and 52.7% of adults did not meet these criteria. Although average adult TC levels have been dropping over the past two decades from 208 to 197 mg/dL, obesity and lack of physical activity (two factors associated with dyslipidemia and diabetes risk) have been on the rise. From 2011 to 2012 only 20.7% of adults and 49.5% of adolescents, respectively, achieved recommended activity levels. These facts and more can be found in the most recent Heart Disease and Stroke Statistics-2014 Update from the AHA published in Circulation.

6. **b.** The JUPITER trial demonstrated that in individuals without documented cardiovascular disease (CVD) and median LDL-C of 108 mg/dL, aggressive statin therapy with rosuvastatin offered greater benefit in individuals with ultrasensitive C-reactive protein (usCRP) >2 versus <2 mg/L. JUPITER demonstrated that primary prevention patients with only modest elevations in LDL-C but elevated usCRP above 2 mg/L benefited from treatment with statins. However, the trial only enrolled individuals with usCRP >2 mg/L. There was no comparison arm to individuals with low LDL-C and low usCRP. While ASCOT-LLA showed reductions in nonfatal MI and CHD death, coronary events or procedures, stroke, and chronic stable angina, but did not show a reduction in total mortality. However, this trial did demonstrate that initiation of moderate intensity statin therapy in higher-risk individuals without clinical CVD and without significant elevations in LDL-C significantly reduced CVD events. The study with average LDL-C at entry of 130 mg/dL was stopped early by the safety monitoring board. Primary prevention

trials WOSCOPS and AFCAPS/TexCAPS and secondary prevention trials including 4S, CARE, PIPID, and Heart Protection Study (HPS) across a wide range of pretreatment LDL-C and using various statins demonstrated approximately 1% reduction in CVD events for every 1% reduction in LDL-C.

7. **b.** 1, 3, and 5. In making treatment decisions regarding initiation and intensity of treatment for dyslipidemia in patients without documented CVD or diabetes, assessment of future risk of CVD development is important. In individuals with two or more standard cardiovascular risk factors (hypertension, family history, low HDL-C, and smoking), the FRS can be used to calculate 10-year risk of MI or coronary disease mortality. The calculator is based on assessment of TC (or LDL-C), HDL-C, hypertension history, age, and smoking stratified by gender. It does not incorporate family history, assessment of metabolic syndrome, or other nontraditional risk markers such as usCRP, lipoprotein(a), and CACS. Risk may be underestimated in younger individuals and data may not be transferable to ethnic groups not well represented in the cohort. Other risk assessment tools include some of these additional risk markers such as the Reynolds Risk Score (usCRP and family history), PROCAM (prospective cardiovascular Münster heart study) Score (TG and family history), and SHAPE (Screening for heart attack prevention and education) guidelines (carotid intimal medial thickness [CIMT] and CACS). The recent 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults has promoted a new Pooled Cohort Equations risk calculator that incorporates race into the calculation and stroke as an outcome event.

8. **c.** HDL-C of <40 mg/dL in men and women. Metabolic syndrome is characterized by abdominal obesity, an atherogenic dyslipidemia with elevated TG, increased number of small LDL particles, low HDL-C, elevated BP, insulin resistance (glucose intolerance), a prothrombotic state, and a proinflammatory state. There is an increased risk of CVD development of two- to fourfold in individuals with metabolic syndrome. Focus of treatment should be on intensive lifestyle intervention. In the NCEP ATP III recommendations for diagnosis of metabolic syndrome, cutoffs for HDL-C are <40 mg/dL in men but <50 mg/dL in women. The other criteria listed are correct. Modifications since initial publication include lowering the fasting glucose cutoff to 100 mg/dL and population-specific waist circumferences such as ≥90 cm in men and ≥80 cm in women of South Asian ancestry. Metabolic syndrome is present if three or more of these criteria are identified.

9. **e.** Both higher-dose statins and addition of fibrates and niacin to achieve non-HDL-

C goals should be considered to achieve secondary targets and to further reduce cardiovascular event rate. Between NCEP ATP III in 2001 and the update in 2004, multiple randomized controlled clinical trials offered new information supporting more aggressive treatment of hyperlipidemia and led to lowering the treatment goals and pretreatment LDL-C cutoffs for treatment in high- and intermediate-risk individuals (Table 12.1). The HPS demonstrated statin benefit in high-risk patients even with low pretreatment LDL-C. The ASCOTT LLA and Collaborative Atorvastatin Diabetes Study (CARDS) trials showed benefit when treating high-risk primary prevention patients with hypertension or DM even if LDL-C was not significantly elevated. Studies such as Treat to New Targets (TNT) and PROVE-IT TIMI-22 demonstrated that increasing the intensity of LDL-C lowering using higher doses or more potent statins in secondary prevention populations was associated with incremental cardiovascular risk reduction. The guidelines recommend that in treating individuals with hyperlipidemia the first priority of treatment is to lower LDL-C; the first line of drug therapy to manage LDL-C is statin therapy and intensity of therapy should be selected to achieve at least a 30% to 40% LDL reduction. Intensity of therapy and LDL-C goals should be based on level of CVD risk. Although NCEP ATP III recommended non-HDL-C (TC minus HDL-C) as a secondary therapeutic goal after achieving LDL-C goals and considering addition of niacin and fibrates to achieve this goal, this has not yet been definitively shown in clinical trials to reduce adverse cardiovascular events when added to adequate statin therapy.

TABLE 12-1 Treatment Goals and Low-Density Lipoprotein Cholesterol Levels for Initiation of Pharmacologic Therapies Based on Modifications of the National Cholesterol Education Project: Adult Treatment Panel III Guidelines in 2004

Risk Category	LDL-C (mg/dL)	Non–HDL-C (mg/dL)	Consider Drug Therapy for LDL-C
CHD/CHD risk equivalents (10-y risk >20%)	<100 Optional <70	<130 Optional <100	≥100 Optional <100
≥2 risk factors (10-y risk 10–20%)	<130 Optional <100	<160 Optional <130	>130 Optional 100–129
≥2 risk factors (10-y risk <10%)	<130	<160	>160
0–1 risk factor	<160	<190	>190 Optional 160–190

CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

10. **e.** Non–HDL-C goal equals the LDL-C goal +30 mg/dL. Although the ADA, the American Association of Clinical Endocrinologists (AACE), and the AHA/ACC women's preventive guidelines set specific goals for TG below 150 mg/dL and HDL-C >50/40 mg/dL in women/men, NCEP ATP III guidelines do not and instead focus on non–HDL-C targets. The primary target for therapy is LDL-C reduction and statins remain the primary therapy for reducing LDL-C. However, in individuals with TGs >500 mg/dL initial therapy with aggressive diet and lifestyle intervention and medications should be first addressed. Non–HDL-C is recommended as a secondary target after achieving LDL-C goals if TG are greater than 200 mg/dL with therapeutic options to lower non–HDL-C including more intense LDL-C lowering or addition of niacin, fibrates, or high-dose omega-3 fish oils. Bile acid sequestrants should be avoided in individuals with TG over 300 mg/dL. NCEP ATP III recognizes a role for HDL-C as an important determinant of risk and if low a reason to achieve LDL-C and non–HDL-C goals as well as cause

to emphasize diet and exercise. Although specific treatment to raise HDL-C may be considered in very high-risk individuals, the best therapies to accomplish this are not known and clinical trials documenting CVD risk reduction with HDL-C–directed therapies are lacking. An appropriate approach to HDL-C management is lifestyle. Dietary changes are associated with a 3% to 15% increase in HDL-C with an average 0.35 mg/dL increase in HDL for each 1 kg of weight loss. About 120 to 180 minutes of aerobic exercise a week and discontinuation of smoking can each raise HDL-C by 5% to 10%.

11. **d.** Omega-3 polyunsaturated fatty acid supplements of 800 to 1,000 mg a day. Diets high in omega-3 saturated fat are recommended but universal use of supplements is not. The AHA recommends 800 to 1,000 mg/day in dietary consumption and to consider supplements in secondary prevention patients without an adequate dietary source. Omega-3 fatty acids have a role in managing high TGs (>500 mg/day) by using high doses of prescription or supplement forms at 2,000 to 4,000 mg/day. Long-term outcome data supporting definitive reduction in CVD events with omega-3 supplementation in primary prevention populations are lacking. All of the other recommendations listed are supported by the guidelines.

12. **a.** Hyperthyroidism. Identifying and treatment of or modifying secondary causes of dyslipidemia is an important component in the management of dyslipidemia. Treating hypothyroidism and better control of diabetes may have significant impact on correcting lipid abnormalities. If possible, identification of medications associated with dyslipidemia and substitution of alternate medications when possible may help. Cholesterol and TGs rise progressively throughout pregnancy. Drugs such as statins, niacin, and ezetimibe are contraindicated during pregnancy and lactation.

13. **b.** FRS indicating a 10-year risk of MI or coronary death of >10%. Any clinically significant non-coronary vascular diseases such as peripheral artery disease, carotid artery disease, and aortic disease would qualify. Diabetics also fall into this category, particularly those >40 years of age and with at least one additional CVD risk factor. CHD risk equivalent status is present in individuals without clinically evident CHD, other CVD, or diabetes but with two or more CVD risk factors and FRS associated with a 10-year risk of a fatal or nonfatal MI of >20% not >10%. All of these individuals would be candidates for aggressive lipid management. The NCEP ATP III guidelines recommend LDL-C goals <100 mg/dL and optional LDL-C goals <70 mg/dL in this group. The ACC/AHA 2013 hyperlipidemia guidelines have eliminated LDL-C goals for therapy and recommend high-intensity statin therapy to achieve LDL-C lowering of >50% in

high-risk groups <75 years old. This includes individuals with coronary and non-coronary disease, diabetics with new Pooled Cohort Equation calculator risk of >7.5% 10-year risk.

14. **a.** LDL <70 mg/dL and non-HDL <100.

15. **f.** Answers a and d.

16. **a.** Atorvastatin 40 mg/day. Patients with diabetes are CHD risk equivalent patients and therefore at high cardiovascular risk and candidates for aggressive lipid-lowering therapy. The NCEP ATP III update in 2004, ACC/ADA consensus statement in 2008, and the ADA and AAACE (American Association of Clinical Endocrinologists) guidelines in 2013 all support a primary LDL-C goal of <70 mg/dL and secondary non–HDL-C goal of <100 mg/dL. In addition, the consensus statement and recent ADA/AACE guidelines recommend considering apoB of <80 mg/dL and LDL-P of <1,000 as secondary targets for therapy. usCRP is a marker for CVD risk and reduced by many therapies including statins and lifestyle interventions but is not a recognized specific target or therapeutic goal (Tables 12.2 and 12.3).

    The first-line therapy is statins, at a dose needed to achieve LDL-C reductions of at least 30% to 40%. Only atorvastatin 40 mg/day would achieve recommended treatment goals. Simvastatin at this dose is unlikely to result in sufficient LDL-C reduction to achieve goals and since the FDA alert in 2011, doses higher than 20 mg are not recommended in combination with amlodipine. Monotherapy with ezetimibe generally lowers LDL-C <20% and outcome benefit has not been demonstrated. Although LDL-C is not significantly elevated and the TG and HDL-C abnormalities may be improved by the other listed therapies, statins remain the primary treatment choice, supported by beneficial outcome data in trials such as CARDS and diabetic subsets in other large prospective trials and meta-analyses. Outcome data regarding cardiovascular risk reduction with these other listed therapies are lacking or less robust. New lipid treatment guidelines from the ACC/AHA published in November 2013 recommend a different approach to the management of lipids. These new guidelines support therapy initiation and intensity dependent on the level of risk and they recognize that most patients with diabetes are candidates for high-intensity statin therapy (defined as a statin able to achieve >50% reduction in LDL-C, e.g., 40 to 80 mg of atorvastatin or 20 to 40 mg of rosuvastatin).

TABLE 12-2 Treatment Goals: American Diabetes Association/ American College of Cardiology Consensus Statement 2008

	LDL-C (mg/dL)	Non–HDL-C (mg/dL)	apoB (mg/dL)
Highest-risk patients			
Known CVD or diabetes plus one or more additional CVD risk factors	<70	<100	<80
High-risk patients			
No diabetes or known CVD but two or more major CVD risk factors or diabetes but no other CVD risk factors	<100	<130	<90

CVD, cerebrovascular disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

TABLE 12-3 American Association of Clinical Endocrinologists Lipid Targets for Patients with Type 2 Diabetes

	Moderate-Risk Patients	High-Risk Patients
LDL-C (mg/dL)	<100	<70
Non–HDL-C (mg/dL)	<130	<100
Triglycerides (mg/dL)	<150	<150
TC/HDL-C	<3.5	<3.0
ApoB (mg/dL)	<90	<80
LDL particle number (nmol/L)	<1,200	<100

ApoB, apolipoprotein B; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; TC, total cholesterol.

17. **f.** All of the above. On statin therapy, the LDL-C goal of <70 mg/dL has been achieved but non–HDL-C remains above an ideal goal of <100 mg/dL. Any of these therapies would help to achieve the secondary non–HDL-C goals. NCEP ATP III recommends intensification of statins, further LDL-C lowering with non-statin therapies, niacin, or fibrates to achieve secondary non–HDL-C goal. There are

clinical trial data to support further risk reduction with intensification of statin therapy although outcome data are absent when niacin, fibrates, fish oil, or ezetimibe is added to adequate statin therapy. Intensification of lifestyle interventions should be a part of any pharmacologic intervention in this patient. The patient is on a high-intensity statin with <50% reduction in LDL-C. Based on new ACC/AHA 2013 guidelines for management of hyperlipidemia, there is insufficient RTC evidence that adding additional therapies will further reduce cardiovascular events. Intensification of statin therapy does appear to offer benefit. In individuals receiving maximum tolerated intensity of statin with less than anticipated therapeutic response and in high-risk groups, the addition of non-statin therapy may be considered if the CVD risk reduction benefits outweigh the adverse effects.

18. **c.** NHANES data from 2010 indicate that although goals of HbA1c <7 mg/dL, systolic BP <130 mmHg, and LDL-C <100 mg/dL are recommended for diabetics, only 32% of diabetics in the survey currently achieve all three of these goals. The NHANES survey in 2010 demonstrated that although greater than 50% of diabetic patients achieved LDL <100 mg/dL, systolic BP <130 mmHg, or HbA1c <7 mg/dL, only <20% achieved all three goals. Studies such as the East-West study in 1998 demonstrated that a diabetic without CHD history had a similar approximate 20% incidence of MI over 7 years compared with a nondiabetic with known previous MI. Diabetics have a two- to fourfold increased risk of CVD events and the majority of deaths in patients with diabetes are due to CVD, accounting for up to 75% of deaths. These observations emphasize the concept of diabetes as a CHD equivalent and a rationale for intensive therapy of hyperlipidemia.

19. **d.** HDL particle size and number. usCRP has been shown in studies such as the Women's Health Study (WHS) to reclassify risk when added to the FRS and in the JUPITER trial to be a factor in determining benefit of early statin therapy for primary prevention of CVD. Similar reclassification of risk has been demonstrated with anatomic measurements for preclinical atherosclerosis such as CACS and CIMT. Post hoc analyses of studies such as the WHS and MESA (multi-ethnic study of atherosclerosis) have demonstrated LDL-P to be a better predictor of future cardiovascular risk, and the National Lipid Association has recommended it as a tool for further risk assessment. However, data supporting the benefit and use of HDL particle size and number in assessing risk and guiding treatment are absent. NCEP ATP III recommends that intermediate-risk patients (FRS 10% to 20% estimated 10-year risk) with these additional risk markers should be considered for more intensive therapies. The ACC/AHA hyperlipidemia guidelines in 2013 suggest that in selected individuals, particularly those with a 10-year CVD risk of 5% to 7.5% not falling into defined treatment groups for high- or moderate-intensity

statin therapy, factors including LDL-C >160 mg/dL, family history of premature CVD, usCRP >2 mg/dL, CACS >300 Agatston units or >75th percentile for age/sex/ethnicity, and ankle brachial index <0.9 may be used to consider initiation or intensification of pharmacologic therapy.

20. **a.** None, all are true. The ACC/AHA 2013 guidelines have attempted to offer recommendations based on a balance of benefit and therapeutic risk of treatment strategies as supported whenever possible by RTCs. The guidelines are based on observations including the absolute benefit in CVD risk reduction is proportional to baseline risk; cholesterol-lowering medications used in clinical trials (particularly statins) reduce risk of cardiovascular events proportional to the intensity of stain therapy rather than LDL-C achieved and therefore more intensive statin therapy could reduce risk more than moderate- or lower-intensity statin therapy; and statins are associated with similar relative risk reductions for CVD events across the majority of patient groups studied, and little clinical trial evidence to support use of other non-statin therapies particularly when added to treatment with statins. Therefore, in these guidelines a greater degree of emphasis is placed on level of treatment with statins and less on other lipid-lowering therapies either alone or in combination with statins. Patients or groups at higher baseline absolute risk will derive greater absolute benefit from initiation of statin therapy over a period of 5 to 10 years as studied in clinical trials. Like the NCEP ATP III recommendations, intensity of therapy is based on a measure of level of CVD risk but defined as dose or potency of statin therapy to be used rather than titration to specific LDL-C and non–HDL-C goals. Both sets of guidelines recommend statin therapy as primary and most beneficial therapy for CVD risk reduction although the ACC/AHA recommendations deemphasize the use of add-on non-statin therapies in the absence of RCT data and balance the risk of pharmacologic therapies in lower-risk populations. The ACC/AHA guidelines position treatment of TGs and use of non–HDL-C in treatment decision making as future clinical questions to be addressed and updated after future clinical trials. It should be mentioned that since these guidelines have appeared many have offered criticism of the document, including the elimination of LDL-C targets and concern with use of a new risk assessment tool that has not been prospectively validated, may overexpand treatment of lower-risk populations, and delay treatment in other high-risk populations. It should be remembered that these are guidelines and not doctrine and individual treatment plans should be tailored to the individual patient's risk and needs after carefully assessing side effects and risk of treatment and discussion with the patient.

21. **b.** Primary elevations of LDL-C ≥160 mg/dL. In these recommendations, LDL-C would need to be above 190 mg/dL to be considered for high-intensity statin

therapy (Table 12.4). Clinical ASCVD is defined as acute coronary syndromes, a history of MI, stable or unstable angina, coronary or other arterial revascularization, stroke, TIA, or peripheral arterial disease of atherosclerotic origin. It is recommended that the absolute 10-year ASCVD risk (defined as nonfatal MI, CHD death, and including nonfatal and fatal stroke) should be used to guide the initiation and intensity of statin therapy and should be estimated using the Pooled Cohort Equations for the primary prevention of ASCVD in individuals without clinical ASCVD and LDL-C 70 to 189 mg/dL and to determine intensity of therapy in diabetics (DM types 1 and 2). For those with clinical ASCVD or with LDL-C ≥190 mg/dL who are already in a statin benefit group, it is not appropriate to estimate 10-year ASCVD risk. In individuals over 75 years of age falling into these groups or diabetics with 10-year risk <7.5%, consider moderate-intensity therapy to reduce possible side effects.

22. **C.** Bile acid sequestrants as initial therapy in younger patients under 16 years of age. The AAP recommends screening beginning as early as 2 years of age and before age 10 in children with family history of hyperlipidemia or premature CVD in parents and grandparents or if family history is not known and other risk factors (overweight, obese, hypertension, smoking, and DM) are present. They now recommend considering pharmacologic treatment with statins as the first choice drug rather than resins and consider beginning pharmacologic therapy as early as 8 years of age if after lifestyle intervention LDL-C remains >190 mg/dL, >160 mg/dL with one or more other cardiovascular risk factors (including obesity), or >130 mg/dL if diabetes is present.

TABLE 12-4 American College of Cardiology/American Heart Association 2013 Guidelines: Four Treatment Groups and Intensity of Statin Therapy

High-Intensity Statin Therapy (average LDL-C lowering >50%)	Moderate-Intensity Statin Therapy (average LDL-C Lowering 30–50%)
Indicated for	**Indicated for**
1. Clinical ASCVD age <75	1. Clinical ASCVD age ≥75
2. LDL-C ≥190 mg/dL	2. LDL-C ≥190 mg/dL (unable to tolerate high-intensity statin)
3. Diabetics aged 40–75 with LDL-C 70–189 mg/dL with 10-y ASCVD risk ≥7.5%	3. Diabetics aged 40–75 with LDL-C 70–189 mg/dL with 10-y ASCVD risk <7.5%
4. Others aged 40–75, LDL-C 70–189 mg/dL and ASCVD risk ≥7.5%	4. Others aged 40–75 with LDL-C 70–189 mg/dL with 10-y ASCVD risk ≥7.5%
Considered high-intensity statins	**Considered moderate-intensity statins**
Atorvastatin (40)–80 mg	Atorvastatin 10 (20) mg
Rosuvastatin 20 (40) mg	Rosuvastatin (5) 10 mg
	Simvastatin 20–40 mg
	Pravastatin 40 (80) mg
	Lovastatin 40 mg
	Fluvastatin XL 80 mg
	Fluvastatin 40 mg bid
	Pitavastatin 2–4 mg

ASCVD, atherosclerotic cardiovascular disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

23. C. 4 and 6. Child and Adolescent Trial for CV Health reported that 13.3% of fourth graders had TC >200. NHANES 2010 notes that approximately 8% of adolescents have TC >200. A population approach including weight maintenance, healthy diet, and exercise is recommended for all children. An individual approach to therapy is reserved for those at higher risk for CVD and with elevated LDL-C levels as summarized in the previous question. Other high-risk children and adolescents for whom earlier pharmacologic therapy may be considered include post transplantation, human immunodeficiency virus (HIV), chronic inflammatory disease such as lupus and rheumatoid arthritis, renal disease (nephrotic syndrome), Kawasaki disease, overweight/obese with metabolic syndrome, and childhood cancer survivors. Statins have not been shown to delay or adversely affect physical and sexual development. Cholesterol levels may drop significantly during pubertal development. Therefore, screening before or after is most representative. Studies in

ages 7 months to adolescents have shown safety of low total fat, saturated fat, and cholesterol diets and initiation of low-fat diet is recommended after age 2 years. Benefits of statin treatment on the atherosclerotic process have been demonstrated in children using surrogate markers such as flow-mediated dilatation and CIMT. However, the impact on clinical outcomes has not been studied in large prospective trials. Since there are little outcome data to show that treatment in childhood decreases adult CVD, treatment recommendations are based on extrapolations from adult studies.

24. **d.** The ACCORD trial demonstrated a benefit of fenofibrate when added to baseline simvastatin therapy in diabetic patients. Observational studies support that for every 1 mg/dL increase in HDL-C, there is a 2% to 3% decrease in CVD risk. The Framingham Heart Study recognized that the lower the level of HDL-C, the greater the risk of a coronary event, regardless of LDL-C level. In fact, a person with a "desirable" LDL-C of 100 mg/dL but a low HDL-C of 25 mg/dL had the same risk of a cardiac event as a person with an LDL-C of 220 mg/dL and an HDL-C of 45 mg/dL. Further strengthening the link between HDL-C and TG and poor CVD outcomes is the observation that patients presenting with a new diagnosis of CHD have higher TGs and lower HDL-C than those without CHD. In the TNT trial, this relationship continued to exist even following aggressive statin therapy. When a subgroup of individuals all achieving LDL-C below 70 mg/dL was examined, CVD events increased significantly when HDL-C was below 42 mg/dL even in this group with very low LDL-C levels. A meta-analysis in 2010 of multiple statin trials reported that the inverse relationship of HDL-C to CVD events was not altered by statin therapy. Meta-analyses have shown a relationship between elevations of TG and CVD risk even when controlling for confounding factors and HDL-C. In the treatment arms of statin placebo-controlled studies and even when including those in which very low LDL-C levels are achieved, a significant residual CVD risk persists. NHANES reports that of the 48% of U.S. adults with dyslipidemia approximately a third have elevations in TGs and/or HDL-C. With the growing prevalence of obesity, diabetes, inactivity, and metabolic syndrome more individuals are presenting with a combined dyslipidemia characterized by only moderate elevation of LDL-C but increased numbers of small dense LDL and other atherogenic apoB particles, elevated TGs, and low high density HDL-C. Particularly in these groups it is reasonable to hypothesize that therapies beyond LDL-C lowering may be beneficial. Evidence supports titration of statin to higher doses or use of more potent statins to achieve greater risk reduction. However, data from long-term outcome studies demonstrating incremental benefit when therapy directed toward low HDL-C and TG is added to statins have been disappointing. The AIM-HIGH (Atherothrombosis Intervention in Metabolic Syndrome with Low

HDL/High Triglycerides: Impact on Global Health) trial and HPS-THRIVE (Treatment of HDL to Reduce the Incidence of Vascular Events) did not demonstrate improved outcomes when niacin preparations were added to individuals with well-controlled LDL-C on statin ± ezetimibe (LDL-C prerandomization of 74 and 63, respectively). The ACCORD trial did not demonstrate benefit when fenofibrate was added to baseline statin therapy in the total population of diabetics studied. A prospectively defined but subanalysis noted a borderline statistically significant 31% CVD event reduction in a subgroup with TG above 204 mg/dL and HDL-C below 34 mg/dL. However, until further studies are available there still may remain a role for niacin, fibrates, or ezetimibe in the management of elevated non-HDL after maximally tolerated statin therapy, those not at LDL-C goal after maximally tolerated statin therapy, or those intolerant to statins. The NCEP ATP III, ADA, and ACCE guidelines do recommend considering therapies including niacin and fibrates to achieve non–HDL-C goals after treating LDL-C. The AHA/ACC 2013 guidelines are less enthusiastic regarding the addition of non-statin therapies. Also note that other recommendations still recommend treatment targets and utilization of non-statin therapies in certain populations.

25. **b.** ATP-binding cassette transporter 1 (ABCA1) and ABCG1 both facilitate free cholesterol efflux to lipid-poor pre-β1-HDL. There are many proposed mechanisms offered to explain the beneficial anti-atherosclerotic activity of HDL-C including increase in nitric oxide production and enhanced endothelial function, inhibition of LDL-C oxidation, reduction of cytokine-induced endothelial vascular cell adhesion molecule induction and macrophage infiltration, as well as anti-inflammatory, antithrombotic (including reduction of platelet activation/ aggregation, activation of protein C–mediated anticoagulant effects, and stimulation of fibrinolysis), and antioxidant effects. However, reverse cholesterol transport, the transfer of cholesterol from the peripheral tissues to the liver for excretion in the feces or bile, appears to offer the greatest cardioprotective role. The mature α-HDL particles are generated from lipid-free apolipoprotein A1 (apoA1) or lipid-poor pre–β1-HDL as the precursors are produced by the liver or intestine, released from lipolyzed VLDL and chylomicrons or released by interconversion of mature HDL particles. ABCA1 facilitates efflux of cholesterol from cells and initial lipidation of these precursors. Lipid efflux to more mature HDL particles also occur via ABCG1-mediated transfer. Enzymatic modification with lecithin cholesterol acyltransferase (LCAT) enables esterification of cholesterol and generates spherical particles that continue to grow with ongoing cholesterol esterification. The larger mature HDL particles are converted into smaller HDL particles via CETP-enabled exchange of cholesterol esters for TGs between HDL and apoB-containing lipoproteins (LDL and VLDL) and scavenger receptor class-B type 1 (SR-B1) selective uptake of

cholesteryl esters into liver and steroidogenic organs. HDL can deliver cholesterol to the liver via the SR-B1 receptor or by holoparticle uptake (direct reverse cholesterol transport). It may also dispose of cholesterol via CETP-mediated transfer of cholesterol esters to LDL and VLDL and removal through normal clearance by hepatic LDL-Rs (indirect reverse cholesterol transport).

Studies in atherogenic animals show that raising HDL-C via genetic modification, infusion of HDL has favorable effects on experimental plague size and structure and reports of the ability of apoA1 Milano infusion therapy to reduce IVUS measured atherosclerotic plaque volume over a short period of 6 weeks in individuals following MI rekindled the interest in newer HDL-directed therapies. This raised hopes that synthetic forms of HDL, HDL mimetics, reconstituted HDL, reinfusion of delipidated HDL, and other therapies designed to increase HDL-C would be potential therapeutic approaches to reduce CVD. Upregulation of liver X receptor (LXR), the nuclear receptor that protects cells from cholesterol toxicity, may be of benefit by resulting in the cellular transduction of the ATP-binding cassette sterol transporters that efflux free cholesterol into either nascent HDL or mature HDL. Enhancing LCAT activity increases the esterification of cholesterol in HDL, resulting in HDL maturation. Modifying the holoparticle uptake of HDL (a possible mechanism of niacin) may delay catabolism by allowing the HDL particle to continue circulating and potentially increase reverse cholesterol transport. Genetic and pharmacologic studies in mice suggest that overexpression of apoA1 and SR-B1 or LXR agonists may be beneficial. Unfortunately methodology, delivery concerns, and off-target adverse effects have so far limited the use of these therapeutic approaches in humans. Despite many new possible therapeutic strategies only inhibiting CETP which increases HDL particle size and delays catabolism of HDL is currently under active clinical phase 3 trial investigations. Two previous studies with CETP inhibitors (which raise HDL-C anywhere from 30% to 140%) were stopped early for adverse events with torcetrapib or lack of benefit/futility with dalcetrapib, but ongoing outcome trials with the more potent anacetrapib and evacetrapib continue.

26. **C.** Renal insufficiency. Statins have not been shown to worsen renal function. There was concern raised when proteinuria was noted in clinical trials with rosuvastatin. However, in analyses of RCTs, creatinine has not been shown to worsen and may improve. The other adverse effects listed above have all been noted with statins. In a meta-analysis by Naci et al. in 2013 comparing statins to placebo, the odds ratio for elevation in LFTs was 1.51, diabetes development 1.09, myalgia 1.07, CPK abnormality 1.13, and cancer 0.96, statistically significant only for liver test abnormalities and diabetes. Concerns have been raised about memory loss but there is a lack of large prospective trials designed to address this question and limited. A

recent report in fact suggests a reduction in dementia with statin therapy.

27. **d.** Myalgia symptoms reported in prescribing information range from 5% to 10%. Definitions specified by the ACC/AHA NHLBI (National Heart, Lung, and Blood Institute) 2002 Clinical Advisory offer the following terminology to describe muscle injury: myalgias (muscle ache/weakness without CPK elevation), myopathy (muscle symptoms with CPK levels more than 10 times ULN), rhabdomyolysis (muscle symptoms with marked CPK elevation typically more than 10 times ULN with creatinine elevation and often with urinary myoglobin). Myalgia is reported in prescribing information at 1.2% to 3.2% but up to 11% in registries. Myopathy occurs in 0.1% to 0.5% of patients in a dose-dependent fashion. Fortunately, the risk of rhabdomyolysis is quite rare and reported <0.1%. Meta-analysis has reported rates of 0.03% to 0.05%. Muscle symptoms are more likely to occur at higher doses and doses should not exceed those recommended to achieve treatment goals. Attention should be paid to factors that may increase risk for myopathy. Concomitant medications such as fibrates, nicotinic acid (rarely), cyclosporine, azole antifungals, itraconazole, ketoconazole, macrolide antibiotics, erythromycin, clarithromycin, HIV protease inhibitors, nefazodone (antidepressant), verapamil, amiodarone, large quantities of grapefruit juice (>1 qt/day), and alcohol abuse may increase drug exposure and increase myopathy risk. This may be particularly true for simvastatin (metabolized via CYP3A) prompting an FDA advisory not to exceed 40 mg dose in general and reduce dose to 10 to 20 mg with concomitant use of drugs such as high-dose niacin, verapamil, ranolazine, and amiodarone. Other factors contributing to a higher likelihood of muscle symptoms include advanced age (especially >80 years; women more than men), small body frame, frailty, multisystem disease (e.g., chronic renal insufficiency, especially due to diabetes), and perioperative periods.

28. **b.** No. Routine measurement of CPK on statin therapy is not recommended but it is reasonable to obtain at baseline prior to therapy in individuals at higher risk for myopathy and if new symptoms develop on treatment. When a patient presents with complaints of pain, tenderness, stiffness, cramping, weakness, or fatigue the first approach should be to document the severity of the symptoms, obtain CPK, creatinine, and urinalysis to exclude rhabdomyolysis, and search for other causes (such as hypothyroidism, rheumatologic disorders, vitamin D deficiency, and steroid use). If there are clinical signs of severe pain, new muscle weakness, CPK greater than 10 times ULN, or myoglobinuria the statin should be stopped. If symptoms are mild to moderate and CPK is less than three times ULN it is reasonable to hold the statin until symptoms can be evaluated. If symptoms resolve rechallenge with the same or lower dose of the statin to establish whether a causal

relationship exists. If so starting a low dose of a different statin is reasonable followed by slow titration. If an asymptomatic individual on statin therapy has an elevated CPK, complete a thorough muscular examination and if unremarkable check for other causes. If greater than 10 times ULN, hold statin and evaluate for other primary or secondary myopathies. If a baseline CPK is known to be elevated prior to therapy, it is not an absolute contraindication to initiate statin therapy if less than three times ULN and asymptomatic. If higher, a search for other causes such as hypothyroidism, recent injury, and other myopathies would be prudent before initiating therapy with a statin and consideration of referral to a rheumatologist for further evaluation.

29. **c.** Statins have been shown to worsen the outcome in persons with chronic transaminase elevations due to hepatitis B or C. Dose-related elevation in AST or ALT has been reported between 0.1% and 2%. Statins have not been shown to worsen the outcome in persons with chronic transaminase elevations due to hepatitis B or C. A search for other causes of LFT elevations is essential including review of prescription and over-the-counter drugs and supplements, recent infections, and alcohol use. In this patient with LFT less than three times ULN, it is reasonable to repeat in 6 to 12 weeks on the same or a lower dose. If LFTs greater than three times ULN repeat in 2 weeks and if continued elevation stop statin, recheck in 2 to 4 weeks and if improving consider rechallenge with a lower-dose or different statin. Reversal of transaminase elevation is frequently noted with a reduction in statin dose, and elevations do not often recur with either readministration or selection of another statins.

30. **d.** Statin therapy may lower LFTs in patients with fatty liver infiltration. Prior to initiation of statin therapy it is reasonable to exclude other causes for LFT elevation. However, there are small studies supporting the safety of use in appropriate patients. Kiyici et al. examined 44 patients with biopsy-proven NASH (nonacoholic steatosis) and found that on atorvastatin 10 mg for 6 months there was a decrease in cholesterol, AST, ALT, AP (alkaline phosphatase), and GGT (gammaglutaryl transferase). Chalasani et al. examined the effect of statins over 6 months in patients with baseline moderate elevations in LFTs. In patients with normal LFTs placed on statin, the incidence of mild/moderate or severe elevation in LFTs was 1.9% and 0.2%, respectively, in those with baseline elevations placed on statin (4.7% and 0.6%) compared with those not placed on statin (6.4% and 0.4%). Progression to liver failure due to statins is not zero but exceedingly rare reported at 0.02 to 0.07 per million treated. In this patient, an ultrasound of the liver confirmed fatty infiltration. Manufacturer's prescribing information lists unexplained ALT greater than three times ULN as a contraindication to statin

therapy. The best approach is to counsel on a diet program low in sugar and carbohydrates, weight loss, and exercise, and start statin therapy following the LFTs more closely.

31. **c.** 2 and 3. Sattar in a meta-analysis of 13 statin trials in 91,140 patients noted that 4,278 developed DM (4.89% on statins versus 4.5% on placebo; 0.39% absolute increased difference and 9% relative risk of incident diabetes). This represented 1 additional case of DM per 1,000 patient-years. Preiss published a meta-analysis of 5 trials in 32,772 patients comparing high- versus moderate-dose statins and reported 2,749 developed DM (8.8% versus 8.4% or an absolute increase of 0.4%). There were two additional cases of DM (18.9 versus 16.9) per 1,000 patient-years of follow-up. The development of diabetes did not appear to reduce the benefits of treatment. Sattar found 5.4 less cardiac events for 255 patients treated over 4 years for each 1 mmol/L reduction in LDL-C compared with 1 extra case of diabetes for the same time period. Preiss noted 1 additional case of diabetes for every 498 patients over 1 year compared with 1 fewer CVD event for every 155 patients over 1 year. In a separate analysis of three high-dose atorvastatin trials, Waters et al. reported no difference in CVD events occurring in 11.3% with new DM and 10.8% without new DM. This compared with those with diabetes at baseline (10.1% versus 17.5%). The FDA reported this association in February 2012 but added that it does not appear to reduce the benefits of statin therapy in appropriately selected patients. Therefore, statin therapy should not be denied or appropriate doses reduced to avoid diabetes. However, since the individuals that developed diabetes are those at risk for diabetes it is prudent to measure for glycemic control more frequently and emphasize lifestyle interventions to reduce diabetes risk. This approach has been supported in the ACC/AHA 2013 guidelines.

32. **b.** 1, 2, 3, and 5. This patient is at very high risk for recurrent events. Since the greatest reduction in CVD events has been demonstrated with statins, further attempts to rechallenge with statins are appropriate. Small clinical trials and observational studies have shown that tolerance may be improved by trying multiple alternate statins, often using a potent statin beginning at low and intermittent rather than daily dosing with slow titration. Small investigations of coenzyme Q10 appear to lower the incidence of muscle complaints when added to statins. An analysis of patients referred to the Cleveland Clinic for intolerance to statins (the majority due to muscle complaints) revealed that over two-thirds of patients were able to tolerate some statin regimen with average LDL-C reduction of ~28% in those able to tolerate daily dosing. Niacin in high doses has been shown in the Coronary Drug Project to reduce recurrent MI and mortality after MI and is a

reasonable component of a combination therapy program in patients resistant to all statins. Both LDL-C apheresis and mipomersen can lower LDL-C but with LDL-C levels in this range he would not meet the FDA recommendation for apheresis and although trials with mipomersen have been shown to be effective in both homozygous and heterozygous FH patients it is only currently approved for homozygotes.

33. **c.** Although difficult to demonstrate in individual studies, meta-analysis of fibrate trials has demonstrated reduction in cardiovascular mortality on therapy. An increase in myopathy has been reported with both gemfibrozil and fenofibrate as monotherapy but to a greater extent when added to statins (5.5-fold increased risk of myopathy when combined with statins) and more so with gemfibrozil compared with fenofibrate. A meta-analysis of monotherapy fibrate trials published in 2007 in the American Heart Journal reported a reduction in nonfatal MI but no reduction in fatal MI or total/cardiovascular mortality. Subanalyses of individuals with a metabolic dyslipidemia in fibrate trials such as BIP (bezafibrate infarction prevention), FIELD (fenofibrate intervention and event lowering in diabetes), and ACCORD trials demonstrated significant reduction in the primary endpoint of combined cardiovascular events, although not in the overall populations studied. Renal status should be evaluated within 3 months of initiation of therapy and every 6 months thereafter. Plasma half-life of fenofibric acid is prolonged in renal insufficiency and requires lower dose with glomerular filtration rate (GFR) 30 to 59 and avoidance if GFR <30. An increase in creatinine of 12% was reported in the FIELD study using fenofibrate, usually reversible with discontinuation of therapy.

34. **d.** Niacin can raise HDL-C from 20% to 25% and lower TGs from 30% to 50% depending on the dose and pretreatment TG levels but has little effect on LDL-C. Flushing and skin reactions are the most common reasons limiting niacin use. Gout episodes are more common in individuals with a prior history of gout. A small increase in blood glucose levels and HbA1c has been reported but is generally not of clinical significance and manageable with adjustments in glucose-lowering therapies. Baseline LFTs, fasting glucose, or HBA1c and uric acid should be obtained prior to therapy. While studies have suggested a benefit on surrogate markers for CVD events such as CIMT in the Arterial Biology for the Investigation of the Treatment Effects of Reducing Cholesterol (ARBITER) trials, there are currently no large longitudinal controlled trials demonstrating incremental benefit on clinical events when niacin is added to adequate statin therapy. Results of the AIM-HIGH and HPS-THRIVE were reviewed in Question 25. Niacin has a beneficial effect on multiple components of the lipid panel including a 20% to 35%

increase in HDL-C, up to 20% lowering of LDL-C, and up to 30% to 50% reduction in TG. The Coronary Drug Project, initiated in the late 1960s, was a large secondary prevention study among men with several treatment arms, one of which utilized up to 3 g/day of niacin (Table 12.5). Compared with placebo, niacin lowered TC by 10% and TG by 26% (although HDL-C data not available) and after 6 years, significantly reduced nonfatal MI by 27%. A 15-year follow-up analysis (9 years after the interventions had ended) revealed a significant 11% decrease ($p < 0.004$) in total mortality. Further analysis has demonstrated equivalent reductions in CVD risk regardless of entry fasting glucose level, presence or absence of diabetes at entry, or change in fasting glucose while on therapy.

TABLE 12-5 Pharmacologic Therapies for Lipid Management

Drug	% Decrease LDL	% Increase HDL	% Decrease TG	Side Effects	Contraindications
Statins	18–55	5–15	7–30	Myopathy, increased LFTs, diabetes	Liver disease
Bile acid sequestrants	15–30	3–5	May increase	GI distress, constipation, decreased drug absorption	Very elevated TG
Cholesterol absorption inhibitor	15–25	1–3	5–14	GI distress, increased LFTs, myopathy	Liver disease
Nicotinic acid	5–25	15–35	20–50	Flushing, GI distress, increased LFTs, increased glucose and uric acid	Liver disease, severe gout, peptic ulcer disease
Fibric acids	5–20, may increase	10–20	20–50	GI distress, gallstones, myopathy	Severe renal disease or liver disease
Omega-3 fish oil	May increase	10–20	20–50	GI distress	Fish allergy

GI, gastrointestinal; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LFTs, liver function tests; TG, triglyceride.

Pericardial Disease

Wael A. Jaber • Parag R. Patel

QUESTIONS

1. A 62-year-old man is admitted with chronic obstructive pulmonary disease (COPD) and mild left ventricular (LV) dysfunction (ejection fraction [EF] 45%) as well as symptomatic, recurrent atrial fibrillation (heart rate [HR] 120s to 150s) despite antiarrhythmic drug therapy and direct current cardioversion in the past. After rate control with intravenous (IV) β-blockers, the HR improves and the patient feels better. Given his recurrent atrial fibrillation despite optimal medical therapy, the patient is referred for radiofrequency ablation of atrial fibrillation (pulmonary vein isolation) procedure. The procedure is performed on anticoagulation (international normalized ratio >2.0) and is deemed a success, with no inducible atrial fibrillation at the end of the case. A small atrial septal defect (ASD) was noted with intracardiac echocardiography at the end of the case, with no other remarkable findings. That evening in the post-anesthesia care-unit (PACU), the patient is noted to be hypotensive and tachycardic with increasing dyspnea. There is a concern for cardiac tamponade; however, the arterial line does not show a significant respiratory variation of the blood pressure (BP) waveform (pulsus paradoxus). An echocardiogram is performed, demonstrating a large circumferential effusion and the patient is referred for urgent pericardiocentesis. Which of the following explains why the patient did not develop a pulsus on the arterial line, despite a large, hemodynamically significant pericardial effusion?

   a. Presence of an ASD
   b. Administration of excess IV fluid during the ablation
   c. LV dysfunction
   d. COPD

2. A 38-year-old patient with no prior medical history presents to the emergency room

with 4 days of chest discomfort. He denies any recent trauma, fever, or use of anticoagulants. The pain is positional and the patient reports mild upper respiratory infection (URI) symptoms in the preceding week. Laboratory work is notable for elevated white blood cell count (neutrophil predominance) as well as elevated erythrocyte sedimentation rate (ESR)/high-sensitivity C-reactive protein (hsCRP); his troponin and other laboratory work is otherwise negative/normal. Electrocardiogram (ECG) is consistent with pericarditis. There is a low suspicion for acute coronary syndrome, and acute pericarditis is diagnosed with small effusion on the echocardiogram; the pain improves with analgesics. Which of the following regimens is the most appropriate therapy for this patient to treat the acute episode and maintain remission?

a. Ibuprofen 600 TID for 2 weeks followed by taper and colchicine 0.5 mg BID for 3 months
b. Aspirin 325 daily and colchicine 0.5 mg BID for 2 weeks followed by taper
c. Ibuprofen 400 BID and colchicine 0.5 mg BID for 2 weeks followed by no taper
d. Prednisone 10 mg daily and ibuprofen 600 TID for 3 months followed by no taper

3. A 62-year-old man with cardiac risk factors of tobacco use, hypertension, and diabetes mellitus returns for follow-up after late-presenting mid-left anterior descending artery (LAD) ST-elevation myocardial infarction (MI). He had an occluded mid-LAD, which was successfully aspirated and stented with a single drug-eluting stent; no significant disease elsewhere is noted. The next day he reports progressive chest discomfort and mild fever and has developed a two-component pericardial friction rub on physical examination. His ECG is concerning for pericarditis (Dressler syndrome) and an echo is performed showing no interval change from discharge other than the presence of a small pericardial effusion. Which of the following regimens would be the most appropriate therapy in this patient?

a. Aspirin 650 TID for 2 weeks with taper to 81 mg daily + colchicine 0.5 mg BID for 3 months
b. Aspirin 325 daily for 2 weeks, then taper to 81 mg daily + ibuprofen 600 mg TID for 3 months
c. Ibuprofen 600 mg TID for 2 weeks with taper + colchicine 0.5 mg BID for 3 months
d. Indomethacin 50 mg TID for 3 months as well as aspirin 650 mg TID for 3 months with taper to 81 mg

4. A 45-year-old male patient with a history of acute pericarditis now returns for

outpatient follow-up with increasing dyspnea and lower extremity edema. The patient was seen and started on high-dose aspirin and colchicine (no nonsteroidal anti-inflammatory drugs [NSAIDs] due to allergy) and has not been able to taper for the past 6 months due to persistent low-level symptoms. He has an elevated jugular venous pulse without inspiratory decline, 2+ pedal edema, and congested liver without ascites, as well as a soft pericardial knock. Laboratory values are notable for mild transaminitis as well as elevated ESR/hsCRP. ECG is unremarkable and echo shows a small persistent pericardial effusion with tubular-shaped LV with normal function, along with diastolic bounce and conical-shaped right ventricle (RV) as well as plethoric inferior vena cava and respirophasic transmitral and trans-tricuspid variation all consistent with constrictive pericarditis. Which of the following would be the next most appropriate step in management?

a. Initiate steroid therapy (0.25 to 0.5 mg/kg/day) along with colchicine, and initiate PO diuretic
b. Admit for IV diuresis and transition to PO diuretic regimen after cardiac catheterization for constriction evaluation
c. Repeat echo in 2 to 3 months aspirin and colchicine at current doses
d. Surgical evaluation for pericardiectomy/stripping

5. A 39-year-old patient with no prior medical visits presents with cardiac tamponade and undergoes urgent pericardiocentesis. He is from sub-Saharan Africa and has never been seen by a physician before—reports feeling progressively ill for the past month and brought to the hospital after syncopal episode today. Fluid analysis is performed and listed below:

Gram stain: no gram-positive/gram-negative bacteria noted
Peripheral cell count: normal (peripheral cell count $<10 \times 10^9$ cells/L)
Pericardial fluid differential (lymphocyte/neutrophil): >1.0 (monocytes present as well)
Protein: elevated
hsCRP: markedly elevated
Lactate dehydrogenase (LDH): elevated (>2.0 times peripheral LDH level)
Adenosine deaminase (ADA): >40 U/L
Interferon gamma: >50 pg/mL
Glucose: low
Culture and cytology/acid fast staining: pending

The most likely etiology for the effusion would be

a. tuberculous pericarditis.
b. endemic malignancy (i.e., Epstein-Barr virus–associated Burkitt's) with

metastatic spread.

c. malarial (Plasmodium vivax).

d. unable to determine—require pericardial biopsy to confirm.

6. A 47-year-old man with constrictive pericarditis is undergoing an echocardiogram for follow-up. The sonographer asks you to explain the difference between the annulus reversus and annulus paradoxus phenomena. Which of the following statements is correct?

   a. Annulus reversus refers to reversal of septal and lateral mitral tissue Doppler velocities (E′ septal > E′ lateral) and annulus paradoxus refers to inverse correlation of E/E' and LV end-diastolic pressure.

   b. Annulus reversus refers to reversal of septal and lateral mitral tissue Doppler velocities (A′ septal > A′ lateral) and annulus paradoxus refers to inverse correlation of E/E′ and LV end-diastolic pressure.

   c. Annulus reversus refers to reversal of septal and lateral mitral tissue Doppler velocities (E′ septal < E′ lateral) and annulus paradoxus refers to positive correlation of E/E′ and LV end-diastolic pressure.

   d. Annulus reversus refers to reversal of septal and lateral mitral tissue Doppler velocities (A′ septal < A′ lateral) and annulus paradoxus refers to a positive correlation of E/E′ and LV end-diastolic pressure.

7. A 51-year-old male patient is admitted to the hospital with anasarca and progressive dyspnea and functional limitation. He has a prior history of coronary artery bypass grafting and post-pericardiotomy syndrome with relapsing pericarditis that has likely advanced to constrictive physiology (despite slow taper steroid therapy), given his presenting symptoms and physical examination findings. During the admission he is aggressively diuresed with IV diuretics with improvement in his renal and liver function, as well as symptom improvement (edema and dyspnea). He is unable to go for a magnetic resonance imaging (MRI) for further assessment (prior metallic implant in his spine for scoliosis) and his echocardiogram images are technically difficult due to his distorted spine and prior cardiac surgery.

   He is referred for dual transducer cardiac catheterization for hemodynamic evaluation of right- and left-sided pressures as part of his diagnostic workup. The catheterization laboratory team begins the procedure and calls you to discuss the case. They note a sinus rhythm at 90 bpm with occasional premature ventricular contraction and a central venous pressure of 4 mmHg and nonelevated end-diastolic pressures at the beginning of the study (due to recent diuresis); they are unable to elucidate diastolic equalization of pressures, significant “dip and plateau,” or respiratory discordance of the ventricular pressure waveforms.

   A potential mechanism for the discordant catheterization findings would be

a. lack of preload due to overdiuresis.
b. borderline tachycardia and ectopy preventing accurate analysis.
c. presence of only mild constrictive physiology.
d. presence of restrictive cardiomyopathy and physiology.

8. A 32-year-old white man presented initially with low-grade fever, cough, and pleuritic chest pain. He was found on ECG to have diffuse ST-segment elevation. A transthoracic echocardiogram (TTE) revealed a large pericardial effusion, and serologies were positive for coxsackievirus B infection. He was diagnosed with acute viral pericarditis and treated with indomethacin. He returns 4 weeks later for follow-up and states that he no longer has any pain, but he notes some mild ankle swelling. His ECG is normal. A repeat TTE shows resolution of the effusion but new findings consistent with mild constriction. What is the next step in managing this patient?

a. Obtain cardiac MRI to better assess the pericardium.
b. Have a cardiothoracic surgical consultation for pericardiectomy.
c. Reassure the patient and observe him over the next 3 months for worsening of symptoms.
d. Start a course of steroids.

9. A 45-year-old woman with a history of treated carcinoma of the breast presents to the local emergency department with a few days of severe chest pain. In the emergency department, she appears ill and pale and in moderate discomfort. Her BP is 135/60 mmHg; her respiratory rate is 24 breaths per minute; her HR is 82 bpm; and her temperature is 100.8°F. The resident on call reads her chest X-ray (CXR) as unremarkable. Her ECG is shown in Figure 13.1. What is the most reasonable next step?

a. Give aspirin and nitroglycerin and prepare to administer thrombolytics.
b. Call the cardiac intervention team and rush the patient to the catheterization laboratory for emergency coronary intervention.
c. Give a nonsteroidal anti-inflammatory medication.
d. Discharge the patient and refer her for a gastroenterology follow-up as an outpatient.

10. A 59-year-old man with a history of coronary artery disease (CAD) and remote coronary bypass surgery presents with progressive dyspnea and vague chest pain. He had a stress echocardiogram for these symptoms that demonstrated normal LV function with no stress-induced wall motion abnormalities. However, he returned to the emergency department a few days later with recurrent symptoms. This time the house officer examining the patient notes 3+ pedal edema. The patient is admitted

and started on diuretics. His blood tests are as follows:

White blood cell count = 11,000
Hemoglobin = 14.2
Platelets = 172,000
Albumin = 4.6
Urea = 11
Creatinine = 0.9

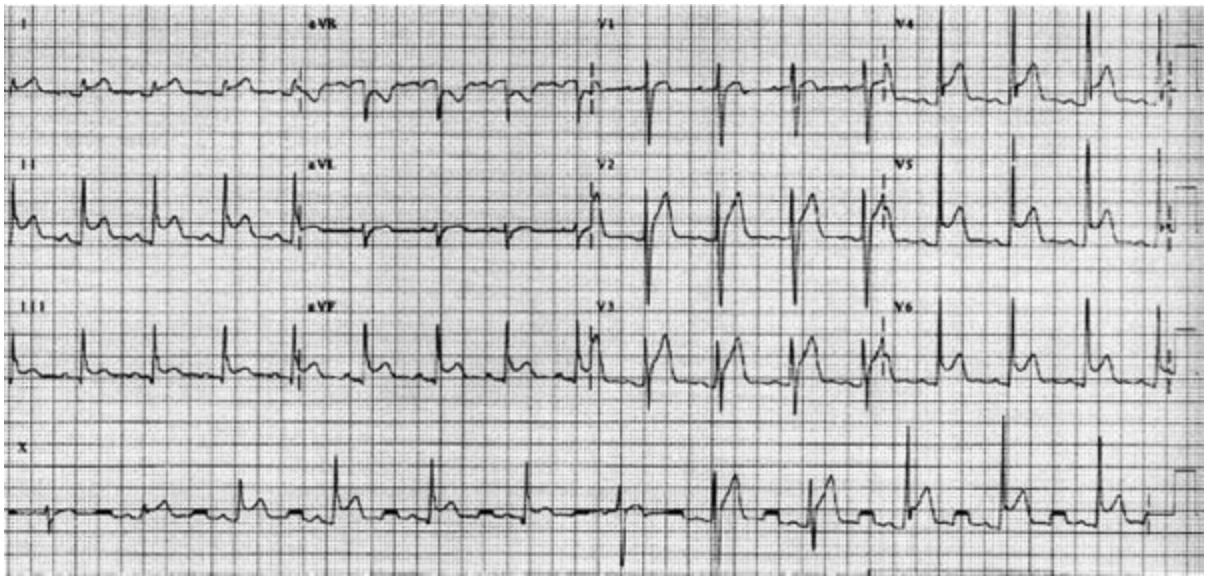

Figure 13.1 • (From Wagner GS, ed. Marriott's Practical Electrocardiography, 9th ed. Baltimore, MD: Williams & Wilkins; 1994, with permission.)

Owing to the recurrent symptoms, his cardiologist decides to refer him for a right and left heart catheterization. The coronary grafts are all patent. The tracings from the study are shown in Figure 13.2. What is the most logical explanation for this patient's symptoms?

a. Constrictive pericardial disease
b. Small-vessel CAD
c. Diastolic dysfunction related to his chronic CAD
d. Cardiac amyloid
e. Cardiac tamponade

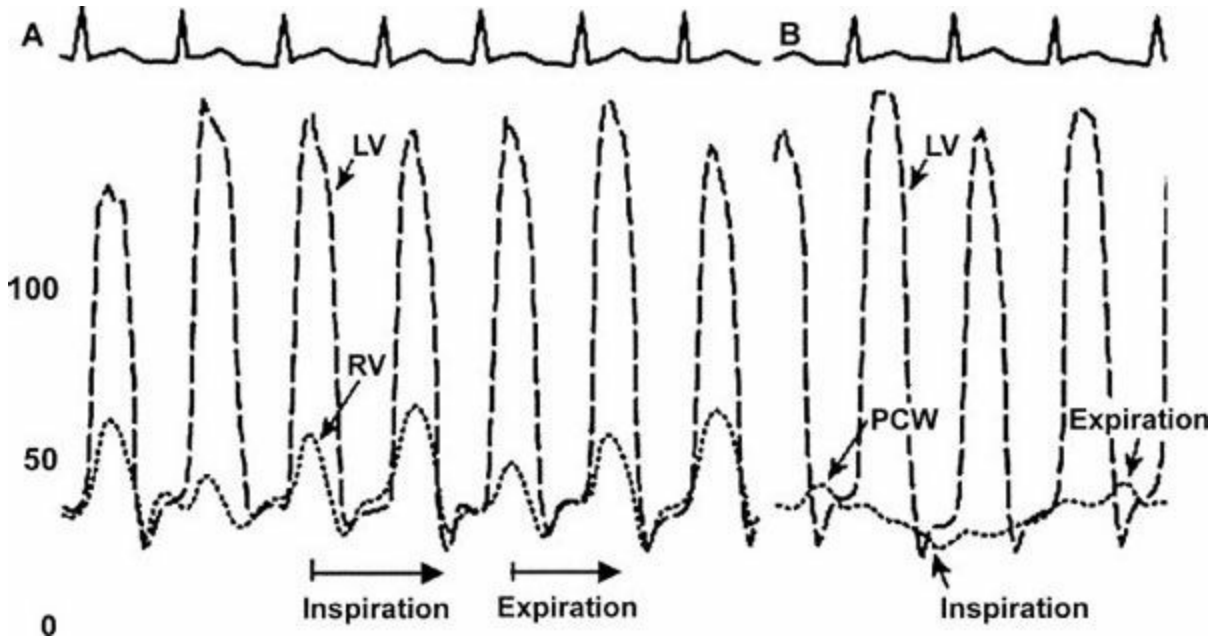

Figure 13.2 • PCW, pulmonary capillary wedge.

11. A 73-year-old man with no cardiac history presents with chronic lower extremities edema. His primary care physician attributed his symptoms to old age. He was treated with hydrochlorothiazide. Initially, he reported a good response to the therapy, but, over the past few months, his edema recurred, and doubling the diuretic dose did not alleviate his symptoms. On his initial examination, you notice distended neck veins and a quiet precordium. He has mild hepatomegaly and 4+ pedal edema. A TTE is suboptimal because of the patient's inability to lie flat and obstructive lung disease. His blood work is as follows:

White blood cell count = 6,000
Hemoglobin = 12.7
Platelets = 225,000
Urea = 43
Creatinine = 2.4
Albumin = 3.6

A cardiac catheterization is performed. He has normal coronary arteries with mild impairment in LV systolic function. The tracings from the study are shown in Figure 13.3. What is your explanation of his symptoms?

a. You agree with his primary care physician. You tell the patient that he probably has peripheral venous insufficiency.
b. This patient has significant diastolic dysfunction, and his prognosis is guarded.
c. This patient's symptoms are due to the LV systolic dysfunction and volume overload.

d. This patient should be referred for surgical evaluation for possible pericardial stripping.

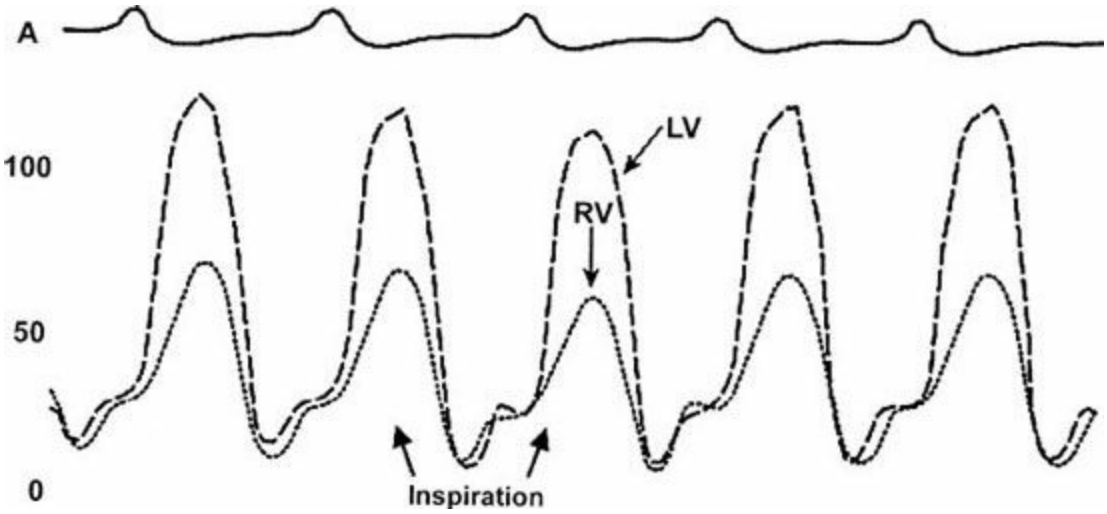

Figure 13.3 • Pressure tracings in the LV and RV.

12. A 56-year-old male smoker with a family history significant for CAD is presenting with dyspnea on exertion and nonexertional vague chest pain. His physical examination and his initial ECG are unremarkable. His CXR demonstrates an increased cardiac silhouette. There is also a small nodule seen in his right upper lobe. The radiologist is not certain about its significance. Given his risk factors and symptoms, he is referred for a perfusion stress test. The images from the stress test are shown in Figure 13.4. Which of the following does the patient clearly have?

a. He has coronary ischemia and should be referred for coronary angiography.
b. There is no evidence of pathology to justify his symptoms.
c. His symptoms are related to impairment of RV filling and pericardial disease.
d. He has mild ischemia and can be treated medically.

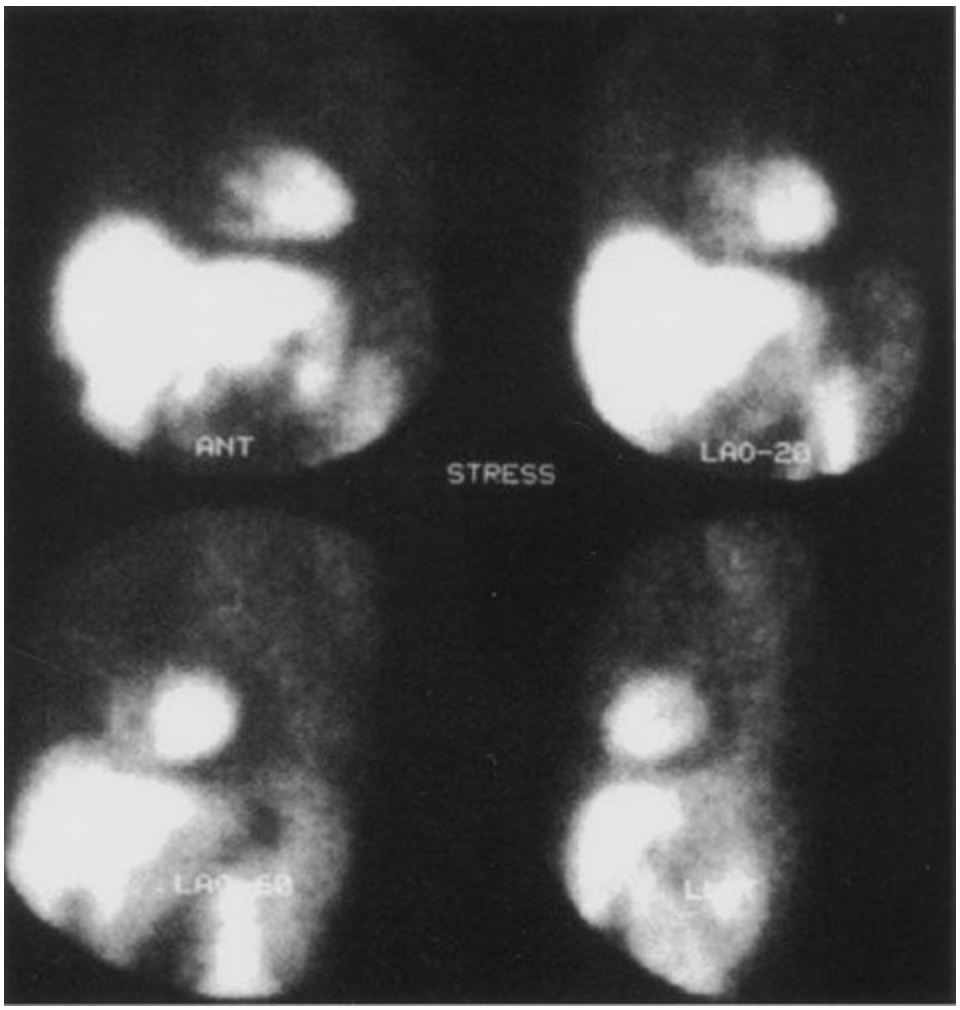

Figure 13.4 • (From Pohost GM, O'Rourke GA, Berman DS, et al., eds. Imaging in Cardiovascular Disease. Philadelphia, PA: Lippincott Williams & Wilkins; 2000, with permission.)

13. A 58-year-old man, with cardiac risk factors of tobacco use, hypertension, and hypercholesterolemia, presented to the emergency department a few days ago with an acute onset of left-sided chest pain. His evaluation revealed a diaphoretic man in moderate discomfort. An ECG was performed and showed a pattern consistent with an inferior wall acute MI. The patient was treated with thrombolytics. Forty-five minutes after the initial dose of the thrombolytics, he felt better and had complete resolution of his symptoms and normalization of the ECG. On the third day after the event, he reports midsternal chest pain, vague in nature, with mild diaphoresis and shortness of breath. An ECG is performed, as shown in Figure 13.5. Which of the following should you tell the patient is the next step in managing his condition?

a. There is evidence of reocclusion of the infarct-related artery, and a percutaneous intervention is needed.
b. There is evidence of reocclusion of the infarct-related artery, and rebolus with thrombolytics and heparin is indicated.
c. He is showing signs of early postinfarction pericarditis, and a nonsteroidal anti-

inflammatory medication should be started.

d. An LV aneurysm has developed, and a TTE is needed to evaluate the extent of the aneurysm.

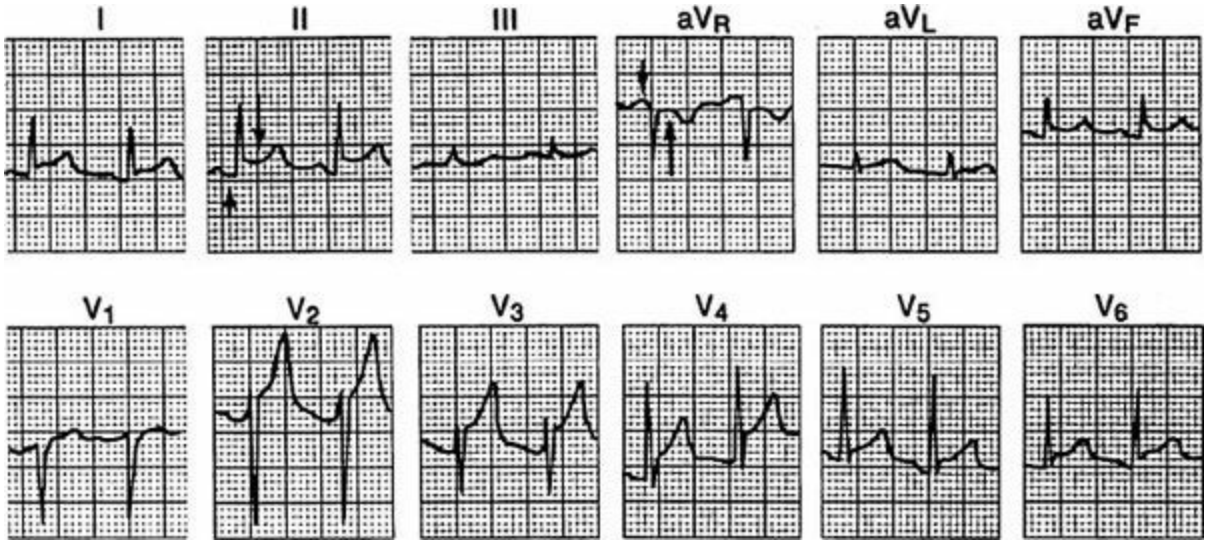

Figure 13.5 • (From Braunwald E, ed. Heart Disease: A Textbook of Cardiovascular Medicine, 5th ed. Philadelphia, PA: WB Saunders; 1997, with permission.)

14. A 19-year-old male college student presents to his local physician for evaluation of a dry cough. His symptoms started 3 days ago but now appear to be resolving. He had planned a trip overseas but was concerned and is now seeking advice. His physical examination is unremarkable. A CXR is performed and is read as showing an enlarged right cardiac silhouette. A TTE is ordered, which is shown in Figure 13.6. The patient most likely has which of the following conditions?

a. He has a pericardial cyst that is benign; no further treatment should be offered.
b. He has cardiac tamponade requiring a pericardial tap.
c. He has a pleural effusion.
d. There is no pathology. The CXR was misread.
e. He has mesothelioma.

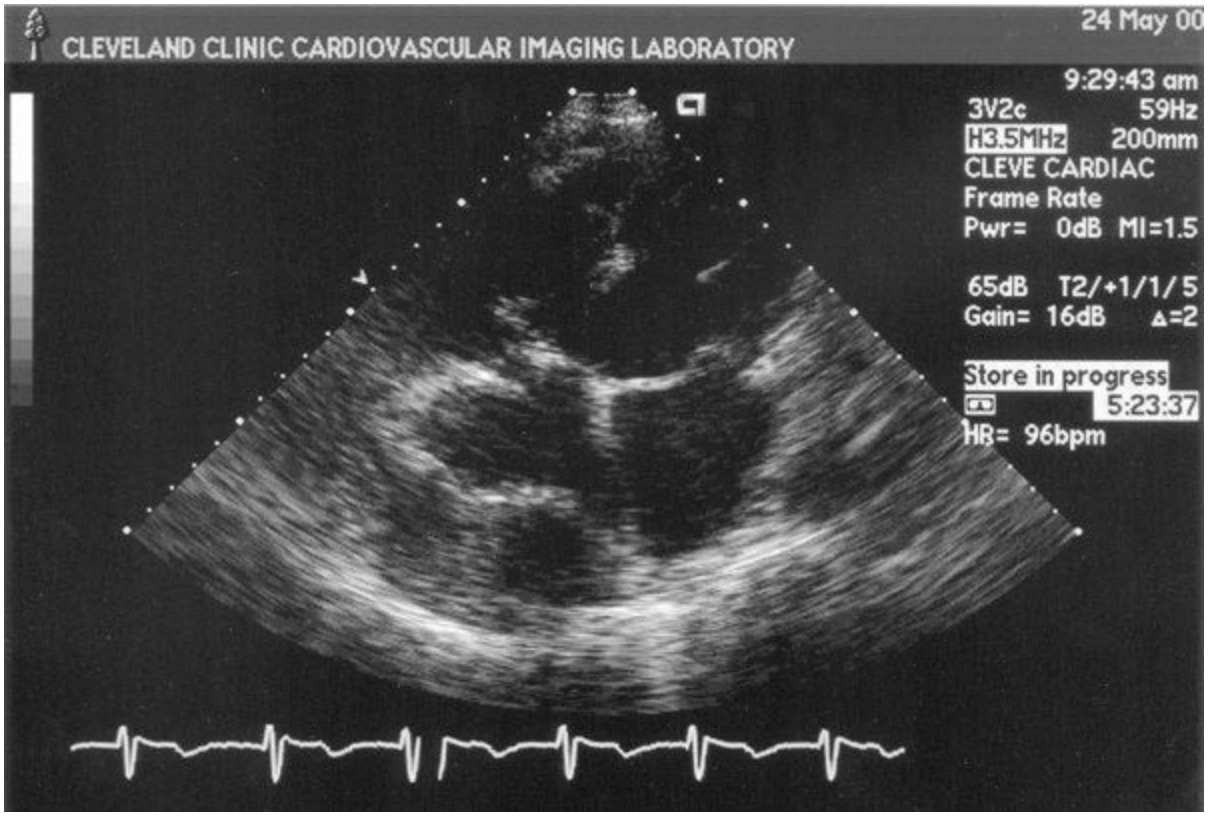

Figure 13.6

15. You are called to the emergency department to see a 74-year-old man. He has a history of heavy smoking and hypertension. The patient cannot remember his medications, but he reports not taking them on a routine basis. In the past few hours before presentation, he experienced a sudden onset of severe left-sided chest pain with radiation to the left scapula. Approximately half an hour later, he noted some difficulty breathing. In the emergency department, he is noted to be diaphoretic and in significant respiratory distress. His physical examination reveals a BP of 160/90 mmHg, elevated jugular venous pressures, and a quiet precordium. His ECG is reported as sinus tachycardia with no acute ST-T changes. After initial pain and BP management, a transesophageal echocardiography (TEE) is performed to rule out aortic dissection. The findings of the TTE are shown in Figure 13.7. What is your recommendation?

a. The patient should have immediate surgical intervention.
b. The patient needs BP control and surgical evaluation once he is medically stabilized.
c. The patient should have percutaneous pericardial drainage to manage the cardiac tamponade and then a surgical evaluation.
d. The diagnosis is unclear; a computed tomographic (CT) scan or an aortic angiogram is needed.

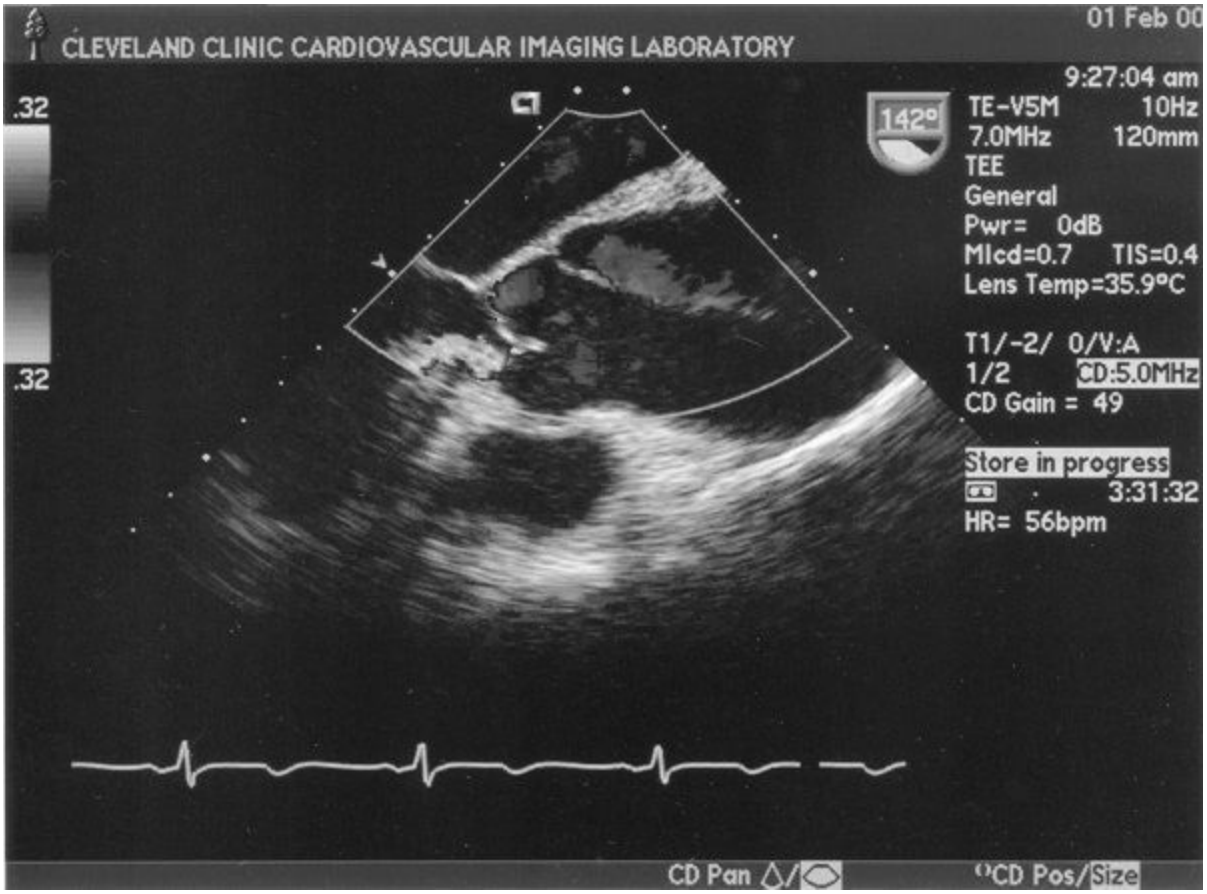

Figure 13.7

16. A 42-year-old man was referred for evaluation of symptomatic mitral regurgitation. He was diagnosed with mitral valve prolapse that was not suitable for repair. Given his family history of CAD and tobacco use, he underwent a coronary angiogram, which revealed no evidence of obstructive coronary disease. He underwent an uneventful mitral valve replacement. He was extubated and transferred from the intensive care unit 48 hours after the operation. On postoperation day 3, you note the patient to be pale and lethargic and in mild respiratory distress. His BP is 100/60 mmHg. His cardiac and lung examination is compromised by the presence of rapid breathing and chest tubes. His ECG reveals normal sinus rhythm (NSR) at 97 bpm with no acute ST-T changes. A TTE is performed. Selected views are shown in Figure 13.8A. As the patient continues to deteriorate and becomes hypotensive, a TEE is performed next, as shown in Figure 13.8B. What should you recommend?

a. Immediate surgical exploration of the pericardium
b. Percutaneous aspiration of the fluid present in the pericardium
c. Immediate surgical intervention for malfunction of the prosthetic mitral valve
d. A 500-cc bolus of IV normal saline solution should be started because the patient is dehydrated, and no further intervention is needed

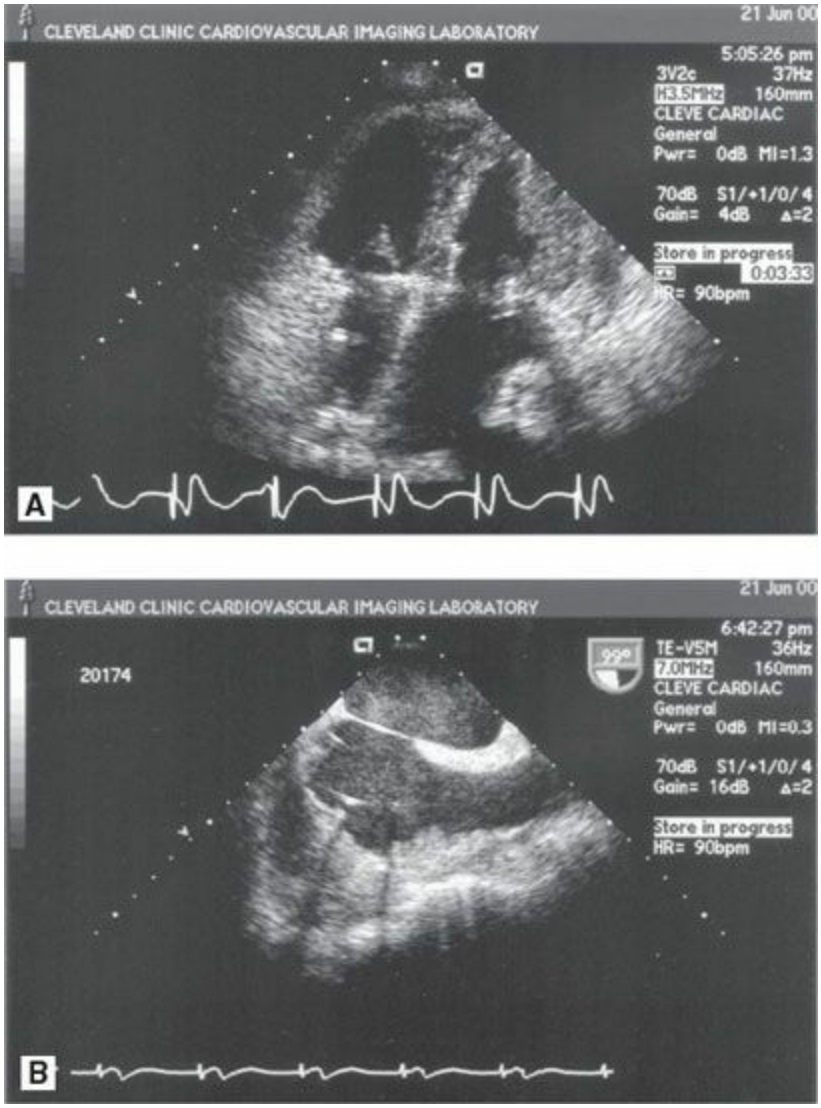

Figure 13.8

17. A 49-year-old black man with hypertension and chronic renal insufficiency presents with dyspnea and fluid overload with decreased urine output. He is treated in the hospital with diuretics, and his symptoms improve. However, his renal function continues to deteriorate with an increasing blood urea nitrogen of 90 and a creatinine of 5.4. In addition, the patient is noted to have several bruises on his arms from needlestick blood draws and IV lines. On hospital day 4, the patient is noted to be hypotensive and tachycardic: BP, 80/40 mm Hg; HR, 110 bpm. No jugular venous distention is noted, but heart sounds are diminished, and a loud pericardial rub is heard. His TTE is shown in Figure 13.9. What is the next step in management?

a. Urgent pericardiocentesis
b. IV hydration
c. Immediate dialysis

d. The continuation of diuretics with serial TTE

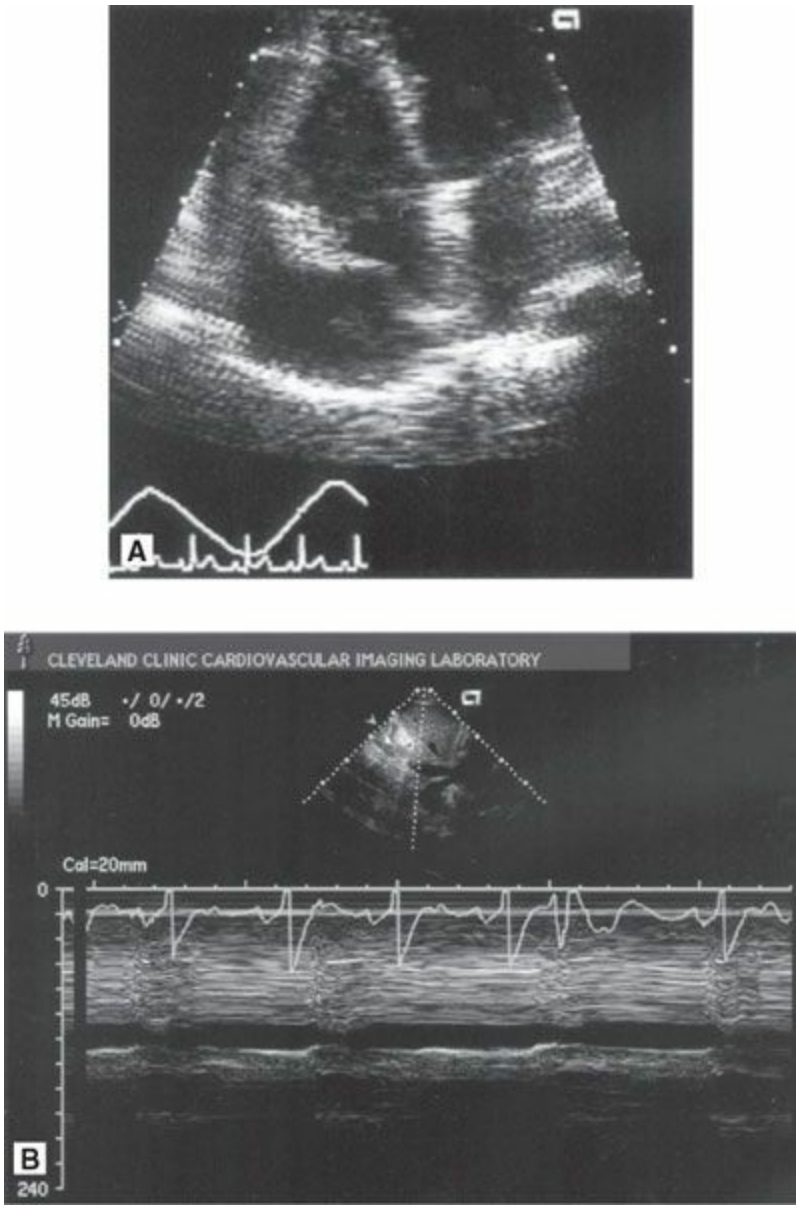

Figure 13.9 • (From Otto CM, Pearlman AS. Textbook of Clinical Echocardiography. Philadelphia, PA: WB Saunders; 1995, with permission.)

18. A 42-year-old white male chef is brought into the emergency department after a motor vehicle accident in which he fell asleep at the wheel and ran into a tree. He is reporting anterior chest discomfort and shortness of breath. He relates no prior medical conditions and takes no medications. Vitals are stable with a BP of 120/60 mmHg and an HR of 90 bpm. His ECG is shown in Figure 13.10A. A TTE is performed. Diastolic images are shown in Figure 13.10B. Laboratory tests show modest elevation of creatinine phosphokinase at 240. Which of the following is the most reasonable next step in managing this patient?

a. Start the patient on a nonsteroidal anti-inflammatory agent with follow-up as an outpatient in 1 week.
b. Admit the patient for observation on telemetry with a follow-up TTE.
c. The patient needs immediate percutaneous revascularization.
d. Send the patient for surgical treatment of pericardial rupture.

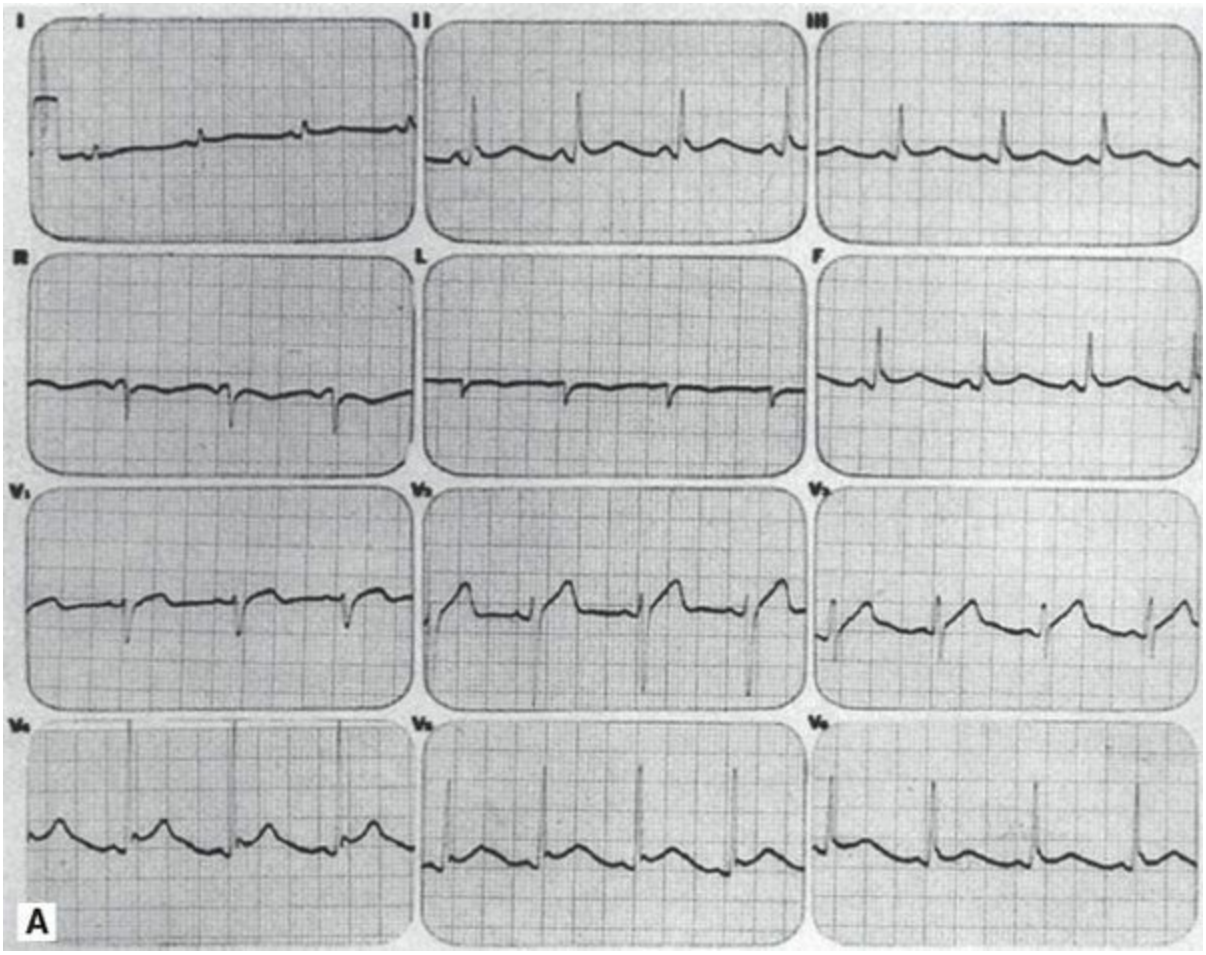

Figure 13.10A • (From Chou T-C. Electrocardiography in Clinical Practice, 4th ed. Philadelphia, PA: WB Saunders; 1996, with permission.)

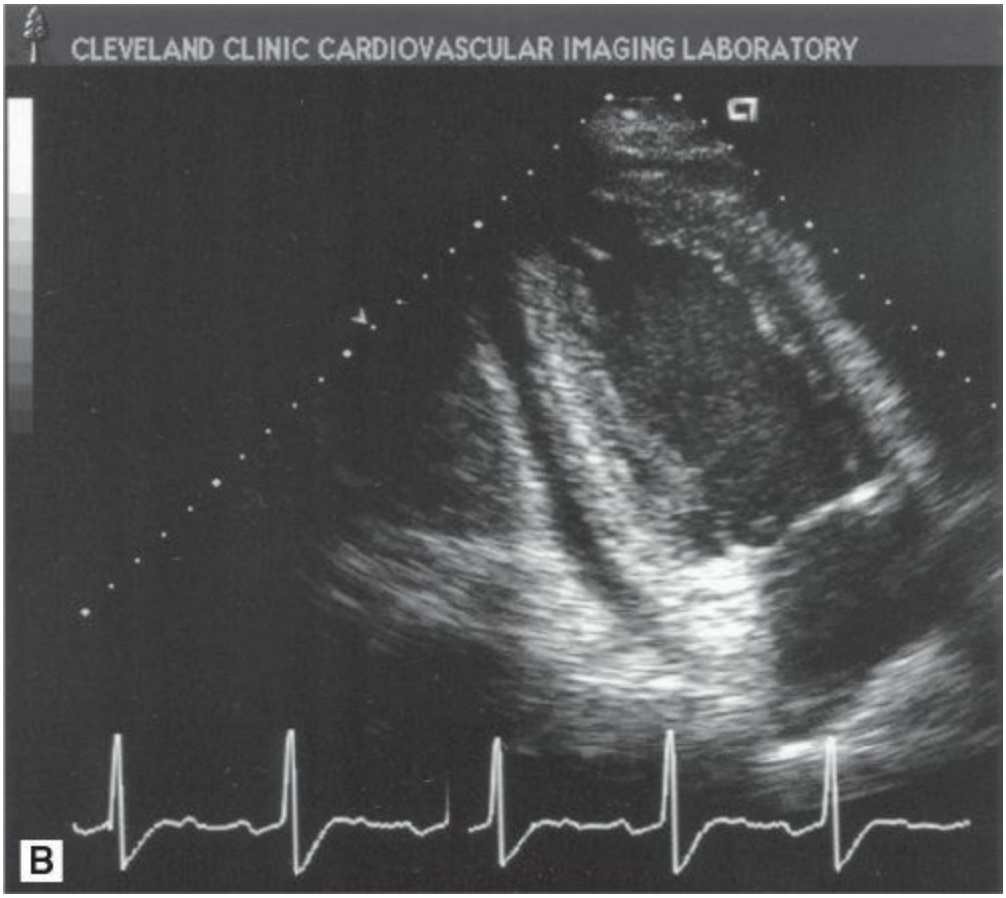

Figure 13.10B • (From Chou T-C. Electrocardiography in Clinical Practice, 4th ed. Philadelphia, PA: WB Saunders; 1996, with permission.)

19. A 22-year-old white man is newly diagnosed with non-Hodgkin lymphoma. He undergoes a metastatic workup that includes an MRI of the chest and abdomen, which is shown in Figure 13.11. The plan is for chemotherapy, but you are consulted for cardiac assessment before beginning chemotherapy. Radionuclide ventriculography shows a normal LV EF of 65%. What should you recommend?

a. Ordering a TTE to delineate the abnormality
b. Cardiothoracic surgical consultation before starting chemotherapy
c. Exercise stress testing
d. Proceeding with chemotherapy without further cardiac evaluation

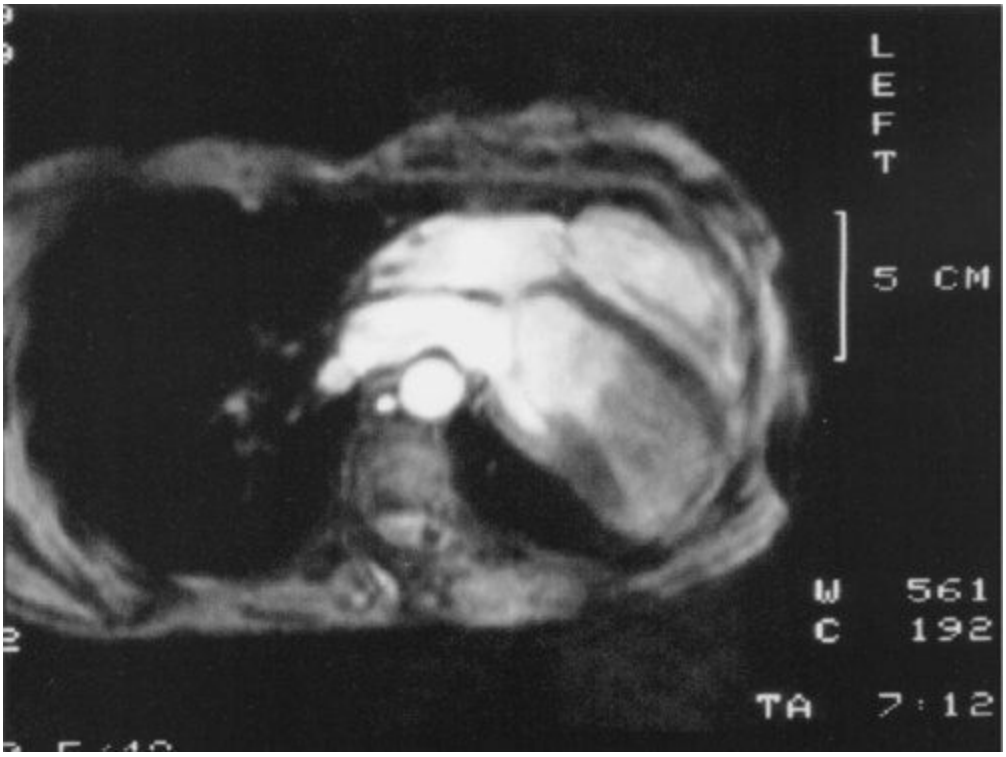

Figure 13.11 • (MRI image was provided by Dr. Richard White, Head, Section of Cardiovascular Imaging, Departments of Radiology and Cardiovascular Medicine, The Cleveland Clinic Foundation.)

20. A 44-year-old white man with rheumatoid arthritis is referred to your office for evaluation after his rheumatologist heard a loud heart sound. On questioning, the patient mainly reports joint pains in his fingers. He denies any chest discomfort or shortness of breath. He has been on methotrexate and prednisone for the past year. His examination is significant for mild erythema and swelling of his distal interphalangeal joints, rheumatoid nodules on his right forearm, clear lungs, distant heart sounds with a loud friction rub, and moderate peripheral edema. You order a TTE to further assess his heart. Selective images are shown in Figure 13.12. What is your recommendation?

a. Because he currently has no cardiac symptoms, no further treatment is needed except to continue methotrexate and prednisone.
b. You want the patient to start indomethacin, continue methotrexate and prednisone, and follow up in 4 weeks.
c. The best treatment at this time for his pericardial effusion is drainage with the instillation of steroids to prevent recurrence.
d. A surgical evaluation for pericardiectomy is necessary because the findings on his TTE indicate that he will develop problems in the future if this is not taken care of soon.

21. A 55-year-old white man presents for evaluation of chest pain. He has no prior

medical problems, but he has noted burning epigastric and chest discomfort for the past few months for which he was taking antacids with some relief of his symptoms. However, because the symptoms persisted, he sought medical attention and was referred for an esophagogastroduodenoscopy, which was performed earlier today. He was found to have a fundal hiatal hernia with a gastric ulcer that was cauterized, and he was started on omeprazole. On returning home, he noted a new sharp anterior chest pain, somewhat positional related, that was not relieved with antacids or omeprazole. This pain progressively worsened over the next few hours, and he came to the emergency department. Examination in the emergency department revealed a temperature of 38.1°C, an HR of 110 bpm, and a BP of 120/70 mmHg. Lung sounds were clear. Heart sounds appeared normal with the patient sitting upright, but they were diminished with the patient lying in the supine position. An ECG did not show any acute ST-T wave abnormalities to suggest infarction. A CXR was performed, as shown in Figure 13.13. You are called to further assess the patient. After reviewing the available data, which of the following is your next step?

a. Immediate surgical consultation
b. Immediate pericardiocentesis
c. Start a nonsteroidal anti-inflammatory medication and admit him for observation
d. No further treatment is needed because his symptoms are caused by the hiatal hernia

22. A 71-year-old man presents to the hospital with palpitations of 2 to 3 days' duration. He has no known medical history, and he is not on any medications. Initial evaluation is unremarkable except for a BP of 160/90 mmHg and an ECG showing atrial fibrillation with a ventricular rate of 120 to 130 bpm. Given the duration of his symptoms, he is treated with β-blockers for rate control and heparin for anticoagulation. On hospital day 2, he is referred for early transesophageal-guided cardioversion. The TEE reveals normal LV and RV function. There are no echocardiographic contraindications for cardioversion. An uneventful cardioversion is performed, and the patient converts to NSR. On hospital day 3, the patient is found in marked respiratory distress. On physical examination, he has a regular HR with a loud audible click over the precordium. A CXR is performed, as shown in Figure 13.14. What does this patient have?

a. He has a pulmonary embolism and should be treated with thrombolytics.
b. He has a hiatal/diaphragmatic hernia with compression of the heart by the fundus of stomach.
c. He has an iatrogenic pneumohydropericardium; immediate drainage and surgical attention are needed.
d. He has a recurrence of atrial fibrillation.

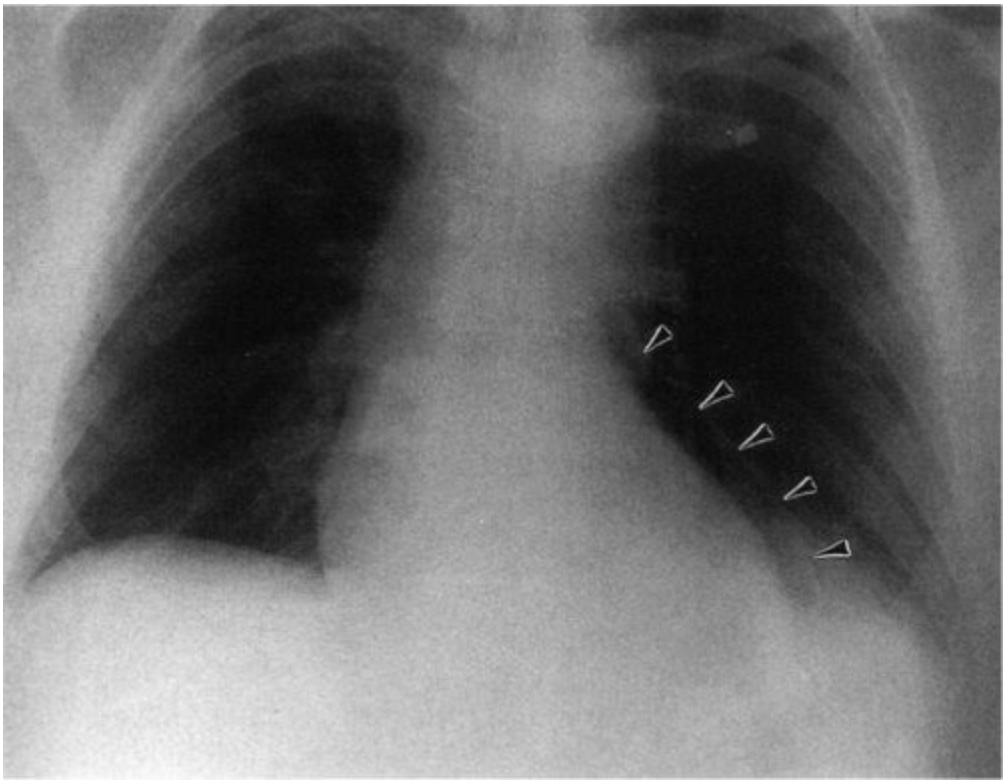

Figure 13.14 • (From Spodick DS. The Pericardium: A Comprehensive Textbook. New York: Marcel Dekker; 1997, with permission.)

23. A 59-year-old woman with a history of chronic renal insufficiency presents to the emergency department with anterior left-sided chest pain. She reports that the chest pain started after her last dialysis 7 days ago. She appears lethargic and in mild respiratory distress. The physical examination demonstrates a BP of 160/90 mmHg and an HR of 100 bpm. On cardiac auscultation, a loud friction rub is heard. An ECG is obtained (Fig. 13.15). What is the most important next step in this case?

a. Perform emergency dialysis.
b. Obtain an echocardiogram.
c. Prepare for pericardiocentesis.
d. Admit the patient to the cardiac care unit to rule out MI.

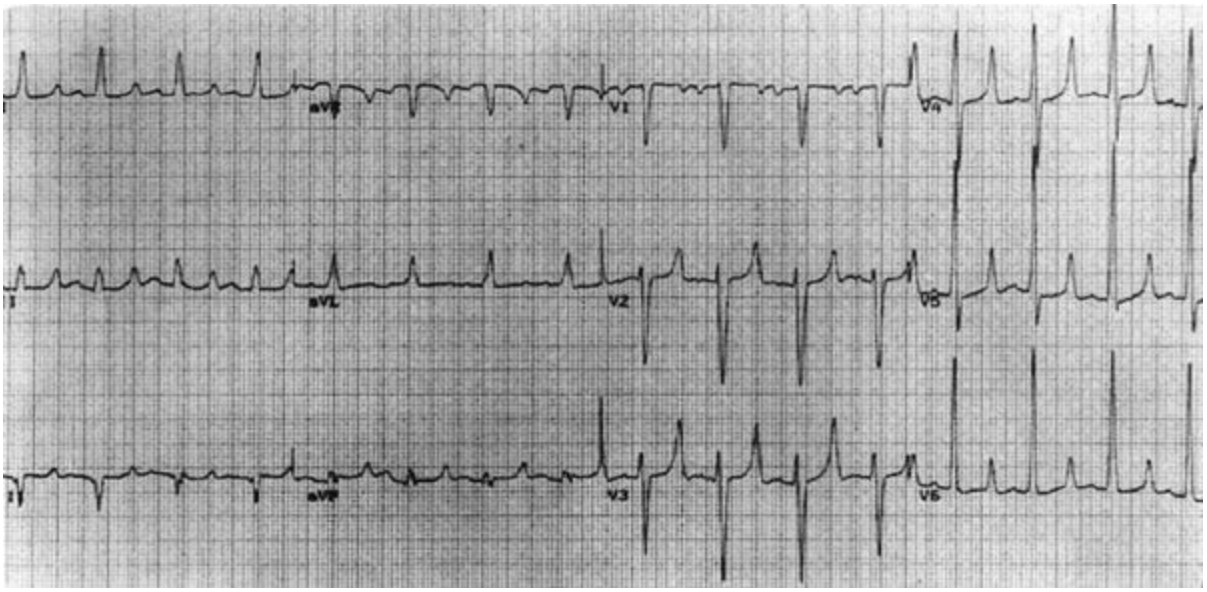

Figure 13.15 • (From Spodick DS. The Pericardium: A Comprehensive Textbook. New York: Marcel Dekker; 1997, with permission.)

24. A 29-year-old woman with known insulin-dependent diabetes mellitus was found unconscious 1 hour after an office party. Initial assessment by the emergency medical service team showed a BP of 90/60 mm Hg. Her pulse was 120, and her blood sugar was 870 mg/dL. She was given SC insulin and rushed to the emergency department. You are called to see her because of her abnormal ECG (Fig. 13.16). She is noted to be semiconscious. The emergency physician has already started her on IV insulin drip and hydration. What is your recommendation at this juncture?

a. She is having an acute MI, and immediate restoration of coronary flow is essential.
b. She has ECG evidence of hyperkalemia, and she needs IV calcium and, possibly, dialysis.
c. Continue the current management; the ECG will improve with the resolution of ketoacidosis.
d. Her ECG predicts high-degree atrioventricular block; a standby external pacemaker should be available.

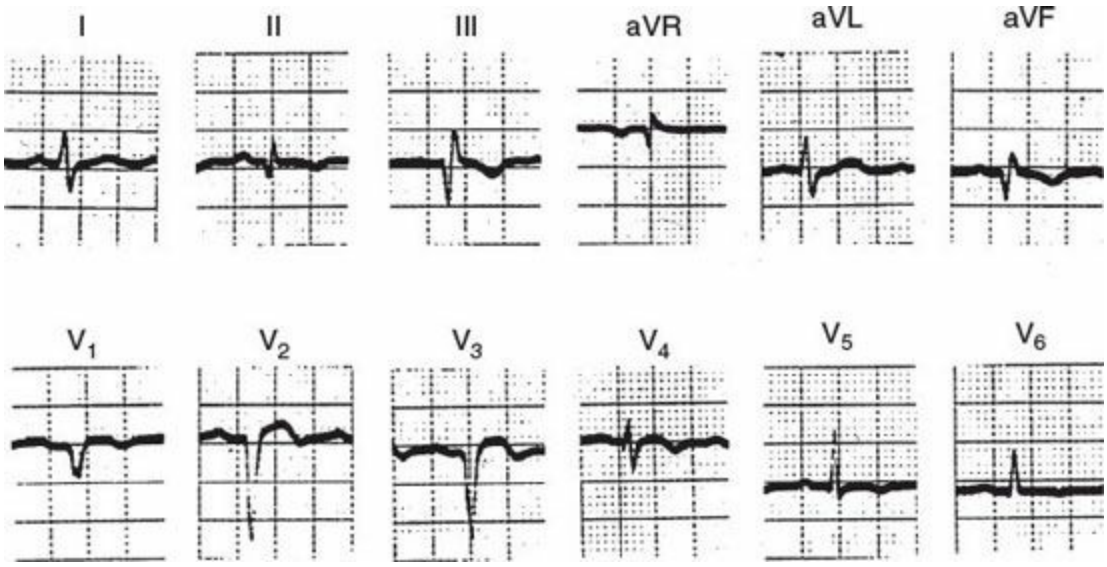

Figure 13.16 • (From Spodick DS. The Pericardium: A Comprehensive Textbook. New York: Marcel Dekker; 1997, with permission.)

25. Which of the following is the most common neoplastic pericardial tumor in adults?

a. Neuroma
b. Hemangioma
c. Mesothelioma
d. Teratoma

ANSWERS

1. **a.** Presence of an ASD. The presence of the iatrogenic ASD after the transseptal puncture for the radiofrequency ablation/pulmonary vein isolation procedure equates right atrial (RA) and left atrial (LA) pressures with inspiration. The predicted decrease in LV filling during inspiration due to interventricular dependence and exaggerated RV filling and septal shift toward the LV is mitigated by the presence of an ASD. With inspiration, the decrease in intrathoracic pressure is transmitted to both atria and thus preload to the LV is maintained and interventricular dependence is not as pronounced. Thus, the variation in systolic blood pressure is not as prominent, resulting in minimal to no pulsus paradoxus. Administration of excess fluid would stave off circulatory collapse in tamponade; however, it would not diminish the pulsus. Answer b is incorrect as with severe LV dysfunction, patients can have a pulsus alternans (variation in peak systolic pressure with every other beat) and Answer c is incorrect as obstructive lung disease can lead to the presence of a pulsus due to exaggerated inspiratory effort and negative intrathoracic pressure.

2. **a.** Ibuprofen 600 TID for 2 weeks followed by taper and colchicine 0.5 mg BID for 3 months. The patient presents with an initial attack of acute pericarditis without any high-risk features (small effusion, negative troponin, no fever/trauma, or anticoagulant use). The appropriate regimen in this case would be an NSAID (ibuprofen 600 to 800 mg TID or indomethacin 50 mg TID) for a course of 1 to 2 weeks with physician follow-up. In addition, the use of colchicine has been studied in two trials with improvement in symptom resolution and maintenance of remission at a dose of 0.5 mg (daily for <70 kg; BID for >70 kg) for a fixed period of 3 months.

   Aspirin and colchicine can be used together; however, the dosing is incorrect for Answer b (650 to 1,000 mg TID) and the colchicine should still be continued for 3 months. Prophylactic Proton-pump inhibitor (PPI) should be utilized during the high-dose NSAID use to prevent gastric ulcer. Answer c is incorrect (dosing of ibuprofen is incorrect). Answer d is incorrect since steroid therapy is only reserved for patients with NSAID or acetylsalicylic acid (ASA) contraindication or patients having relapsing pericarditis that is refractory to NSAID/ASA therapy.

3. **a.** Aspirin 650 TID for 2 weeks with taper to 81 mg daily + colchicine 0.5 mg BID for 3 months. The patient has postinfarction pericarditis with a typical presentation after reperfusion for late-presenting MI. Although not as frequent, postinfarction pericarditis (Dressler syndrome) is still seen in a small percentage of patients after large MI, and cardiac/pericardial trauma. The regimen used in these patients is modified to include aspirin (instead of NSAIDs) for two reasons: (a) aspirin is required for patients with CAD, with or without recent stenting; and (b) NSAIDs are postulated to impair scar formation and wound healing after an MI. Colchicine is still part of the regimen despite the recent MI and helps with symptom resolution. Correct answer is a—with high-dose aspirin initially with gradual taper once symptoms improve. The clopidogrel is continued despite high doses of aspirin, due to the placement of a recent intracoronary stent.

4. **a.** Initiate steroid therapy (0.25 to 0.5 mg/kg/day) along with colchicine, and initiate PO diuretic. The patient had acute pericarditis, which transformed into a chronic effusive constrictive pericarditis. There is evidence of therapy failure (persistent symptoms and elevated biomarkers) and ongoing inflammation, leading to symptomatic constrictive pericarditis with increasing hemodynamic significance (as demonstrated by symptoms/physical examination and echo findings). The next step would be to escalate anti-inflammatory therapy to include glucocorticoids (prednisone) to help abate the ongoing symptoms and pericardial inflammation. Glucocorticoids are generally not first-line therapy since patients who receive them early in the course of the disease process are more likely to have relapsing

pericarditis and eventually develop constrictive pericarditis. In the case of this patient, he does not have any other treatment options due to his NSAID allergy, so steroids should be initiated at a low dose and maintained with very gradual taper (weeks to months) that involves assessment of his symptoms, biomarker trend (ESR/hsCRP), as well as MRI findings to assess for inflammation/edema within the pericardium to help quell the disease process.

Admission for IV diuresis is not necessary as the patient has not proven resistance to PO diuretics and although a cardiac catheterization may be required alternative noninvasive diagnostic modalities should be performed prior to catheterization to make the diagnosis. Answer c is incorrect since the patient has demonstrated treatment failure with progression of symptoms in the interim. Answer d is incorrect as medical therapy options (steroids, diuresis) are still available. Pericardiectomy is generally reserved in medically refractory cases.

5. **a.** Tuberculous pericarditis. The patient presents with acute tuberculous pericarditis with large exudative effusion. Indolence of the effusion is likely over months; however, the salient findings in the fluid analysis are the elevated interferon gamma, ADA, and normal peripheral white blood cell count with pericardial lymphocyte predominance. The presence of interferon gamma elevation had a 92% sensitivity, 100% specificity, and 100% positive predictive value for tuberculous pericarditis. ADA was also linked to tuberculous pericarditis; however, it was not as sensitive or specific (87%/92%).

Although Answers b and c are epidemiologically possible, the fluid analysis is not suggestive of either. Pericardial biopsy (Answer d) is incorrect as tuberculous pericarditis can be defined by the interferon gamma and ADA elevation. Also Acid-Fast Bacilli (AFB) staining will reveal AFB + organisms confirming diagnosis. Biopsy should be reserved for patients with unrevealing fluid analysis who are still symptomatic and require further diagnostic testing to make a diagnosis.

6. **a.** Annulus reversus refers to reversal of septal and lateral mitral tissue Doppler velocities (E' septal > E' lateral) and annulus paradoxus refers to inverse correlation of E/E' and LV end-diastolic pressure. The annulus reversus phenomenon describes a reversal of mitral lateral and septal tissue Doppler velocity. Normally, E' lateral > E' septal; however, in constrictive pericarditis it is postulated that tethering of the free wall prevents longitudinal motion of the annulus at the lateral border, thus decreasing the lateral E' and the septal E' concurrently is mildly exaggerated.

The annulus paradoxus phenomenon was initially described after data looking at the correlation between the E/E' ratio and pulmonary capillary wedge pressure

were established. In a small subset of patients with constrictive pericarditis, inversion of the correlation between E/E' and PCWP was noted, and named annulus paradoxus.

7. **a.** Lack of preload due to overdiuresis. Volume loading is required to elucidate the diagnostic findings described above. Constrictive pericarditis is a preload-dependent condition and with overdiuresis and low central venous pressure, the hemodynamic findings of elevated and equal end-diastolic ventricular pressure waveforms as well as respiratory discordance of the LV/RV waveforms are not seen. Often in these cases, the patient is given a bolus of 1 to 2 L of normal saline to increase the RA pressure >12 to 15 mmHg and the study is performed once they are adequately volume loaded. Of note, in cases of atrial fibrillation, the patient may require a temporary venous pacemaker to regularize the rhythm for analysis purposes.

8. **c.** Reassure the patient and observe him over the next 3 months for worsening of symptoms. The natural history of acute viral or idiopathic pericarditis is usually short and self-limited. Occasionally, mild forms of constriction may develop weeks after the initial event, but they usually resolve without any specific treatment. No further treatment is indicated unless he becomes more symptomatic or develops signs of cardiac tamponade.

9. **c.** Give a nonsteroidal anti-inflammatory medication. The clinical presentation of a few days of severe chest pain does not favor an acute MI. Furthermore, the ECG tracing supports the diagnosis of pericarditis. Therefore, cardiac catheterization and thrombolytics are not appropriate. The only reasonable answer is to start the patient on anti-inflammatory medications and obtain a TTE to rule out pericardial effusion.

10. **a.** Constrictive pericardial disease. This patient did not have evidence of ischemia on a recent stress test. Furthermore, there is no evidence of obstructive disease in his coronaries or grafts. His tracings mostly support the diagnosis of constriction, given the diastolic equalization of pressures in the cardiac chambers and the typical square root sign. Amyloidosis would typically show signs of restrictive hemodynamics with no respiratory variation. Echocardiography typically shows increased LV wall thickness. Additionally, a diagnosis of tamponade should have been evident by echocardiography, which the patient had before heart catheterization. Otherwise, hemodynamic tracings of cardiac tamponade would look exactly the same as for constriction.

11. **b.** This patient has significant diastolic dysfunction, and his prognosis is guarded. He has evidence of restrictive LV filling (advanced diastolic dysfunction) in the absence of CAD. The differential diagnosis in his age group includes amyloidosis (especially considering concomitant renal dysfunction), hemochromatosis, and other infiltrative processes.

12. **c.** His symptoms are related to impairment of RV filling and pericardial disease. This patient with the main presentation of dyspnea has an increased cardiac silhouette. The nuclear image provided shows a circumferential echolucency surrounding the heart. This is consistent with a large pericardial effusion, and he most likely has RA and RV diastolic compromise. There is no evidence of a perfusion defect to suggest ischemia.

13. **c.** He is showing signs of early postinfarction pericarditis, and a nonsteroidal anti-inflammatory medication should be started. This patient had an MI 72 hours ago that was successfully treated with thrombolytics. The ECG shows diffuse ST elevation with PR depression. These findings support the diagnosis of post-MI pericarditis. The ECG changes are new and nonlocalizing. Most patients improve with nonsteroidal anti-inflammatory medications.

14. **a.** He has a pericardial cyst that is benign; no further treatment should be offered. The TTE and CXR show a pericardial cyst. Pericardial cysts are usually smooth structures containing transudative fluid. They are frequently only 2 or 3 cm in diameter, often located at the right cardiodiaphragmatic angle, and clinically silent. However, cysts can be associated with chest pain, dyspnea, cough, and arrhythmias likely caused by compression of adjacent tissues. They can also become secondarily infected. In this patient, whose nonspecific symptoms appear to be resolving, no further treatment is needed.

15. **a.** The patient should have immediate surgical intervention. This patient has evidence of acute type A aortic dissection with extension to the pericardium, as evidenced by the pericardial effusion on the TEE. He should be immediately referred for surgical repair. If the diagnosis were not certain based on the TEE, then CT, MRI, or aortic angiography would be needed to better define the anatomy. The safest and most efficient management of patients with aortic dissection is to carry out all diagnostic procedures in the operating room. Pericardial drainage often gives only temporary relief or no relief of the tamponade, and the subsequent increase in BP disrupts sealing clots, accelerating intrapericardial leakage.

16. **a.** Immediate surgical exploration of the pericardium. The TTE and TEE

demonstrate a pericardial hematoma compromising RA and RV filling. This is an indication for surgical exploration and evacuation of the hematoma.

17. **b.** IV hydration. This patient has evidence of pericarditis likely related to uremia, as he is close to requiring dialysis. Although his TTE shows signs of tamponade (RA collapse, moderate-sized effusion, and respiratory variation across the mitral inflow), there is no jugular venous distention, and the inferior vena cava is small sized, indicating that this patient has been overdiuresed. His hypotension and tachycardia are related to dehydration. He should, therefore, be treated with IV hydration.

18. **b.** Admit the patient for observation on telemetry with a follow-up TTE. The ECG shows findings consistent with an anterior wall injury, and the TTE shows a small pericardial effusion. Given this patient's history, he most likely has a cardiac contusion. Although the prognosis for recovery is generally excellent, these patients require careful monitoring and follow-up for late complications, which range from ventricular arrhythmias to cardiac rupture. Hence, the most logical answer to this question is to admit the patient to a telemetry bed with follow-up TTE.

19. **d.** Proceeding with chemotherapy without further cardiac evaluation. This patient's MRI shows congenital absence of the pericardium. This is a benign condition usually found incidentally. No specific cardiac treatment is needed unless there is entrapment of one of the cardiac chambers.

20. **d.** A surgical evaluation for pericardiectomy is necessary because the findings on his TTE indicate that he will develop problems in the future if this is not taken care of soon. The patient is currently symptomatic with edema of the lower extremities. Furthermore, he has a pericardial friction rub suggestive of an active pericardial process likely related to his rheumatologic disease process. He is already on methotrexate and prednisone as anti-inflammatory medications. Pericardial effusions related to rheumatoid arthritis often progress to constriction despite anti-inflammatory therapy, and early management consisting of pericardial stripping is recommended.

21. **b.** Immediate pericardiocentesis. The next step is an immediate pericardiocentesis. This patient has signs of early sepsis. Furthermore, the CXR shows pneumopericardium that likely developed secondary to gastric perforation from the esophagogastroduodenoscopy and cauterization of the ulcer. This patient needs immediate referral to surgery for repair.

22. **c.** He has an iatrogenic pneumohydropericardium; immediate drainage and surgical attention are needed. This patient had a TEE that most likely resulted in an esophageal tear with communication to the pericardial sac. On the CXR, there is a lucent triangle outlining the pericardium with pericardial passage over the aortic arch.

23. **a.** Perform emergency dialysis. This patient has missed her dialysis session and is now presenting with hyperkalemia (note peaked T waves on ECG) and uremic pericarditis. The most essential step is to start dialysis to treat the hyperkalemia.

24. **c.** Continue the current management; the ECG will improve with the resolution of ketoacidosis. Patients presenting with diabetic ketoacidosis can have ECG features that are typical of stage I pericarditis and hypokalemia. The treatment is usually that of ketoacidosis. The ECG returns to normal after resolution of the acidosis.

25. **c.** Mesothelioma. Teratoma is the most common pericardial tumor in infancy and childhood. Neuroma and hemangioma are uncommon enough to be considered curiosities.

QUESTIONS

1. The three-dimensional (3D) transesophageal echocardiographic (TEE) image in Figure 14.1 demonstrates a patient with
   a. normally functioning bioprosthetic mitral valve replacement (MVR).
   b. normally functioning bileaflet mechanical MVR.
   c. mitral valve (MV) endocarditis with a vegetation.
   d. abnormal mechanical MVR.
   e. abnormal bioprosthetic MVR.

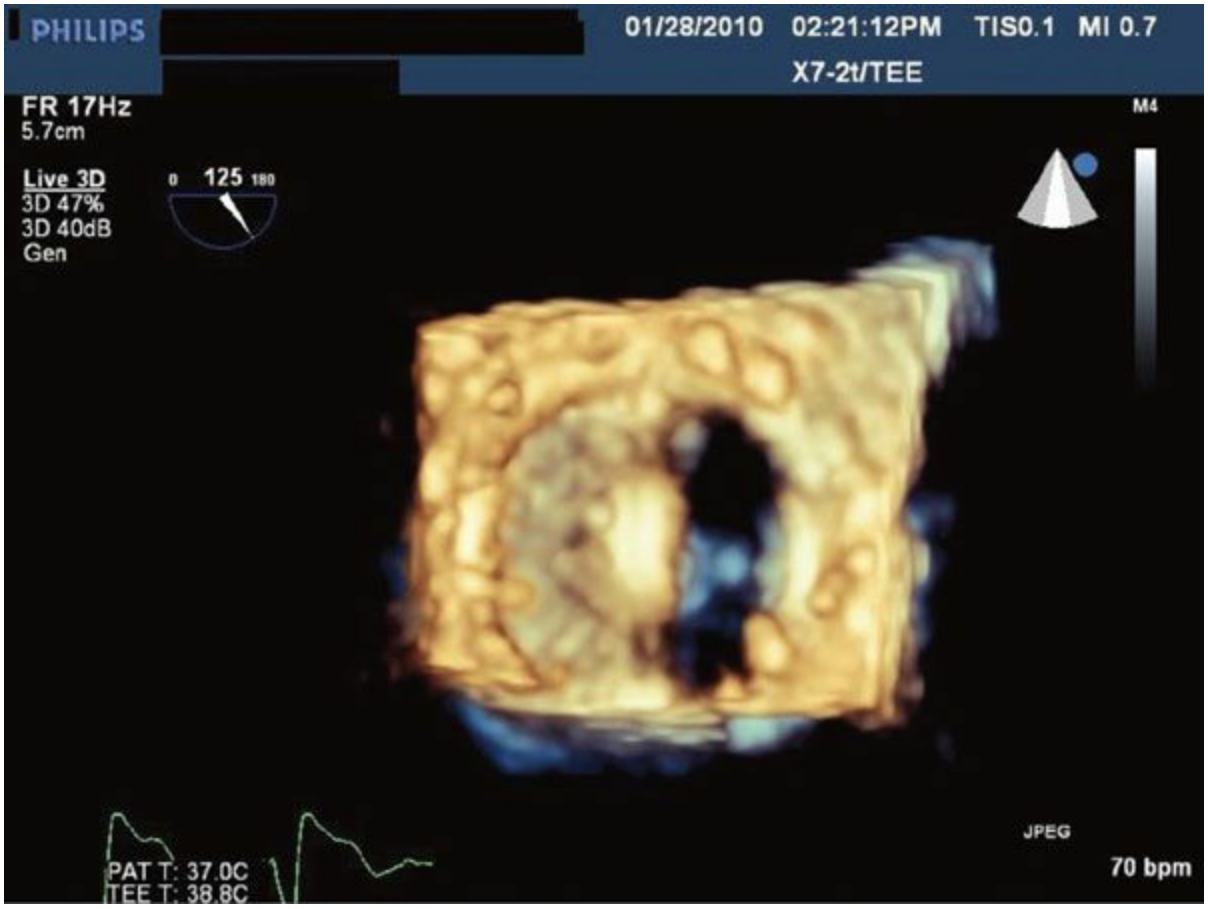

Figure 14.1

2. The images in Figure 14.2A–E come from an 18-year-old young man with marked shortness of breath (SOB). The most appropriate course of action would be

   a. closed mitral commissurotomy because he has a split score of 0 to 4 and minimal mitral regurgitation (MR).
   b. percutaneous mitral valvuloplasty (PMV) because he has a split score of 4 to 8 and minimal MR.
   c. surgical MVR because he has a split score of 8 to 12 and minimal MR.
   d. surgical MVR because he has a split score of 0 to 4 with significant MR.
   e. surgical MVR because he has a split score of 4 to 8 and significant MR.

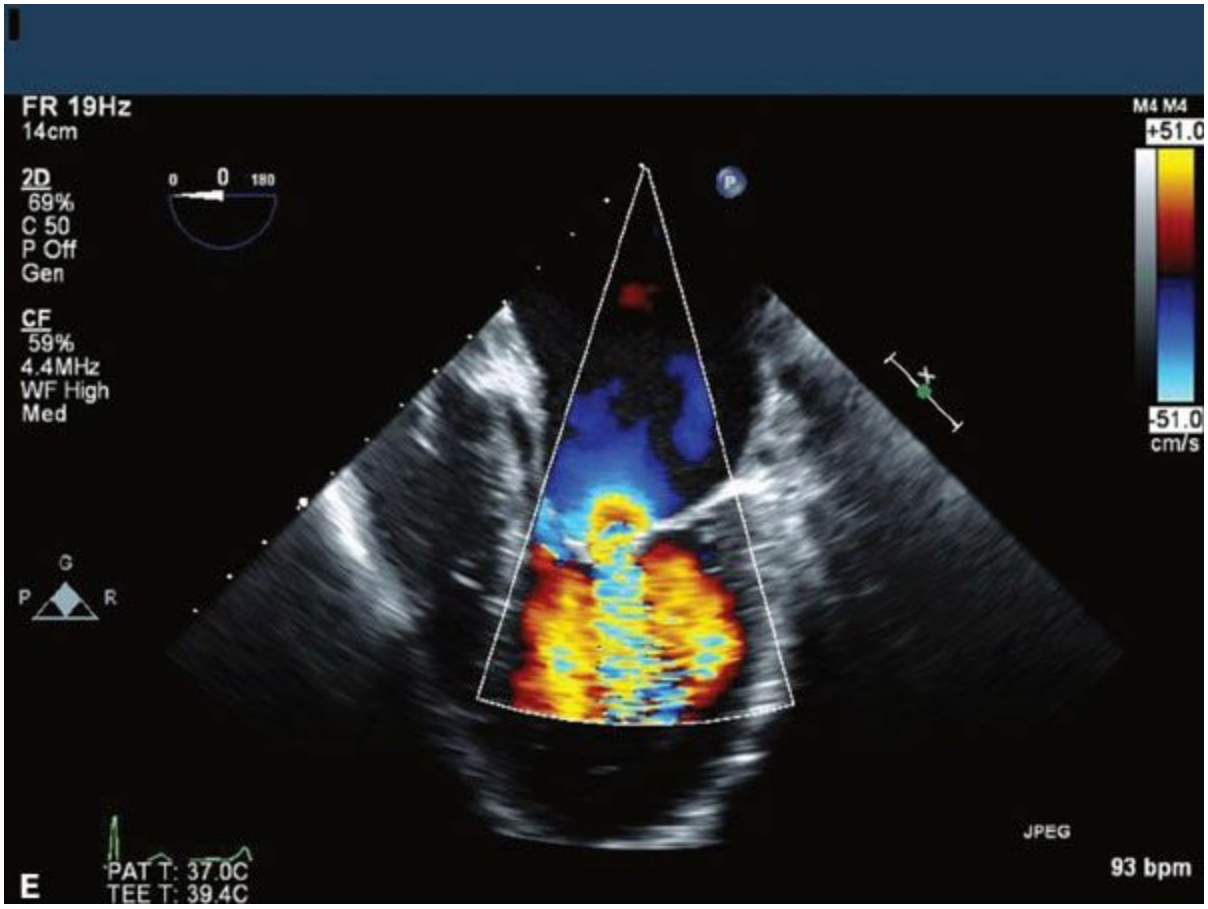

Figure 14.2

3. The images in Figure 14.3A–C belong to a 65-year-old woman with lung cancer and a central venous catheter for chemotherapy. The structure seen on these images is most likely to be

   a. prominent Chiari network.
   b. implantable cardioverter-defibrillator (ICD) wire.
   c. right atrial (RA) thrombus or thrombus on central venous catheter.
   d. RA myxoma.

4. The images in Figure 14.4A and B are associated with which of the following?

   a. Moderate risk of endocarditis
   b. No risk of heart failure
   c. Large jugular venous v waves
   d. Radiofemoral delay

5. The images in Figure 14.5A–C are from a 43-year-old s/p carpentier edwards aortic valve replacement (CE AVR) with fevers and night sweats. These images demonstrate all of the following except

   a. paravalvular abscess.
   b. fistula.
   c. aortic stenosis (AS).
   d. aortic insufficiency (AI).
   e. vegetations.

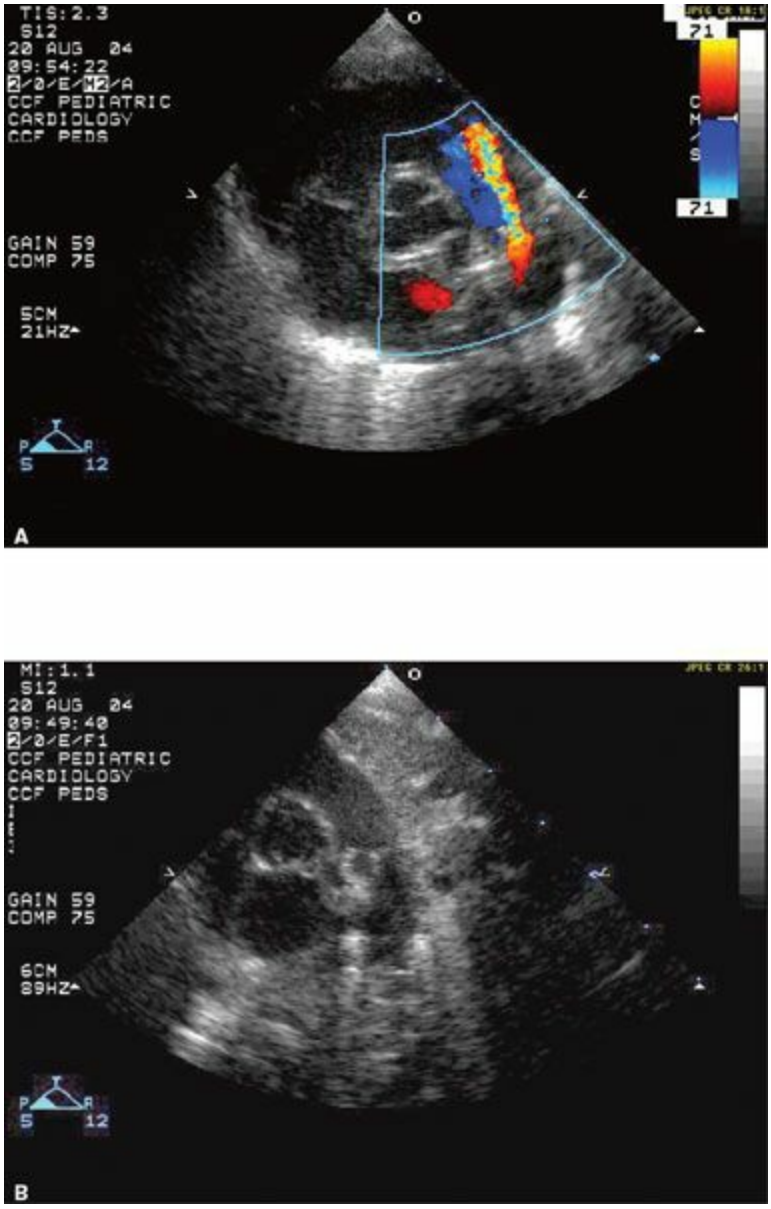

Figure 14.4

6. The images in Figure 14.6A and B are from a transthoracic echocardiogram (TTE) from a patient who is a 57-year-old woman with lung cancer who presents with chest pain (CP) and SOB. The most likely cause of her CP and SOB based on these images is

   a. myocardial infarction (MI).
   b. aortic dissection.
   c. pericardial effusion with pericarditis/tamponade.
   d. pulmonary embolus.
   e. pneumonia.

7. The patient is a 70-year-old woman with a history of hypertension, but no prior cardiac history, who comes in with sudden onset of CP, which later migrates to her back. She is diagnosed with a computed tomography (CT) of her chest to have a type I aortic dissection. Her blood pressure is 100/70 mmHg and her heart rate is 115 bpm. Images from her TTE are in Figures 14.7A–C. The next step in her care would be

   a. aortic stent graft.
   b. coronary angiography.
   c. intraaortic balloon pump placement.
   d. pericardiocentesis.
   e. emergent cardiac surgery.

8. The finding in the transthoracic images in Figure 14.8A and B is commonly associated with which of the following lesions?

   a. Congenitally corrected transposition
   b. Cleft MV
   c. Coarctation of the aorta
   d. Right ventricular (RV) infarction
   e. Bicuspid aortic valve (AV)

9. A 36-year-old man with a history of hypertension on medications for 5 years presents to your office with complaints of dyspnea on exertion and is found by his internist to have a heart murmur. Below are some representative views from his TTE (Fig. 14.9A–E). What is the diagnosis?

   a. Patent ductus arteriosus (PDA)
   b. Rheumatic AV with AI
   c. Rheumatic AS
   d. Coarctation of the aorta with bicuspid AV with AI
   e. Marfan's with aortic dissection

10. A 37-year-old patient presents with fever, weight loss, and blood cultures that are positive for Pseudomonas and the transthoracic echo finding in Figure 14.10. The patient's most likely demographic for this clinical scenario is

   a. patient with hypertrophic obstructive cardiomyopathy (HOCM) who had a dental procedure 3 weeks ago.
   b. patient with myxomatous MV disease with mitral valve prolapse (MVP).
   c. patient with subaortic stenosis after dental procedure 3 weeks ago.
   d. patient with a patent ductus.
   e. intravenous (IV) drug abuser.

11. This M-mode tracing (Fig. 14.11) demonstrates a patient with

   a. HOCM with systolic anterior motion (SAM) of the MV leaflets.
   b. MVP.
   c. AS.
   d. rheumatic mitral stenosis (MS).
   e. severe left ventricular (LV) dysfunction.

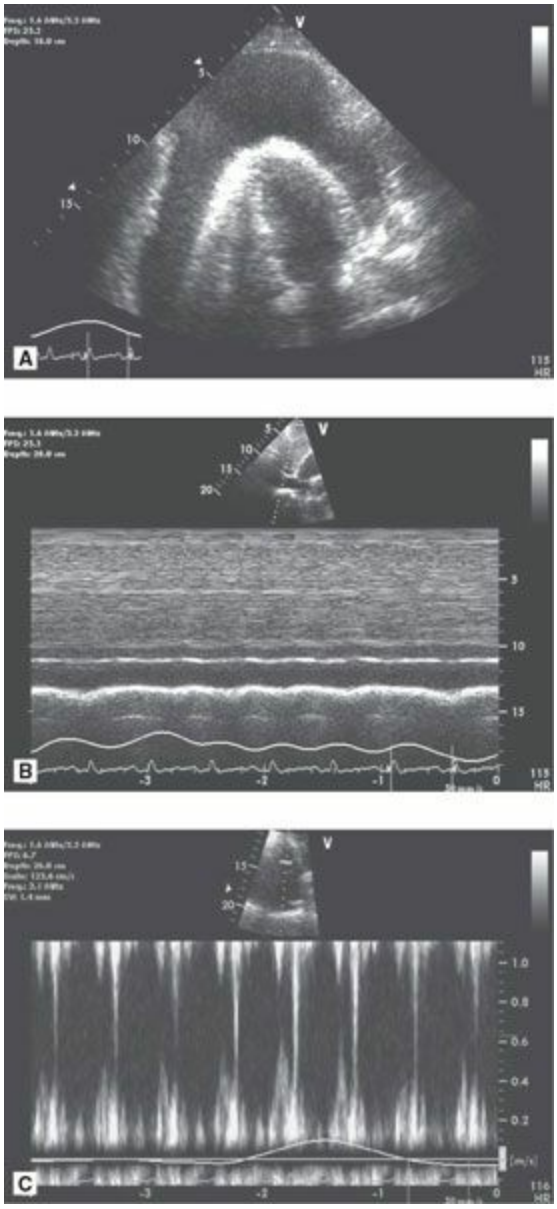

Figure 14.7 • **A.** Apical four-chamber view (TTE). **B.** M-mode through the IVC in the subcostal view (TTE). **C.** Continuous-wave Doppler through the mitral valve showing mitral valve inflow pattern.

12. The following TEE image (Fig. 14.12) demonstrates a patient with

a. trileaflet AV.
b. bicuspid AV with fusion of right coronary cusp (RCC) and noncoronary cusp (NCC).
c. bicuspid AV with fusion of RCC and LCC.
d. bicuspid AV with fusion of left coronary cusp (LCC) and NCC.
e. unicuspid AV.

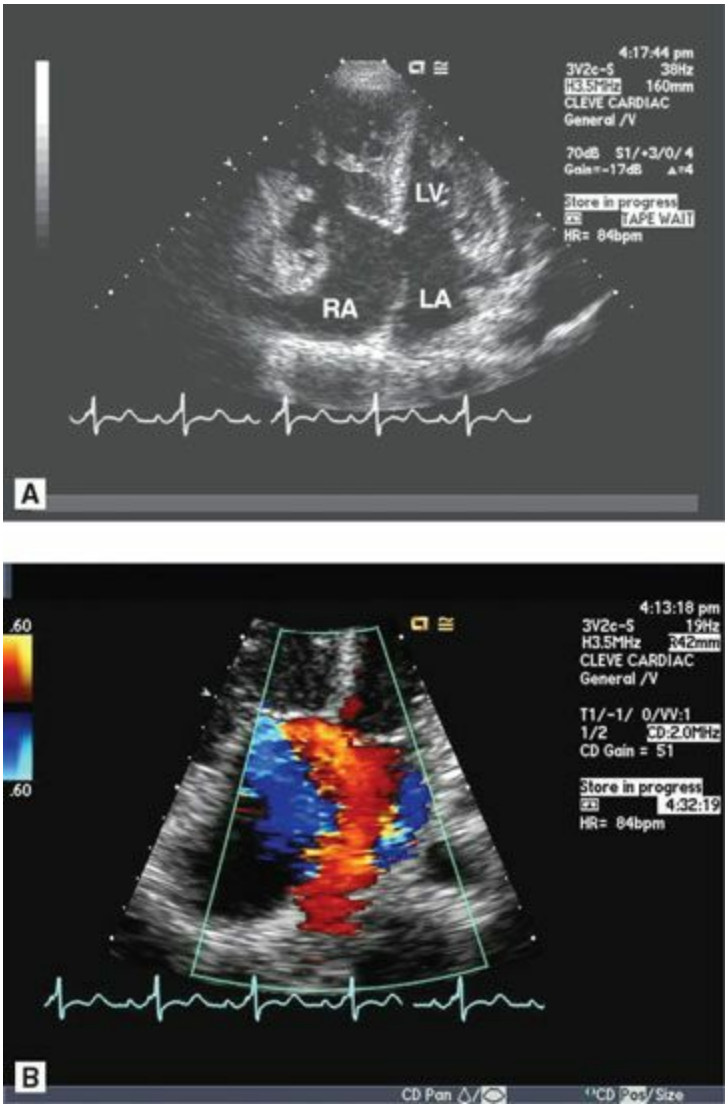

Figure 14.8 • **A.** Apical four-chamber view (TTE). **B.** Apical four-chamber view with color Doppler.

13. The patient is a 22-year-old with a systolic and diastolic murmur with the following echo images (Fig. 14.13A and B). These images demonstrate

- **a.** membranous ventricular septal defect (VSD).
- **b.** supracristal VSD.
- **c.** Ebstein anomaly.
- **d.** pulmonic stenosis (PS)/pulmonic insufficiency.
- **e.** PDA.

15. This parasternal short-axis view (Fig. 14.15) would be most consistent with which of the following patients?

a. Patient with severe MR
b. Patient with severe AI
c. Patient with severe tricuspid regurgitation (TR)
d. Patient with severe LV systolic dysfunction
e. Patient with a subaortic membrane

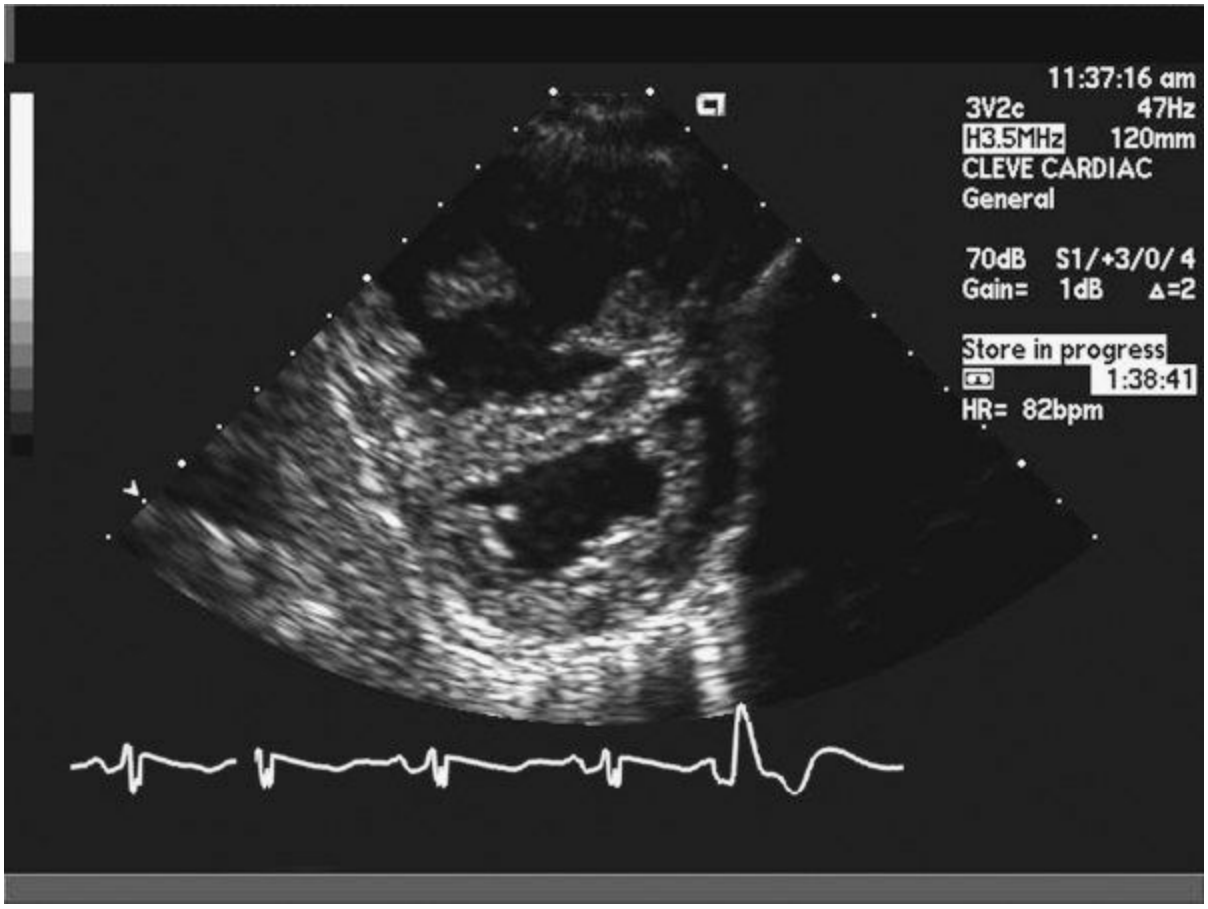

Figure 14.15 • Parasternal short-axis view (diastole).

16. The TEE images below are from a patient who has marked dyspnea on exertion and one episode of presyncope (Fig. 14.16A–C). The patient is now in the operating room for a procedure. The most appropriate operation for this patient would be

a. MV repair.
b. septal myectomy.
c. MVR.
d. coronary artery bypass grafting (CABG).
e. ascending aortic conduit.

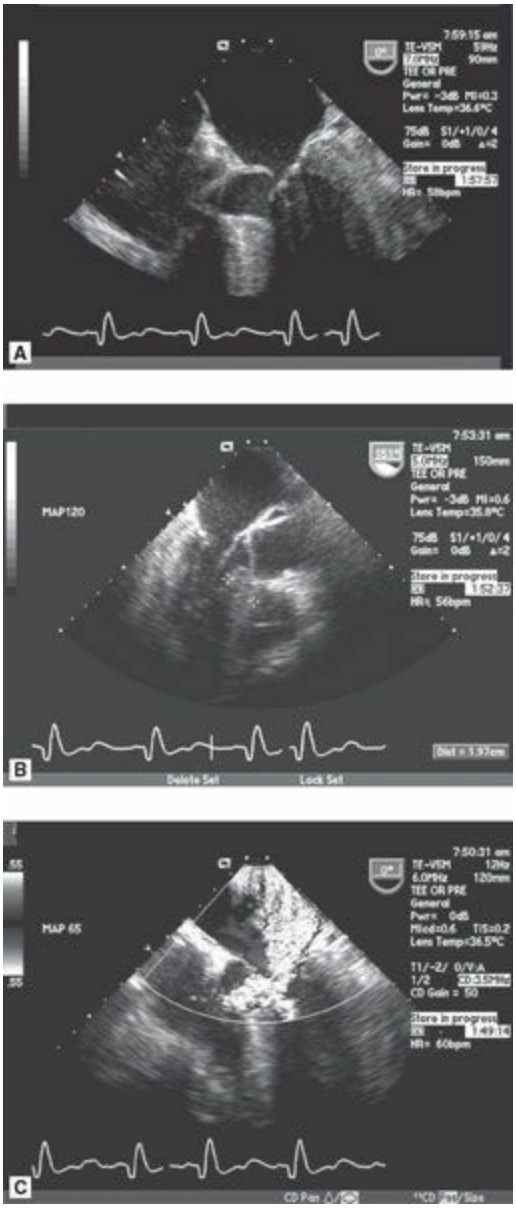

Figure 14.16 • **A.** Mid-esophageal four-chamber view (TEE). **B.** Mid-esophageal long-axis view (TEE). **C.** Mid-esophageal four-chamber view with color Doppler.

17. The following TEE images (Fig. 14.17A and B) demonstrate a large mass noted in the LV apex. This mass is located in a region of myocardial thinning and akinesis in a dilated LV. Although there is some mobility there does not appear to be a stalk. This mass is most likely which of the following possibilities?

a. Teratoma
b. Myosarcoma
c. Fibroelastoma
d. Thrombus
e. Adenocarcinoma

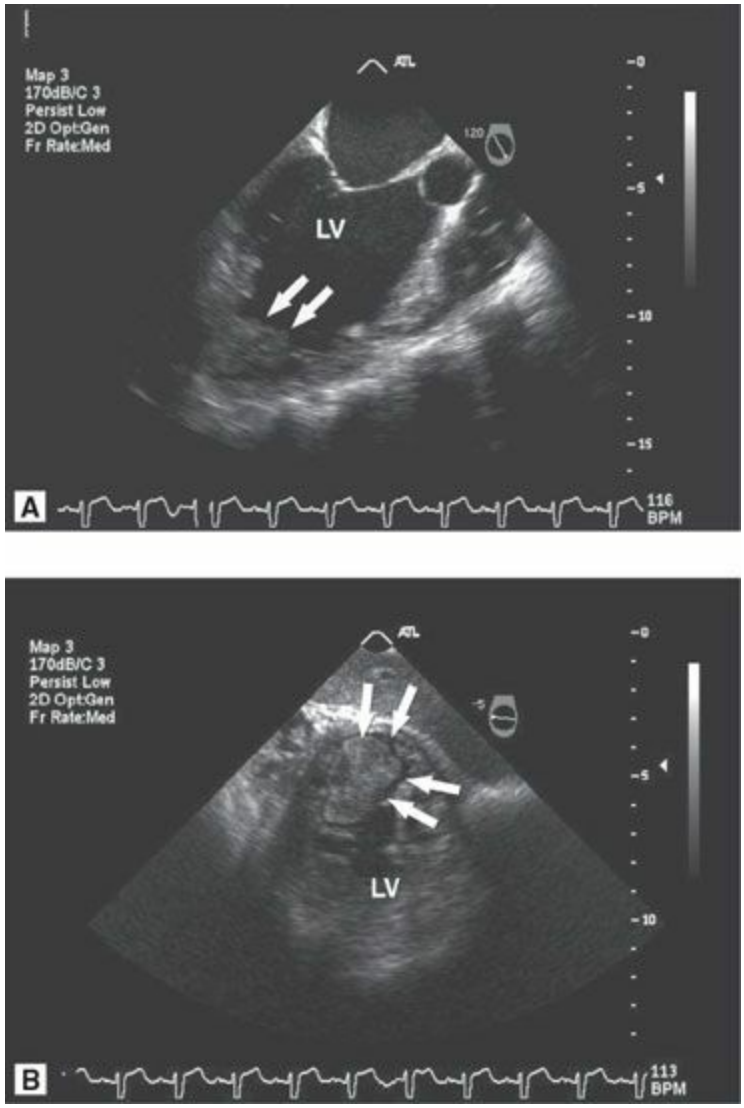

Figure 14.17 • **A.** Mid-esophageal long-axis view (TEE). **B.** Transgastric short-axis view of the LV (TEE).

18. The patient is a 56-year-old man with hypertension, diabetes, and obesity who was admitted 6 months ago to an outside hospital with a late presentation of an anterior MI. He presented approximately 3 days post MI and underwent cardiac catheterization at 1 week, which showed a total occlusion in the mid-left anterior descending artery (LAD), severe stenoses of the first and second diagonals, and no significant disease in either the right coronary artery (RCA) or left circumflex artery (LCx). The patient was then referred to your hospital for revascularization. The patient, however, failed to show for his appointment and finally presented 8 months later with CP and SOB. Prior to revascularization you order a positron emission tomography (PET) rubidium (Rb)/fluorodeoxyglucose (FDG) using $Rubidium^{82}/F18_A$ (flourine-18–labeled deoxyglucose) to determine the degree of inducible ischemia and viability. The images obtained are in Figure 14.18. The images from the PET scan demonstrate

a. scar in the LAD territory.
b. inducible ischemia in the LAD territory.
c. hibernating myocardium in the LAD territory.
d. a combination of inducible ischemia and hibernation in the LAD territory.
e. scar in the RCA territory.

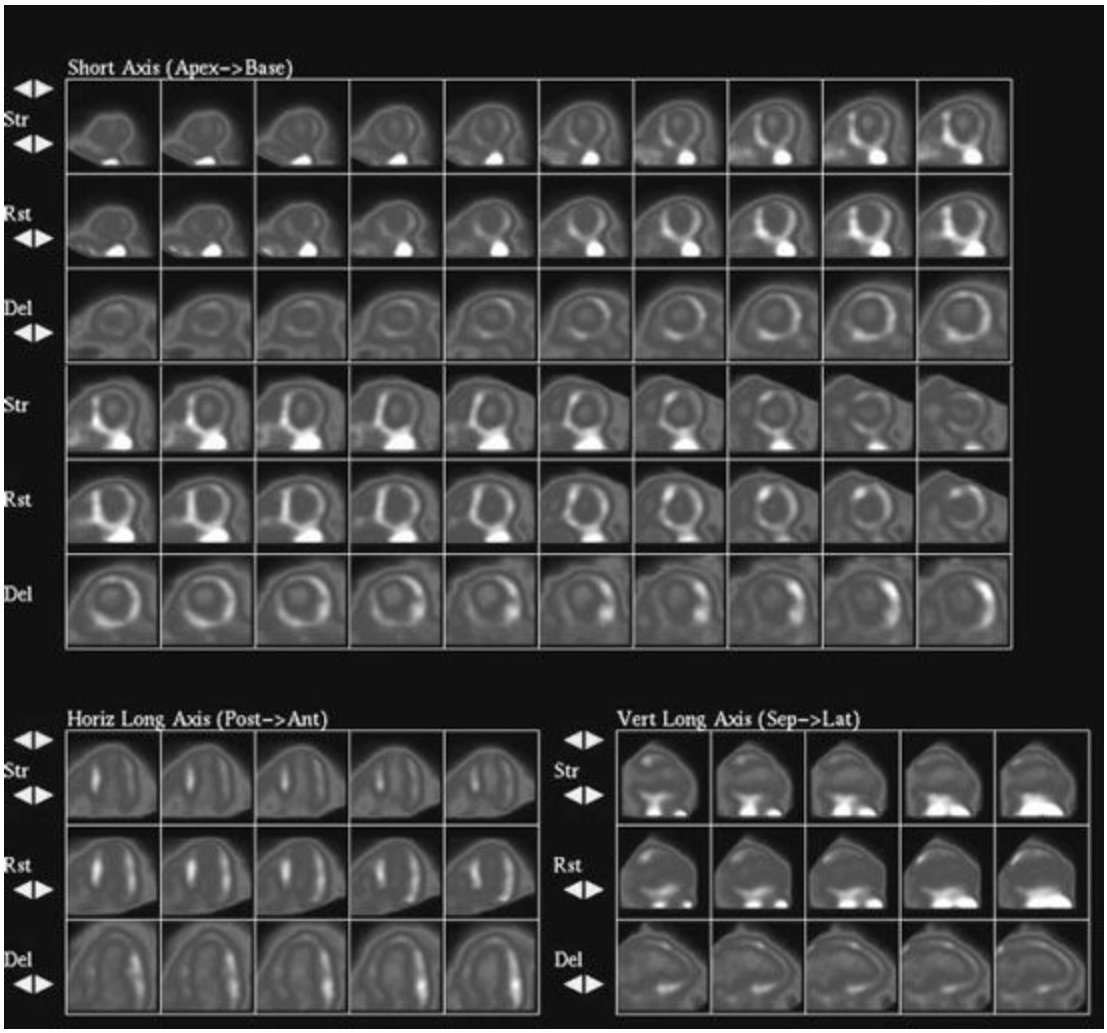

Figure 14.18 • Rubidium/FDG PET scan with the stress images displayed on top, the rest images next, and the delayed metabolic FDG images displayed on the bottom.

19. The patient is a 75-year-old man with hypertension, diabetes, hypercholesterolemia, and coronary artery disease (CAD) who is 10 years s/p CABG: left internal mammary artery to LAD, saphenous vein graft (SVG) to RCA, and SVG to first obtuse marginal. He is asymptomatic on a good medical regimen, although he is relatively sedentary. TTE demonstrated normal LV systolic function with left ventricular ejection fraction (LVEF) 60%, moderately severe left ventricular hypertrophy (LVH), and no significant valvular disease. The patient is now sent for cardiac evaluation prior to surgery on his dilated abdominal aorta (7.5 cm in diameter). An adenosine nuclear stress test is ordered for preoperative risk

assessment. During the adenosine stress he remained asymptomatic although he developed 2-mm ST depressions in I, L, and V_2–V_6. There were no significant changes in blood pressure. Figure 14.19 shows the scan. The scan demonstrates

a. marked attenuation.
b. multivessel ischemia.
c. infarct but no ischemia.
d. mixture of infarct and ischemia.
e. motion artifact.

20. The patient is a 62-year-old man with CAD risk factors including diabetes (16 years), hypertension, family history of CAD, and obesity. The patient had a silent inferior MI 2 years earlier detected by ECG. The patient is now sent for preoperative evaluation for bilateral knee surgery. The patient has no CP with exertion; however, his exercise capacity is limited by knee pain. He does occasionally have mild post-prandial dyspnea. His medications include insulin, a statin, an angiotensin-converting enzyme inhibitor, a β-blocker, and an aspirin. A pharmacologic dual-isotope (Thal/Tc) scan was performed and is shown in Figure 14.20. The gated images showed an LVEF of 42% with a wall motion abnormality in the inferolateral wall. There were no ECG changes or symptoms during the adenosine infusion. The rest and post-stress images demonstrate

a. scarred RCA/LCx territory.
b. scarred LAD territory.
c. normal test with artifacts.
d. scar and ischemia in the LCx/RCA territory.
e. scar and ischemia in the LAD territory.

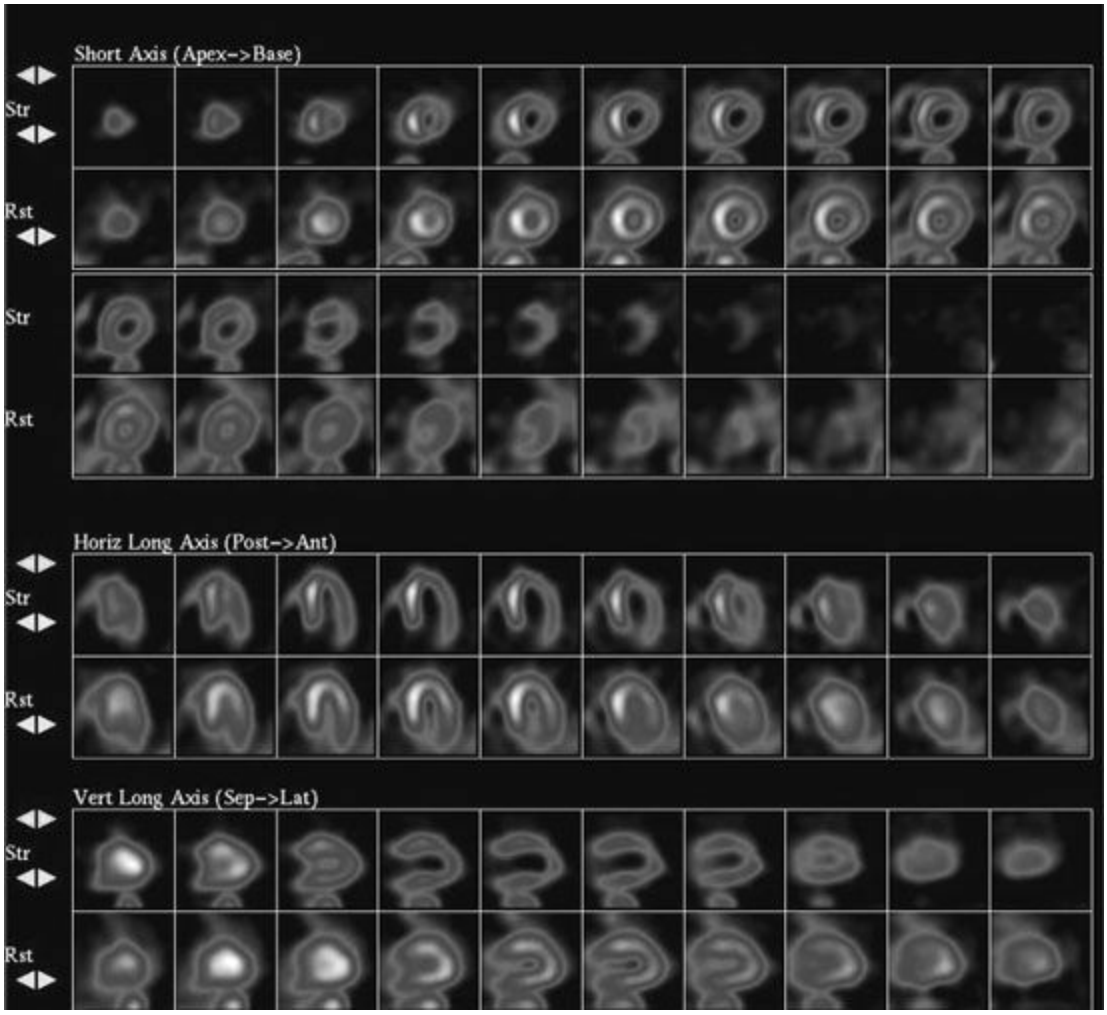

Figure 14.19 • Adenosine technetium-99m nuclear stress test with the stress images on top and the resting images below.

21. The patient is a 60-year-old man with hypertension, diabetes (newly diagnosed), and CAD (s/p percutaneous coronary intervention with drug-eluting stent in his mid-LAD 5 years ago, and bare metal stent to distal RCA, and a posteroventricular branch 7 years ago). The patient is now sent for symptom evaluation. The patient notes the onset of CPs with exertion while playing squash approximately 2 months ago. The pain occurs only with activity and resolves within a few minutes with rest. He denies other associated symptoms or discomfort at rest. A treadmill nuclear stress test was performed. The patient exercised using a standard Bruce protocol having completed eight metabolic equivalents and reached 98% maximum predicted heart rate (MPHR). There was a normal ST-segment response to stress, and there was no CP with exercise. He did, however, develop new ST depressions in recovery and new atrial fibrillation in recovery, requiring treatment with β-blockers. The scan images are shown in Figure 14.21. The appropriate interpretation of this scan is

a. RCA territory infarct.
b. LAD territory infarct.
c. RCA territory ischemia.
d. LAD infarct with peri-infarct ischemia.
e. LAD and LCx versus left main ischemia.

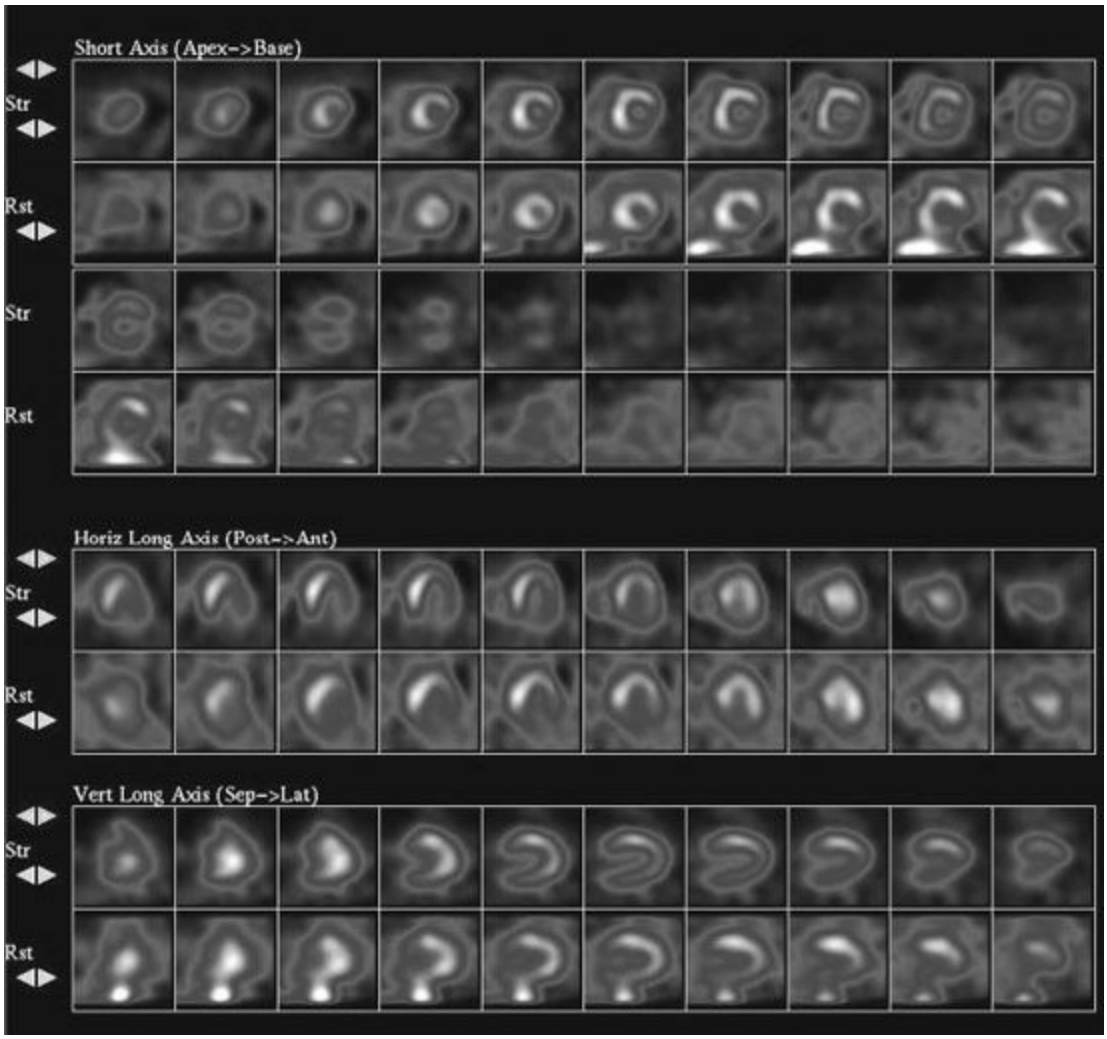

Figure 14.20 • A pharmacologic (adenosine) dual-isotope (Thal/Tc) scan with the stress images displayed on top with the resting images below.

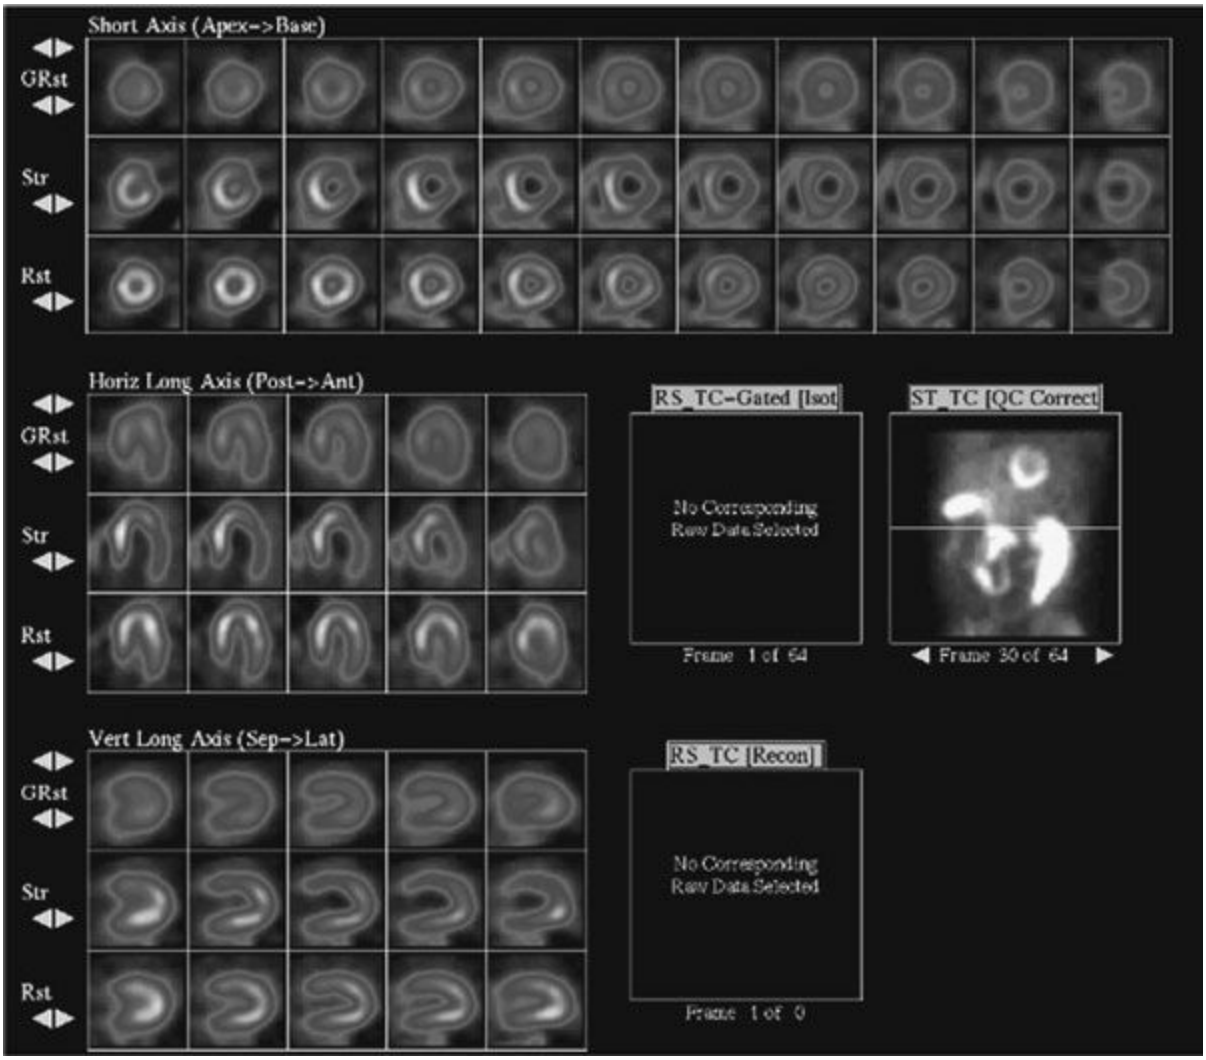

Figure 14.21 • An exercise technetium-99m nuclear stress test with the stress images with the gated images (currently still) on top, the post-stress images next, and the resting images on the bottom.

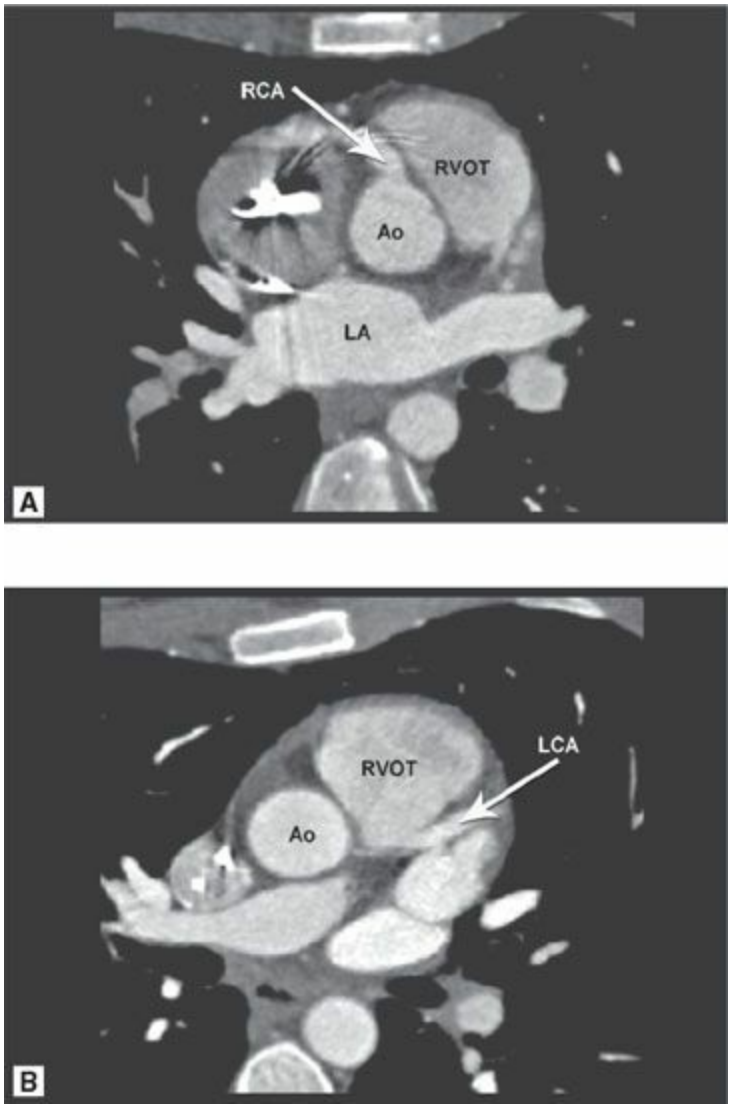

Figure 14.22 • **A.** Double-oblique image of the aortic root at the level of the right and left sinuses of Valsalva. Ao, aorta; LA, left atrium; RCA, right coronary artery; RVOT, right ventricular outflow tract. **B.** Oblique axial image at the level of the left coronary artery origin. LCA, left coronary artery.

22. A 19-year-old young woman is referred to your office for evaluation of congestive heart failure (CHF) and MR. She has a history of complete heart block and has previously undergone pacemaker implantation. On physical examination, her heart rate is 85 bpm, respiratory rate of 16, and blood pressure 108/65 mmHg. Her jugular venous pulse is visible 6 cm above the sternal angle at 45 degrees. The point of maximum impulse is sustained but normal in location. She has a grade II/VI holosystolic murmur at the apex that radiates to the axilla. There is trivial bilateral pedal edema. A posterior–anterior and lateral chest X-ray demonstrates mild cardiomegaly. A TTE reveals moderately reduced LV systolic function with an EF of 35%. There is 2+ to 3+ posteriorly directed MR. A cardiac CT with contrast is obtained to evaluate the coronary arteries (Fig. 14.22A and B). Which of the following is true regarding this patient's condition?

a. This condition is a common cause of sudden cardiac death in athletes.
b. The anomaly shown represents origin of the left coronary artery from the right coronary ostium.
c. Surgical reimplantation of the anomalous coronary artery is indicated.
d. Patients with this condition who survive past childhood often present with varying degrees of heart failure, myocardial ischemia, and MR, depending on the development of collateral circulation.
e. This condition is usually inoperable and best left alone.

ANSWERS

1. **d.** Abnormal mechanical MVR. Figure 14.1 is a 3D echo image showing a malfunctioning bileaflet mechanical MVR. This image demonstrates one leaflet that is open (to the right of the image), while the other remains shut. You can see the sewing ring of the prosthesis well. This is most likely due to thrombus although impingement by a chord or piece of valve could do this as well.

2. **b.** Percutaneous mitral valvuloplasty (PMV) because he has a split score of 4 to 8 and minimal MR. The MV "split score" as it pertains to " splittability" of a rheumatic MV with MS is derived by grading four features of the stenotic valve. The features, which are graded on a scale of 1 to 4, include leaflet thickening, leaflet calcification, leaflet mobility, and involvement of the subvalvular apparatus. Grade 1 denotes the least abnormality while 4 denotes the most severe abnormality. Because each feature is graded on a scale of 1 to 4, the total score can range from 4 (more splittable) to 16 (least splittable). A valve with a score of ≤8 is considered amenable to PMV as long as there is no significant MR. Of note, the degree of MR typically increases by 1 grade when a patient undergoes balloon mitral valvuloplasty. A score of >8 denotes a valve that would not be amenable to PMV and if the patient is symptomatic or has significant pulmonary hypertension or other indication for an intervention (other than maximizing medical therapy), the patient would undergo a surgical valve replacement as long as they were considered a surgical candidate. The images presented for this example show a patient with severe MS due to rheumatic disease with minimal leaflet thickening or calcification, and no subvalvular involvement with preserved mobility. The stenosis is due almost entirely to commissural fusion and as such has a split score of 4. In addition, the color Doppler still frame in systole showed only trivial MR. For these reasons, the patient is an ideal candidate for PMV. The images in Figure 14.23A and B were taken following the balloon inflations during the PMV.

Figure 14.23 • **A.** Three-dimensional images of the mitral valve showing a larger orifice and the split commissures compared with the pre-PMV image. **B.** The transmitral gradient post balloon inflation. The mean mitral gradient has decreased from 30 to 9 mmHg.

3. **C.** Right atrial (RA) thrombus or thrombus on central venous catheter. The patient discussed in this question has a malignancy and is likely in a hypercoagulable state. The mass noted within the RA appears to be broad based and may be in association with her central venous catheter. In this situation, this is most likely to be an RA thrombus. The prosthetic appearing structure within the RA appears to be the central venous catheter and does not go through the tricuspid valve (TV) into the RV, and therefore is not an ICD. An RA myxoma typically has a thin stalk and is most often associated with the interatrial septum. It can be seen within the RA or left atrium (LA). Figure 14.24A and B demonstrates a classic myxoma, one showing surgical pathology and the other showing an echo image of a myxoma. A Chiari network is a more fenestrated mobile structure seen at the junction of the vena cava and RA.

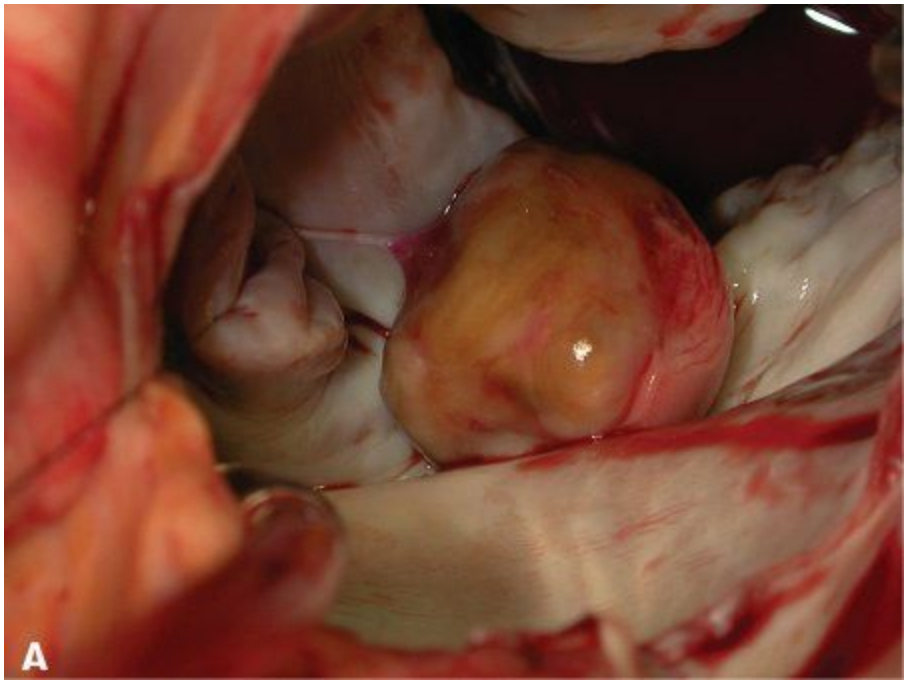

Figure 14.24

4. **a.** Moderate risk of endocarditis. The images in Figure 14.4 demonstrate a PDA. This is seen as the color flow into the pulmonary artery (PA). In this example, the PDA is large and its orifice can be seen in the two-dimensional (2D) images opening into the PA. The complications that can be associated with a PDA include the development of CHF and a moderate risk of endocarditis (although antibiotic prophylaxis is not recommended unless the unrepaired PDA is complicated by pulmonary hypertension/Eisenmenger syndrome causing cyanosis). The clinical manifestations of the PDA depend on the size of the left-to-right shunt. The larger the shunt, the worse the clinical manifestations. The murmur associated with a PDA is a continuous murmur (since the left-sided pressures are higher than the right side throughout the cardiac cycle), not a systolic murmur.

5. **d.** Aortic insufficiency (AI). Although all of the answers are possible complications of infective endocarditis, the images displayed in Figure 14.5 do not show any significant AI. Figure 14.5A shows the short axis of a bioprosthetic AV with a paravalvular abscess with vegetations. It also shows the valve during systole which although it is open, the opening is restricted suggestive of AS which is confirmed by the peak AV gradient of 92.6 mmHg shown in Figure 14.5B. Figure 14.5C shows

the long-axis TEE view of the AV with a small fistula into the LA (seen at the top of the image).

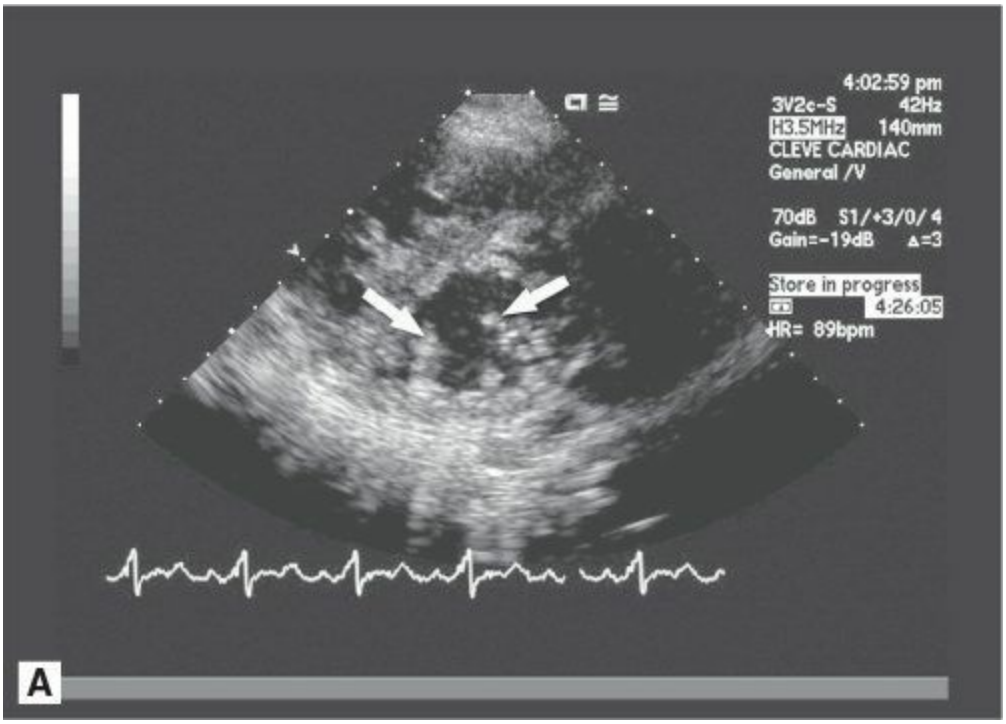
6. **d.** Pulmonary embolus. The images in Figure 14.6 show the parasternal short axis showing specifically the main PA/PA bifurcation. Both images show a large multilobulated echodensity or mass within the main PA which represents a clot in transit. The patient is hypercoagulable due to her malignancy and has developed a deep venous thrombosis which has embolized and is on its way to the lungs. The multilobular appearance shows that this mass is a cast from a deep vein in the leg. The remaining answers are causes of CP; however, these answers do not describe the situation found on TTE. Patients with malignancy can present with tamponade from a pericardial effusion but no effusion is seen on these images.

7. **e.** Emergent cardiac surgery. The images demonstrate a patient with cardiac tamponade. Findings include significant respiratory variation of MV inflows (>25%) and RV diastolic collapse, RA inversion, and inferior vena cava plethora (dilated >2 cm and does not collapse normally with inspiration). A patient with a type I dissection and cardiac tamponade needs to go to emergent cardiac surgery as soon as possible for drainage of the pericardium and repair of the aorta. Pericardiocentesis could potentially cause complete rupture of the flap into the pericardium, causing cardiac arrest and death. An aortic stent graft is currently not the treatment of choice for a type I dissection and could certainly not address the problem of tamponade. Coronary angiography in this patient would only delay the definitive therapy (surgery) as well as possibly further propagate the dissection flap. Recall that delay of surgery in a patient with a type I dissection is associated with a 1% per hour increase in mortality in the first 48 hours of the process. (Note that this patient has not had prior cardiac surgery—if the person had prior cardiac surgery, that would likely change the need for cardiac catheterization prior to surgery, although in this patient emergent surgical drainage of the pericardium would be needed.)

8. **b.** Cleft MV. The image displays an apical four-chamber view of a patient with a primum ASD. (Note Fig. 14.8B with color Doppler shows left-to-right shunting through the ASD.) This is part of either a partial or complete AV canal defect. A complete AV canal defect includes a primum ASD, a cleft anterior mitral leaflet, and a widened anteroseptal tricuspid commissure. A partial AV canal defect is as above but without the VSD. Note that because of the long-term, significant right-to-left shunt through the ASD in this patient the right side is dilated and there is right ventricular hypertrophy from pulmonary hypertension. The short-axis view of the MV (Fig. 14.25A) demonstrates the cleft anterior mitral leaflet, which “splits” in

the center, as opposed to opening like a fish mouth as is seen with normal MVs. Figure 14.25B is a drawing showing normal short axis of MV versus cleft MV.

9. **d.** Coarctation of the aorta with bicuspid AV with AI. The patient is a young man with hypertension beginning in his late 20s or early 30s. Secondary hypertension must be considered and ruled out in this patient. When he was initially diagnosed he should have had his blood pressure checked in both arms and legs in consideration of a coarctation of the aorta. Note: Someone may also notice rib notching on a chest X-ray. Other etiologies that should have been excluded include renal artery stenosis (more commonly seen in women if caused by fibromuscular dysplasia), pheochromocytoma, Cushing syndrome, or primary aldosteronism. This patient's heart murmur was a diastolic murmur from AI caused by prolapse of a bicuspid AV. At least 50% of patients with a coarctation have a bicuspid AV. Fewer patients with bicuspid AV have a coarctation. Note that bicuspid AVs dome (doming aortic leaflets are seen in Fig. 14.9D) and could be mistaken on initial glance in long axis with a rheumatic AV. However, in addition to doming there is prolapse of the conjoined cusp (which would not be seen in a rheumatic valve) and the anatomic situation could be clarified with a good short-axis view.



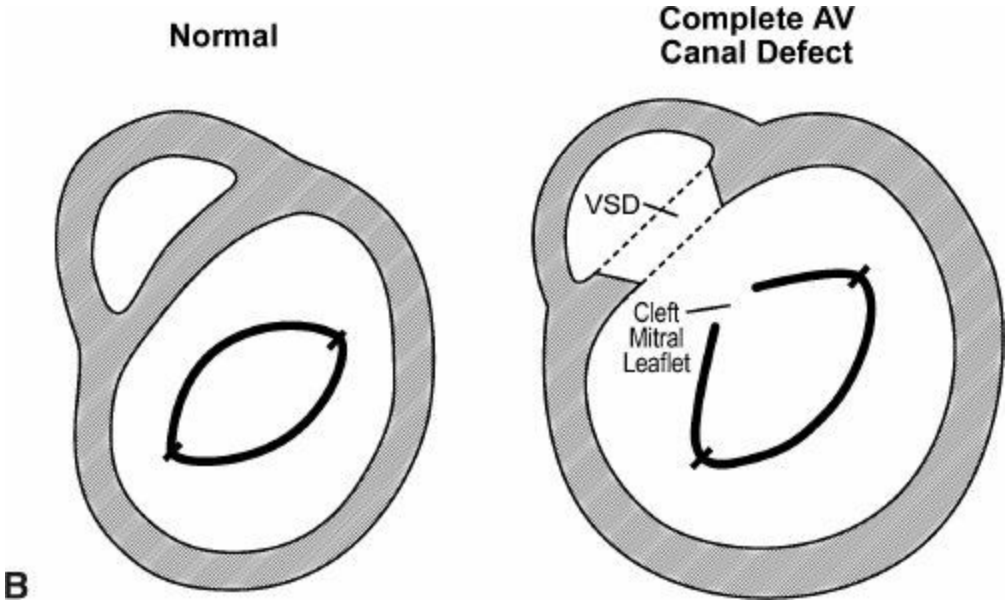


Figure 14.25 • **A.** Parasternal short-axis view of the mitral valve (TTE). **B.** Drawing comparing the parasternal short-axis view of a normal mitral valve to the opening of a cleft anterior mitral leaflet.

10. **e.** Intravenous (IV) drug abuser. Right-sided endocarditis is less common than left-sided endocarditis. The TEE image (Fig. 14.26) shown demonstrates a patient with a vegetation on the tricuspid valve, and the organism identified by culture is Pseudomonas. This is associated with IV drug use with contamination at the time of injection. Although the other clinical situations listed are at increased risk for endocarditis (typically left sided), Pseudomonas would be a very unusual pathogen in those situations.

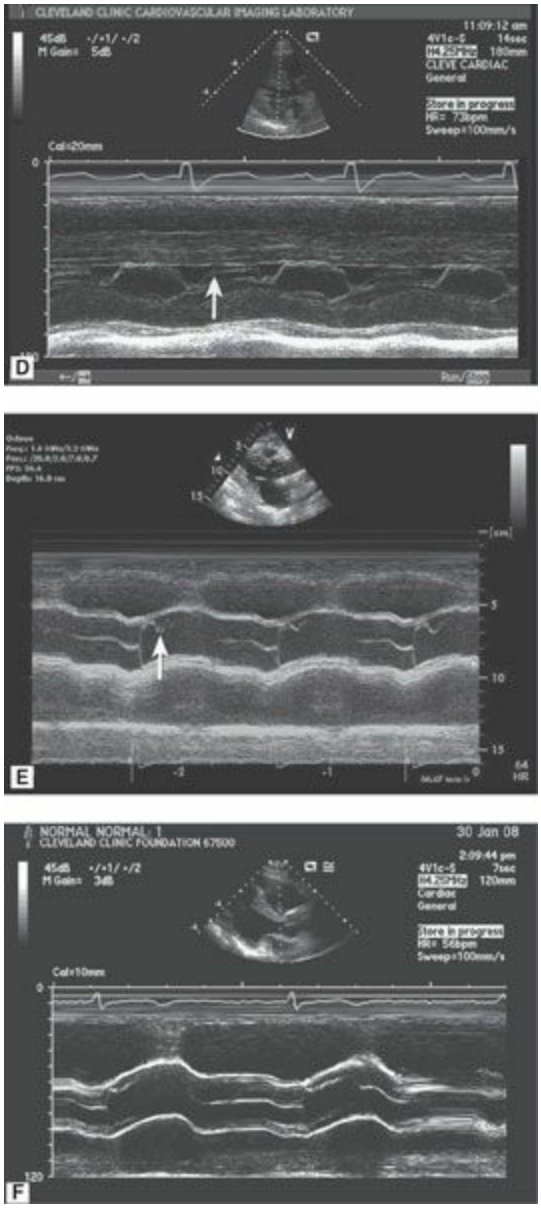

Figure 14.27 • **A.** M-mode through the mitral valve. **B.** M-mode through the mitral valve. **C.** M-mode through the mitral valve. **D.** M-mode through the mitral valve. **E.** M-mode through the aortic valve. **F.** M-mode through the aortic valve.

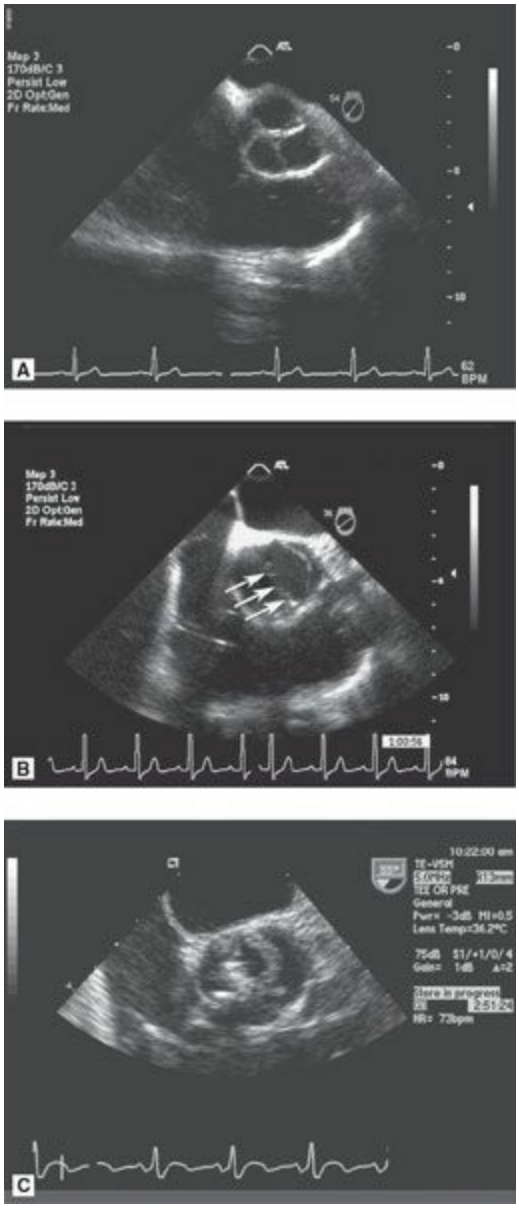
11. **b.** MVP. The M-mode trace is performed through the MV in a patient with myxomatous MV disease with bileaflet prolapse. Note the marked dip backward of the MV leaflets after the closure point (see Fig. 14.11). Note that there is full systolic range of motion creating the "M" trace of the anterior mitral leaflet and the normal "W" trace of the posterior leaflet. This is in contrast with a normal MV M-mode, which would not have the systolic dip (Fig. 14.27A). Thus, there is no rheumatic MS, which would look like Figure 14.27B in which there are still pliable but tethered leaflets causing a loss of the normal "M" and "W" appearance of the mitral leaflets. More advanced MS with thickened and calcified leaflets would have thicker and brighter appearance of the leaflets together with more restriction

of the leaflet motion (Fig. 14.27C). M-mode for a patient with HOCM and SAM would appear like the images in Figure 14.27D and E. Note the SAM of the mitral leaflets in Figure 14.27D and the early closure of the AV in Figure 14.27E (compared with the M-mode of a normal AV [Fig. 14.27F]).



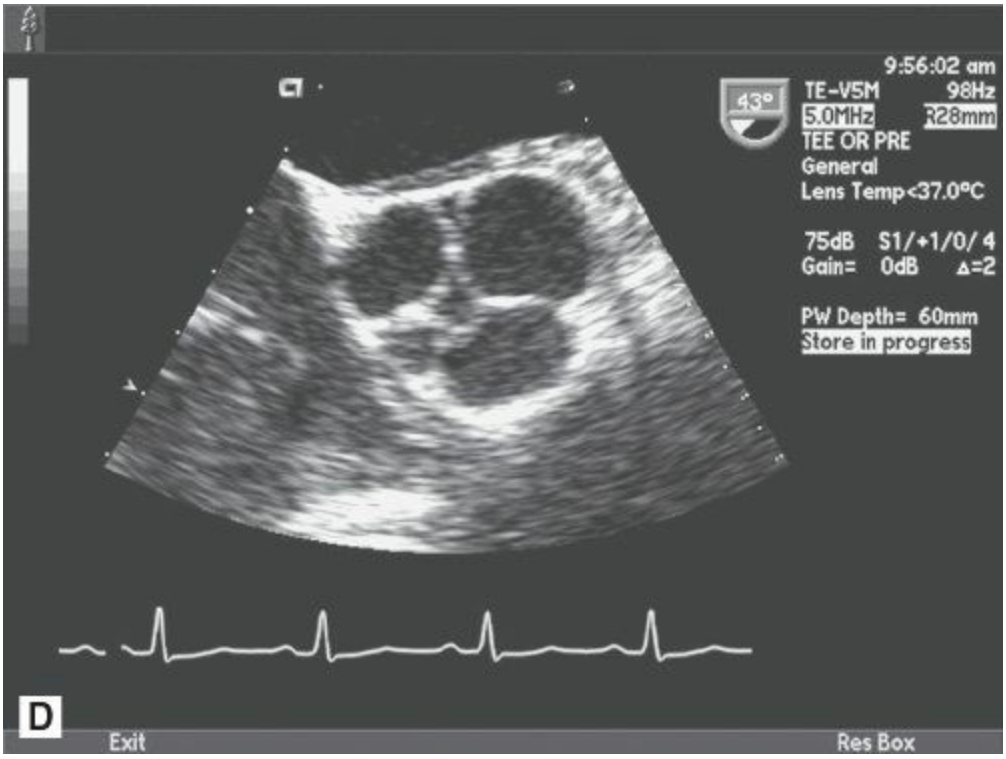


Figure 14.28 • **A.** Mid-esophageal short-axis view of the aortic valve (diastole). **B.** Mid-esophageal short-axis view of a bicuspid aortic valve with fusion of the RCC and NCC. **C.** Mid-esophageal short-axis view of a unicuspid aortic valve. **D.** Mid-esophageal short-axis view of a quadricuspid aortic valve.

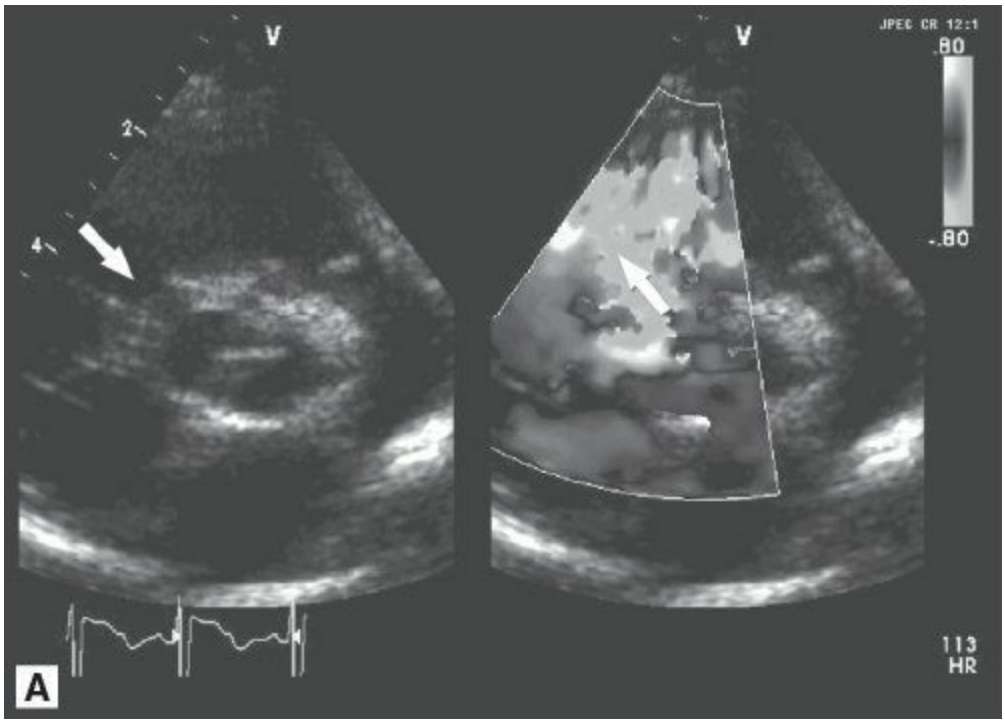
12. **c.** Bicuspid AV with fusion of the RCC and LCC. The 2D TEE mid-esophageal view (see Fig. 14.12) demonstrates a bicuspid AV in short axis. To determine cusp anatomy one must view the AV in systole. If one looks for a "Mercedes Benz" image of the valve in short axis during diastole (Fig. 14.28A), one may mistake a bicuspid valve for a tricuspid valve, not realizing that one of the arms in the Mercedes Benz sign is actually a calcified raphe between two fixed cusps. Thus, it is important to look at the valve in systole to determine the true cusp anatomy. The most common form of bicuspid AV is fusion of the RCC and LCC. Bicuspid AVs are also associated with a dilated aorta with an aortopathy involving cystic medial necrosis. Another form of bicuspid AV is fusion of the RCC and NCC (Fig. 14.28B). There are other congenitally abnormal AVs, including unicuspid valves (Fig. 14.28C) and quadricuspid valves (Fig. 14.28D). The unicuspid and quadricuspid valves are much less common than bicuspid valves.

13. **b.** Supracristal VSD. This image demonstrates a supracristal VSD. The VSD is located just under the pulmonic valve, best seen in the parasternal short-axis view (seen at 1 o'clock). A membranous VSD would be seen at 10 or 11 o'clock in short-axis view (Fig. 14.29A). Ebstein anomaly involves apical displacement of the tricuspid valve with atrialization of some of the RV (Fig. 14.29B). Patent ductus can also be seen in the parasternal short-axis view seen best by color Doppler

showing a flow entering the PA (from the aorta) (Fig. 14.29C). PS is seen on 2D in the parasternal short-axis view with doming pulmonic valve leaflets with color acceleration across the valve. In diastole there may also be some PI as the leaflets may have restricted closing.

14. **b.** Rheumatic MV disease with MS and MR. The images shown demonstrate a doming anterior mitral leaflet and a fixed posterior leaflet. There is color acceleration across the MV, suggestive of MS, which is supported by the high gradients found by continuous-wave Doppler through the MV. There is also significant MR (posteriorly directed) seen in the systolic frame with color Doppler. The mechanism of MR in this case is restricted leaflet motion. Myxomatous MV disease (Fig. 14.30), in contrast, is characterized by markedly redundant, prolapsing leaflets, which prolapse back into the LA, occasionally with a torn chord causing a flail leaflet. Typically, the jet of MR is very eccentric if only one leaflet is involved (the jet is in the opposite direction from the most involved leaflet). If there is balanced bileaflet prolapse, the jet is usually centrally directed.



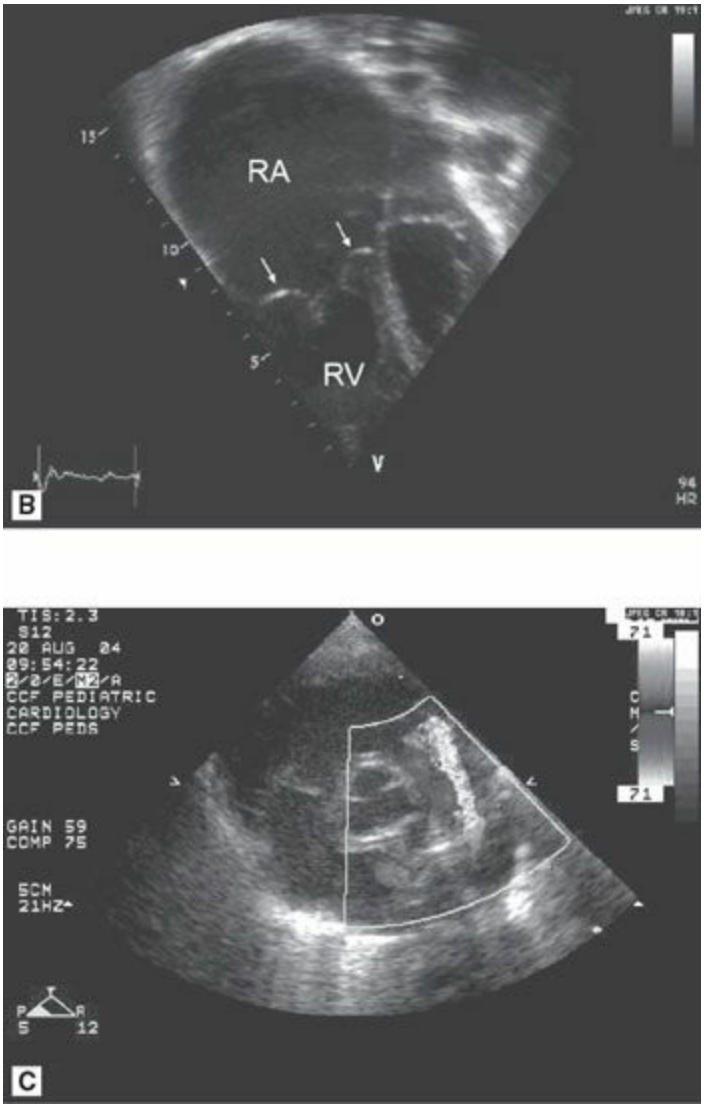


Figure 14.29 • **A.** Parasternal short-axis view (both 2D and with color Doppler). **B.** Apical four-chamber view (pediatric display with atria at the top of the screen). **C.** Parasternal short-axis view.

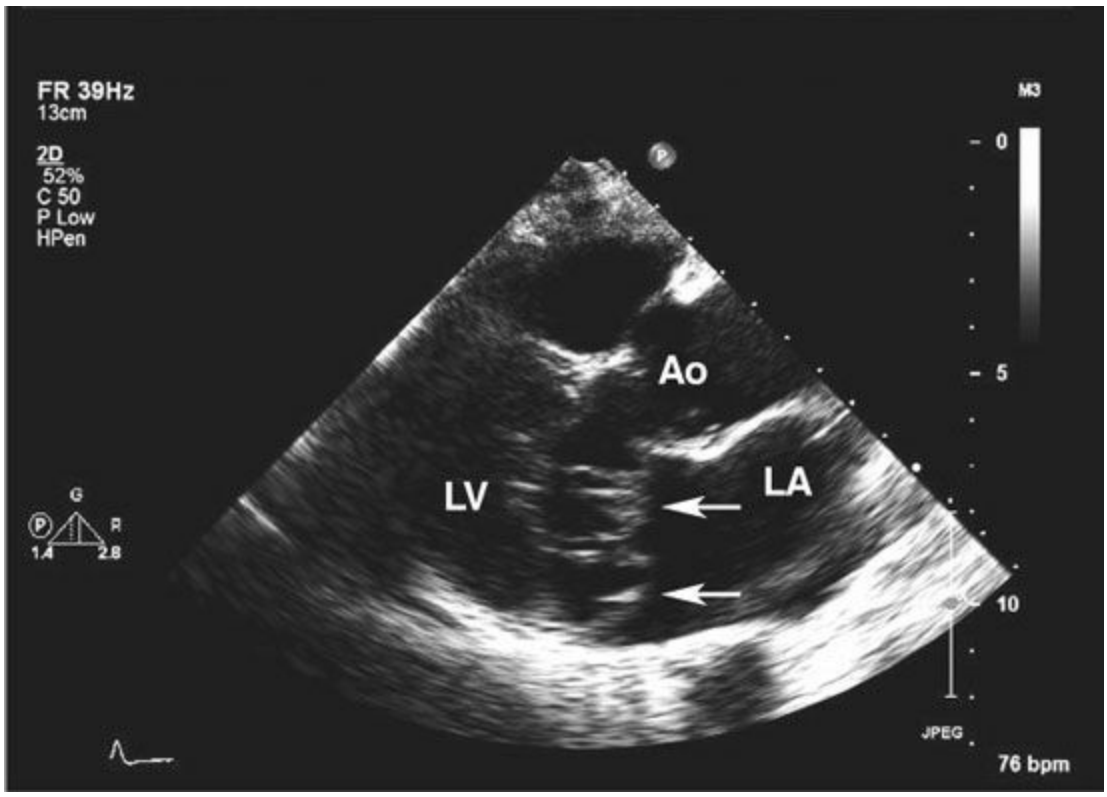

Figure 14.30 • Parasternal long-axis view of a patient with mitral valve prolapse.

15. **c.** Patient with severe tricuspid regurgitation (TR). The parasternal short-axis still frame in diastole demonstrates a patient with diastolic septal flattening. This is found in a patient with right-sided volume overload. You can also see patients with systolic septal flattening, which is consistent with right-sided pressure overload. The patient with severe TR has right-sided volume overload and would have diastolic septal flattening as shown. Patients often have both diastolic and systolic septal flattening if they have both volume and pressure overload on the right side, for example, in a patient with chronic pulmonary embolisms who has developed pulmonary hypertension and also developed significant TR. The lesions of MR and AI are volume loads for the LV, and the subaortic membrane is a pressure load on the LV.

16. **b.** Septal myectomy. The TEE images demonstrate a patient with HOCM. There is septal hypertrophy and the systolic frame demonstrates SAM, which is SAM of the mitral leaflets (Fig. 14.31). The color Doppler images for this patient demonstrate severe MR that is posteriorly directed, which is classic for MR caused by SAM of the mitral leaflets. SAM can involve either the anterior or posterior leaflet alone, or a patient may have bileaflet SAM. Typically, if the mitral leaflet has not been too damaged by years of contact with the septum, performing a septal myectomy can fix the severe MR by eliminating the left ventricular outflow tract (LVOT) obstruction

and eliminating the SAM. This type of MR is often hemodynamically labile depending on the loading conditions of the LV. The SAM can be brought out or accentuated by giving the patient amyl nitrite or isuprel. The SAM is decreased by volume loading the ventricle or increasing the systemic pressure. If the mitral leaflets, however, have been scarred by years of contact with the septum, a simultaneous MV repair or replacement may need to be performed. If the MV has to be replaced, often the surgeon has to use a lower-profile valve (typically a bileaflet mechanical valve) because of the narrowed LVOT. Neither a CABG nor an ascending aortic conduit would help this patient unless he had concomitant CAD or an ascending aortic aneurysm, in which case these procedures would have to be performed in addition to the myectomy.

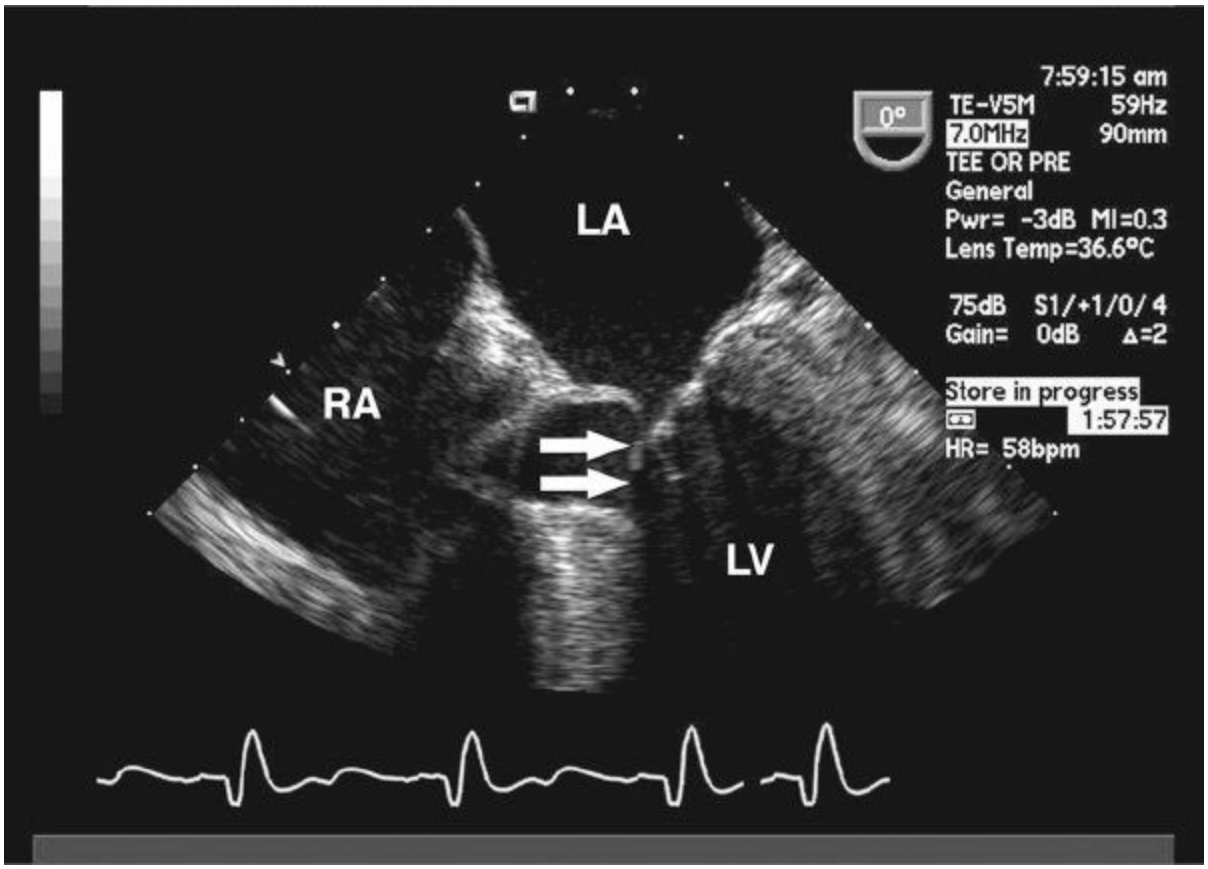

Figure 14.31

17. **d.** Thrombus. This patient had a very large anterior MI and has significant thinning and akinesis of the anterior wall and LV apex. Because of this significant wall motion abnormality, there is stasis of the blood and the patient is at risk for forming a thrombus, which this patient has done. The homogeneous nature of the mass with an echogenicity similar to that of the myocardium (or slightly less echogenic than the myocardium) suggests that the thrombus is relatively fresh. As this heals or organizes over time, calcium may be deposited, and old, organized thrombi in the

heart are often quite echogenic. A sarcoma, on the other hand, would be an invasive mass and would not respect the boundaries of the myocardium, but rather would infiltrate the myocardium. Teratomas if found in the heart arise from the pericardium, not within the LV cavity. These are typically benign although may compress the heart. A teratoma would also have a more heterogeneous appearance on echo. Myxomas are the most common benign tumor of the heart and 80% of those are located in the LA, and most of the remaining ones are found in the RA. Papillary fibroelastomas are the second most common benign cardiac tumors and are typically pedunculated (with a stalk) and mobile. Most (>80%) are located on heart valves.

18. **c.** Hibernating myocardium in the LAD territory. There is a matched defect in the LAD territory seen on the resting and post-stress images involving the apex and four periapical segments as well as the mid-anterior and anteroapical segments. This is consistent with a large LAD territory infarct without any inducible ischemia. The metabolic FDG images show a perfusion/metabolism mismatch with FDG uptake seen in the previously mentioned LAD segments, suggesting a large region of hibernation in the LAD territory without any significant scar. (Note that there is significant gastrointestinal [GI] uptake near the inferior wall.) The degree of hibernation involved 40% of the myocardium (6% for each involved segment except for the apex, which represents 4% of the myocardium). A study by Hachamovitch et al.[1] in 2003 showed that revascularization was superior to medical therapy if the amount of myocardium at risk (ischemic and hibernating) exceeded 20%. Since the above patient demonstrated a large area of hibernating myocardium in the LAD territory, the patient would benefit from revascularization of the LAD territory as well as the diagonals. This patient underwent surgical revascularization of all three vessels.

19. **b.** Multivessel ischemia. The resting scan showed GI activity, but overall normal tracer uptake. There was increased septal uptake caused by the moderately severe LVH. Post stress there is severely reduced tracer uptake involving the mid- and apical anterior, entire anteroseptal, and inferolateral walls and inferior wall and apex. There was also cavity dilation post stress. This is known as transient ischemic dilation (TID). The gated images that accompanied this study demonstrated hypokinesis of the above segments. Note that the post-stress gated images are acquired post stress, but at rest. That is to say that there is a delay between stress and imaging, which may allow for some recovery of function. This scan is of high risk in that there is ischemia in all three vascular territories with TID and extensive wall motion abnormalities. Although the patient was asymptomatic under his baseline conditions, it was appropriate to order the

adenosine nuclear stress test since the patient is diabetic with prior revascularization and with a questionable functional status who was going to undergo a high-risk surgical procedure (aortic aneurysm repair).

20. **d.** Scar and ischemia in the LCx/RCA territory. The full interpretation of the study was that there was marked GI activity in the rest images, but there was also a severe resting perfusion defect involving the basal and mid-inferolateral segments. Although GI activity can make the basal and mid-inferior segments difficult to interpret at rest, the post-stress images clearly show that the defect now involves the entire inferolateral and inferior walls, showing infarct with peri-infarct ischemia in the LCx/RCA territory. Cardiac catheterization demonstrated a total obstruction of the proximal LCx (a dominant LCx) with collaterals from the RCA and LAD. There were no obstructions in the RCA and LAD. Important points from this case include that diabetics are at high risk for CAD and clinical parameters do not predict ischemia (from the detection of ischemia in asymptomatic diabetes (DIAD) trial). Myocardial perfusion imaging can be performed safely post MI to assess infarct size and the amount of myocardium at risk. It is also a good test to assess the adequacy of collateral blood flow.

21. **e.** LAD and LCx versus left main ischemia. The resting images demonstrate normal perfusion. Post stress, however, there are significant perfusion defects in the anterior, anterolateral, and inferolateral walls. There is also cavity dilatation, which is consistent with either left main disease or multivessel ischemia. The gated images showed new wall motion abnormalities in the LAD and LCx territories. The presence of stress-induced perfusion defects in multiple vascular territories as well as TID and new wall motion abnormalities on the gated images are all findings associated with high-risk scans. The cardiac catheterization in this patient demonstrated 70% stenosis in the proximal LAD, while the stent in the mid-LAD was patent. There was a large obtuse marginal with a 90% proximal stenosis. There was mild disease in the proximal RCA, and the stents in posterior descending artery and posteroventricular branch were patent.

22. **d.** Patients with this condition who survive past childhood often present with varying degrees of heart failure, myocardial ischemia, and MR, depending on the development of collateral circulation. This CT demonstrates an anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA). Also known as Bland-White-Garland syndrome, ALCAPA is a rare but serious congenital anomaly. It is caused by either (a) abnormal septation of the conotruncus into the aorta and PA or (b) persistence of the pulmonary buds together with involution of the aortic buds that eventually form the coronary arteries. Occurrence is similar

between men and women and is not considered an inheritable congenital cardiac defect. Because of the low pulmonary vascular resistance, left coronary artery flow reverses and enters the pulmonic trunk (coronary steal phenomena). As a result, the LV myocardium remains underperfused, leading to infarction of the anterolateral LV wall. This often causes anterolateral papillary muscle dysfunction and variable degrees of mitral insufficiency. Consequently, the combination of LV dysfunction and significant MV insufficiency leads to CHF symptoms (e.g., tachypnea, poor feeding, irritability, and diaphoresis) in the young infant. Collateral circulation between the right and left coronary systems eventually develops. Approximately 85% of patients present with clinical symptoms of CHF within the first 1 to 2 months of life. Left untreated, the mortality rate in the first year of life is 90% secondary to myocardial ischemia or infarction and MV insufficiency leading to CHF. In unusual cases, the clinical presentation with symptoms of myocardial ischemia may be delayed into early childhood. Rarely, a patient may stabilize following infarction and may present with MV regurgitation, periodic dyspnea, angina pectoris, syncope, or sudden death later in childhood or even adulthood, as in this patient. Treatment consists of surgical ligation of the anomalous coronary artery origin and bypass grafting to the left coronary artery. Reimplantation onto the native aortic root is typically not possible because of the friable quality of the anomalous left coronary artery ostium.

CODING SHEET

General Features

1. Normal electrocardiogram (ECG)
2. Borderline ECG or normal variant (specify in other section)
3. Incorrect electrode placement

P-Wave Abnormalities

4. Right atrial abnormality
5. Left atrial abnormality
6. Nonspecific atrial abnormality
7. Sinoventricular condition with absent P wave

Supraventricular Rhythms

8. Normal sinus rhythm (without other abnormalities of rhythm or atrioventricular (AV) conduction)
9. Sinus rhythm (in presence of abnormality of rhythm or AV conduction)
10. Sinus arrhythmia
11. Sinus bradycardia
12. Sinus tachycardia

13. Sinus pause or arrest
14. Sinoatrial exit block
15. Ectopic atrial or junctional rhythm
16. Wandering atrial pacemaker
17. Atrial premature beats, normally conducted
18. Atrial premature beats, nonconducted
19. Atrial premature beats with aberrant intraventricular conduction
20. Atrial tachycardia (regular, sustained, 1:1 conduction)
21. Atrial tachycardia, repetitive (short paroxysms)
22. Atrial tachycardia, multifocal (chaotic atrial tachycardia)
23. Atrial tachycardia with AV block
24. Atrial flutter
25. Atrial fibrillation
26. Retrograde atrial activation
27. Supraventricular tachycardia, unspecified

Atrioventricular Junctional Rhythms

28. AV junctional premature beats
29. AV junctional escape beats or escape rhythm
30. AV junctional rhythm, accelerated rhythm (nonparoxysmal junctional tachycardia)
31. AV junctional tachycardia

Ventricular Rhythms

32. Ventricular premature beat(s), uniform, fixed coupled
33. Ventricular premature beats, R on T phenomenon

34. Premature ventricular contractions, in pairs

35. Ventricular parasystole

36. Ventricular tachycardia

37. Accelerated idioventricular rhythm

38. Ventricular escape beats or rhythm

39. Ventricular fibrillation

Atrioventricular Conduction Abnormalities

(Also see items 48 to 53)

40. AV block, primary

41. AV block, secondary—Mobitz type I (Wenkenbach)

42. AV block secondary—Mobitz type II

43. AV block, 2;1, 3:1, 4:1

44. AV block, complete

45. AV block, varying

46. Short PR interval (with sinus rhythm and normal QRS duration)

47. Preexcitation (Wolff-Parkinson-White) syndrome(s)

Atrial Ventricular Interactions in Arrhythmias

(Also see items 40 to 47)

48. Fusion beats

49. Reciprocal (echo) beats

50. Ventricular capture beats

51. AV dissociation (without complete AV block)

52. Isorhythmic AV dissociation

53. Ventriculophasic sinus arrhythmia

Abnormalities of QRS Voltage or Axis

54. Low voltage, limb leads only

55. Low voltage, limb and precordial leads

56. Left axis deviation (>30 degrees)

57. Right axis deviation (>+100 degrees)

58. Electrical alternans

Ventricular Hypertrophy

59. Left ventricular hypertrophy by voltage only

60. Left ventricular hypertrophy by left ventricular hypertrophy by voltage and ST-T segment (secondary repolarization changes)

61. Right ventricular hypertrophy

62. Combined ventricular hypertrophy

Intraventricular Conduction Disturbances

63. Right bundle branch block (RBBB), incomplete

64. RBBB, complete

65. Left anterior fascicular block

66. Left posterior fascicular block

67. Left bundle branch block (LBBB), complete with ST-T waves suggestive of acute myocardial injury or infarction

68. LBBB, complete

69. Intraventricular conduction disturbance, nonspecific type

70. Aberrant intraventricular conduction with supraventricular arrhythmia (specify rhythm)

Transmural Myocardial Infarction

(Also see items 88 and 89)

	Age Recent or Probably Acute	Age Indeterminate or Probably Old
Anterolateral	71	72
Anterior	73	74
Anteroseptal	75	76
Lateral or high lateral	77	78
Inferior (diaphragmatic)	79	80
Posterior	81	82

83. Probable ventricular aneurysm

ST-, T-, and U-Wave Changes

84. Subendocardial or subepicardial nontransmural infarction

85. Normal variant, early repolarization

86. Normal variant, juvenile T wave

87. Nonspecific ST- and/or T-wave changes

88. ST- and/or T-wave changes suggesting myocardial ischemia

89. ST- and/or T-wave changes suggesting myocardial injury

90. ST- and/or T-wave changes suggesting acute pericarditis

91. ST-T segment changes secondary to intraventricular conduction distribution or hypertrophy

92. Post extrasystolic T waves

93. Isolated J-point depression

94. Peaked T waves

95. Prolonged QT interval

96. Prominent U waves

Suggested Probable Clinical Disorder

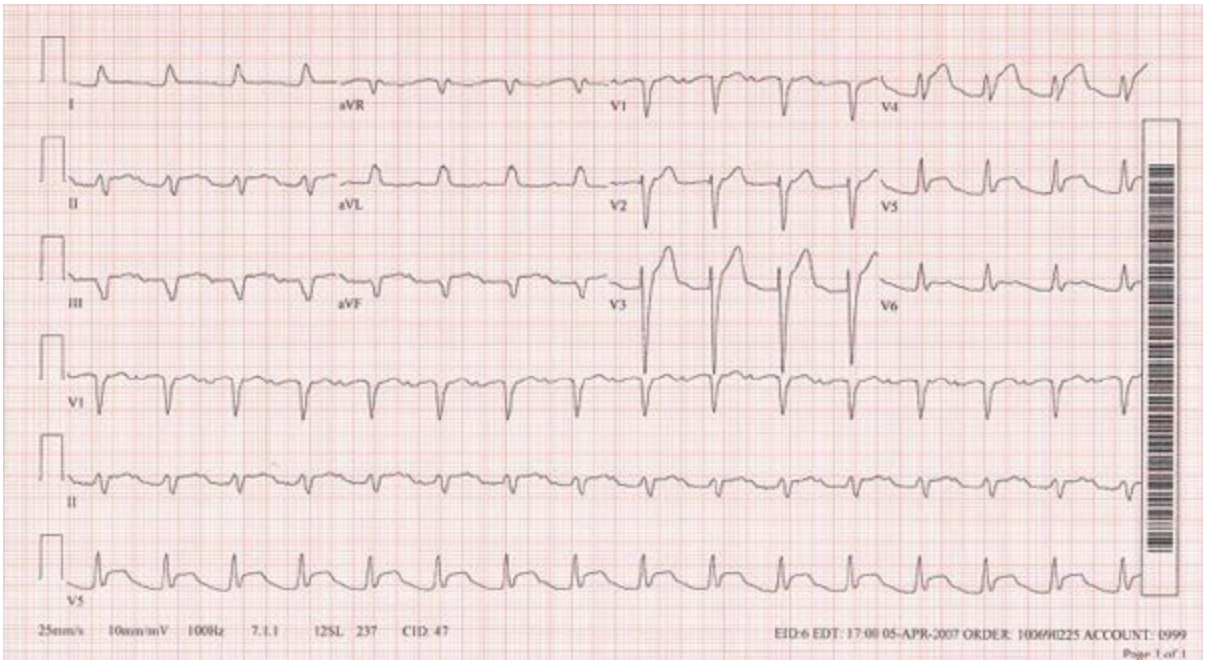

Figure 15.33

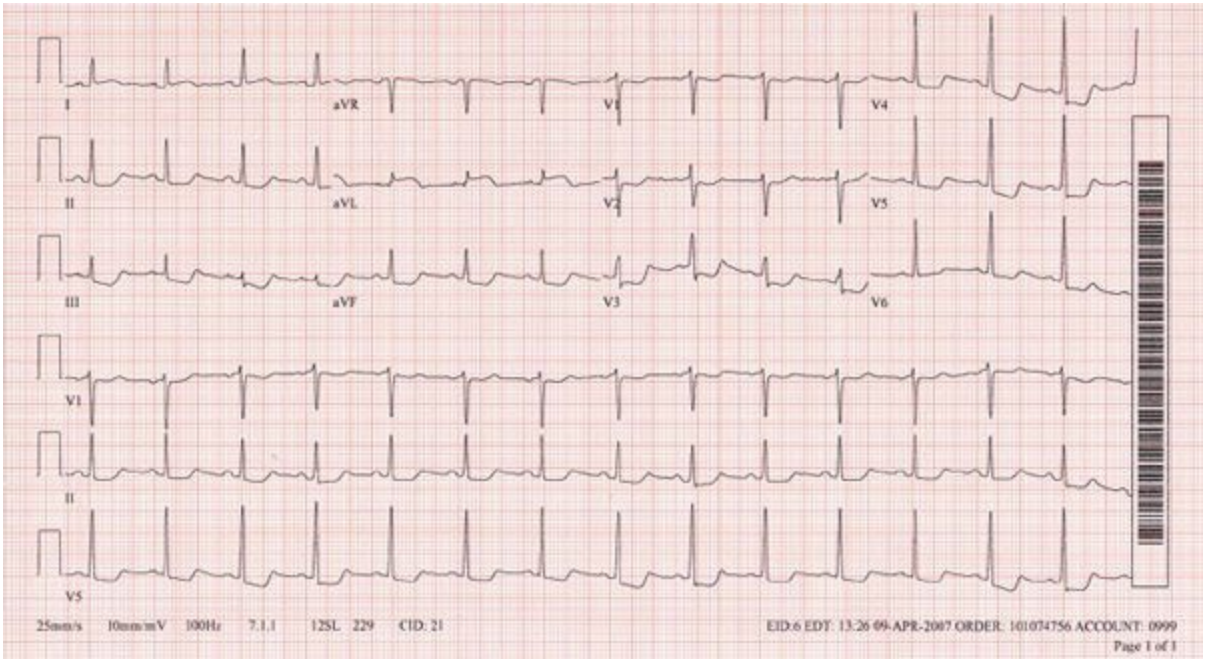

Figure 15.34

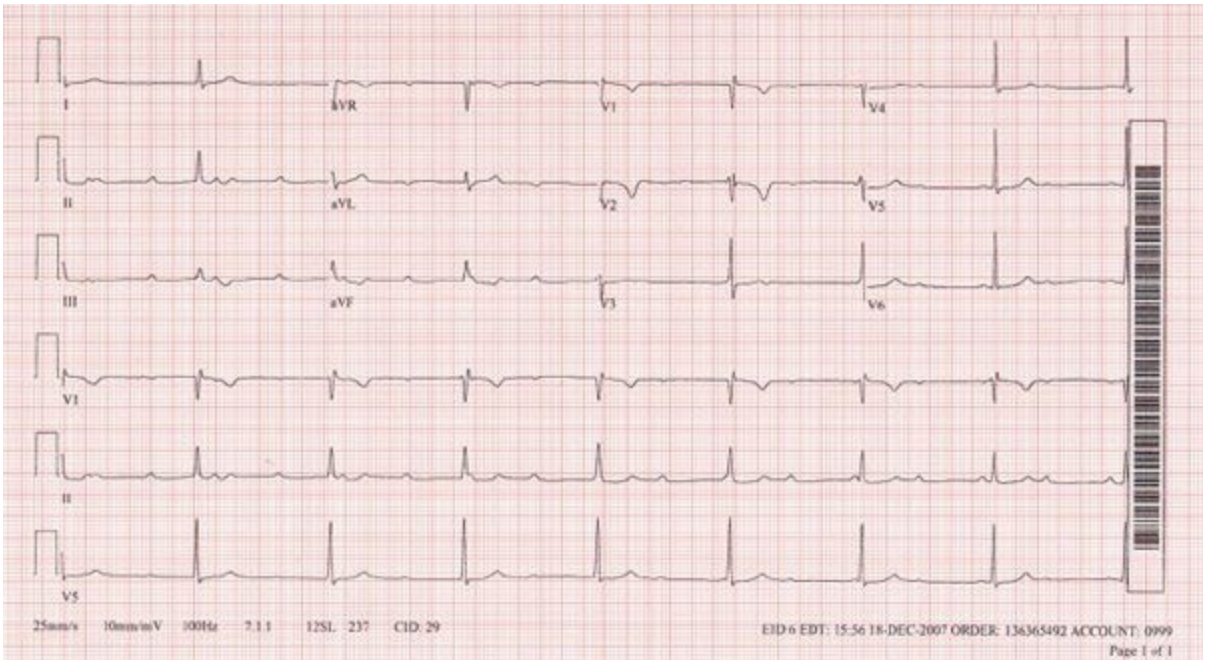

Figure 15.35

1. FIGURE 15.1: On this electrocardiogram, there is a sinus tachycardia. The voltage is low and in the V_1 and II rhythm strips, electrical alternans can be seen. This is an ECG from a patient with cardiac tamponade. Electrocardiographic coding is 12, 58, and 109.

2. FIGURE 15.2: This electrocardiogram shows a sinus tachycardia. There is a generalized T-wave inversion. The T waves are symmetric, deep, and have a long QT interval. This is an electrocardiogram from a patient with a major CNS event such as a subarachnoid or intraventricular hemorrhage. Electrocardiographic coding would be 12, 95, and 114.

3. FIGURE 15.3: This electrocardiogram shows a sinus rhythm. There is prolongation of the QT interval. The T wave has a fairly normal duration and contour, however. This is an example of hypocalcemia. (Type III congenital long QT syndrome also has this appearance.) Electrocardiographic coding would be 8, 95, and 102.

4. FIGURE 15.4: On this electrocardiogram, there is a sinus rhythm. It is sinus bradycardia. There is a prolongation of the QT interval. In this case, there is ST-segment depression, T-wave flattening, and TU fusion with prominent U waves in the lateral precordial leads. This should suggest hypokalemia. Another possibility is digitalis plus an antiarrhythmic drug's effects (such as quinidine or procainamide). Electrocardiographic coding would be 11, 96, and 100.

5. Figure 15.5: This patient has a sinus tachycardia. There is symmetry of the T waves

and there is a degree of QT prolongation. This is an example of a mixed electrolyte abnormality, hyperkalemia, and hypocalcemia. Values at the time were potassium of 7.2 and calcium of 80. This would be coded 12, 94, 95, 99, and 102.

6. FIGURE 15.6: On this electrocardiogram, there is a narrow complex tachycardia. The complexes are regular. In lead V_1, there is an atrial wave that has a short RP, long PR relationship. This is an example of supraventricular tachycardia or AV nodal reentrant tachycardia (AVNRT). If the atrial wave seen in V_1 extends to 70 or 80 milliseconds out into the ST segment, then this type of tracing could be an example of AV reentrant tachycardia (AVRT), which usually involves a larger reentrant loop and a bypass tract. Electrocardiographic coding is 27.

7. FIGURE 15.7: Here there is a narrow complex tachycardia. It is chaotically irregular and there are multiple P-wave vectors. This is not atrial fibrillation, which also is chaotic, but instead is a multifocal atrial tachycardia. This patient also shows aberrancy in the 6th and 14th beats. Electrocardiographic interpretation is 22, 87, 70, and 107.

8. FIGURE 15.8: This patient has a regular rhythm, but the baseline as seen in lead V_1 is chaotic. It is an example of atrial fibrillation with a regular ventricular response. This is actually an accelerated junctional rhythm most likely caused by digitalis excess. In lead V_6 there is ST-segment sagging that is smooth and associated with QT interval shortening. This suggests digitalis "effect." Digitalis effect is seen in the repolarization changes with ST-segment scooping. Digitalis "excess" is usually suggested by arrhythmias and in this case the accelerated junctional rhythm. The coding would be 25, 30, 97, and 98.

9. FIGURE 15.9: This patient shows an rSR′ pattern in lead V_1 that might suggest a volume-overload right ventricular hypertrophy (RVH). That is supported in part by the right axis deviation. However, in looking at the rhythm strip in lead II, there is a basic sinus rhythm with a first-degree AV block and in addition there is a second atrial rhythm that is dissociated from the basic PQRS sequence. This is accessory atrial activity related to cardiac transplantation. This would be coded 9, 40, 57, 63, and 118.

10. FIGURE 15.10: On this electrocardiogram, there is a regular atrial activity, but the P waves are inverted in the inferior leads, suggesting an ectopic atrial tachycardia. This conducts with group beating and gradual PR prolongation. This is an example of atrial tachycardia with Mobitz type I AV block. This would be coded 23 and 41.

11. FIGURE 15.11: This electrocardiogram shows a sinus rhythm. There is a first-degree AV block and intermittent 2:1 block. In addition, there is ST-segment depression that is scooping in quality in the lateral leads. This is an example of digitalis excess with intermittent second-degree AV block and digitalis effect. It would be coded 11, 41 or 42, 97, and 98.

12. FIGURE 15.12: This patient has a right bundle branch block and left axis deviation. He also has pauses. In this case, the P waves are regular and the PR intervals do not change. This is an example of a Mobitz type II second-degree AV block. The P-wave vectors are prominent in both leads II and V_1, suggesting left atrial enlargement. This would be coded 8, 42, 5, 56, and 64.

13. FIGURE 15.13: This patient has a right bundle branch block. There is also left axis deviation which probably is enough to qualify as an anterior hemiblock. There are occasional pauses. In this case, the pauses are preceded by P waves, which are within the preceding T waves, and so this is an example of blocked PACs and not an example of more advanced AV block associated with bifascicular block. This would be coded 11, 18, 56, 64, and 65.

14. FIGURE 15.14: This patient shows a sinus rhythm with a 2:1 AV block. This can either be a Mobitz type I or II AV block. It is impossible to tell which. This also shows ST-segment elevation with Q waves in the inferior leads with reciprocal changes in leads I and aVL and is an example of an acute inferior infarction with 2:1 AV block. This would be coded 8, 43, and 79.

15. FIGURE 15.15: This patient shows a sinus rhythm. There is ST elevation in the inferior leads, especially leads III and aVF. There are reciprocal depressions in leads I and aVL. In leads V_1 and V_2, there is also ST elevation. This is an acute inferior infarction plus acute right ventricular infarct. This would be coded 8 and 79. At least on this code sheet, the ability to call right ventricular infarction would not be available to you.

16. FIGURE 15.16: This electrocardiogram has a sinus rhythm. There are lateral T-wave changes that are not specific, and there are QS waves in leads V_1 through V_3. This is an anteroseptal infarction of uncertain age. It would be coded 8, 76, and 87.

17. FIGURE 15.17: Here, there is a normal sinus rhythm and marked left axis deviation. There are small Q waves in leads I and aVL with a slight activation delay in aVL. This is anterior hemiblock. Anterior hemiblock produces small Q waves in the right precordial leads. The QRS pattern seen in V_2 is often very suggestive of

anteroseptal infarction, but the specificity is much less in the presence of anterior fascicular block. This would be coded 8 and 65.

18. FIGURE 15.18: In this patient, there are symmetric, prominent T waves that are upright. These are seen in the inferolateral leads and are associated with ST depression in leads V_1, V_2, and V_3. There are no Q waves so this is not an acute infarct, but it is an acute current of injury. The rhythm is sinus. Electrocardiographic coding would be 8 and 89.

19. FIGURE 15.19: On this electrocardiogram, there is a sinus rhythm. It is slow so sinus bradycardia. There are significant inferior Q waves and also Q waves in leads V_5 and V_6. There is also a prominent R-wave vector in lead V_1, and the T waves are upright despite the presence of a right bundle branch block. Usually with a right bundle branch block, ST-segment and T-wave inversion are expected. In this case, the upright T wave is an example of a "primary" T wave. A prominent initial vector and upright T wave in V_1, associated with inferior and lateral Q waves, are interpreted as an inferoposterior and lateral infarct. Electrocardiographic coding is 11, 80, 82, 78, and 64.

20. FIGURE 15.20: This electrocardiogram has a sinus rhythm. There is a prominent initial vector in lead V_1 that is greater than the S wave. T wave is upright. This is compatible with posterior infarct. That is supported by the presence of pathologic Q waves in leads III and aVF. Electrocardiographic coding would be 8, 80, and 82.

21. Figure 15.21: This electrocardiogram shows a sinus rhythm. There are inferior Q waves and prominent R vector in leads V_1 and V_2. This might suggest inferoposterior infarction, but in leads V_3 and V_4, especially there is a short PR interval and a delta wave suggesting that this is preexcitation or Wolff-Parkinson-White syndrome. Electrocardiographic coding would be 8 and 47.

22. FIGURE 15.22: This patient has a sinus rhythm. Lead II does suggest left atrial enlargement with a P wave that is broad and notched. There is an rSR′ pattern in lead V_1 with T-wave inversion and R′ greater than S. This type of pattern is commonly seen in volume-overload-type RVH. Volume-overload RVH and left axis should suggest ostium primum ASD. Usually an ASD will not affect P waves greatly, at least in the early phases of the process. Ostium primum ASDs, however, very often have mitral valve and notable mitral insufficiency plus left atrial enlargement. Electrocardiographic coding would be 8, 5, 63, 61, 56, and 104.

23. FIGURE 15.23: This electrocardiogram shows a sinus rhythm. There was a very

prominent vector in lead V_1 associated with upright T waves. This drops down to a more typical appearance in lead V_2. This is not an example of posterior infarction but instead is an example of switched leads, V_1 and V_5 having been transposed. There is also ST-segment elevation throughout and perhaps some PR-segment elevation in aVR. This suggests acute pericarditis. Electrocardiographic coding would be 8, 3, and 90.

24. FIGURE 15.24: This patient has a wide complex tachycardia. There is AV dissociation and there is anterior, positive concordance in the chest leads. This is ventricular tachycardia. Electrocardiographic coding would be 9, 51, and 36.

25. FIGURE 15.25: This patient has marked right axis deviation and loss of voltage across the precordium. The P waves are inverted in leads I and aVL. Inverted P waves in leads I and aVL (if it is not an ectopic atrial rhythm) are caused by either dextrocardial or switched arm wires. Loss of voltage across the precordium suggests that this is dextrocardia. Electrocardiographic coding would be 8 and 105.

26. FIGURE 15.26: This patient has a sinus rhythm and right axis deviation. The vectors in leads I and aVL are incompatible with those seen in the other lateral leads, V_5 and V_6. The discrepancies are explained by the inverted P waves in leads I and aVL, which suggest switched arm wires. This is a normal ECG with a technical error. This would be coded 8 and 3.

27. FIGURE 15.27: The patient is a 6-year-old with an outflow tract murmur. Rhythm is sinus with a narrow complex. V_1 shows small rSR′ with a large R′. There is right axis deviation. This is right ventricular hypertrophy. It is a volume-overload-type pattern. Most likely an ostium secundum ASD. Coded 8, 57, 61, and 103.

28. FIGURE 15.28: Here there is sinus bradycardia with left ventricular hypertrophy (voltage) and secondary T-wave changes extending into the right precordium. Most likely this is a hypertrophic cardiomyopathy with apical hypertrophy. This is occasionally called Yamaguchi syndrome after the initial describer of the variant. Coded 11, 60, and 112.

29. FIGURE 15.29: Although leads I, aVL, and III might suggest an atrial tachycardia, other leads clearly show a sinus rhythm. This is a motion artifact due to unilateral tremor and Parkinson disease. Coded 8 and 87.

30. FIGURE 15.30: Here is a sinus rhythm with minor lateral T-wave flattening. The last beat is premature and is an aberrant PAC. Characteristics of aberrancy are

preceding atrial activity (seen in the T wave) and initial narrow vector with broadening toward the end of the complex and often a right bundle branch block type of pattern. Coded 8, 19, and 87.

31. FIGURE 15.31: This shows a sinus rhythm with first-degree AV block, generalized broadening of the QRS (with a right bundle branch block-like pattern), and symmetric broadening of the T wave. This is hyperkalemia. Potassium at the time was 6.2 mEq/L. Coded 8, 64, and 99.

32. FIGURE 15.32: Here is a sinus bradycardia with a sinus arrhythmia. There is terminally a symmetric T-wave inversion in leads V_2 and V_3 plus a qrS pattern in V_3. This is an anteroseptal infarct of uncertain age. Also there are lateral T-wave changes that are not specific. Coded 11, 76, 87, and 113.

33. FIGURE 15.33: Rhythm is sinus with a first-degree AV block. There was a wide complex without septal Q waves in leads I and V_6 (a left bundle branch block pattern) and left axis deviation. ST and T waves are "discordant" in the anterolateral leads (and also generally). There is also PR-segment elevation in lead aVR. This could be anterior "injury," but more suggests acute pericarditis. Coded 8, 40, 56, 68, and 90.

34. FIGURE 15.34: There is a sinus rhythm with ST-segment elevation in lead aVL and reciprocal changes in the inferior and lateral leads. This is an acute high lateral infarct. Coded 8, 77, and 113.

35. FIGURE 15.35: A sinus rhythm with AV dissociation (complete heart block) and junctional escape. V_1 shows an incomplete right bundle branch block pattern. T waves are not entirely normal in V_3. Coded 12, 44, 63, and 87.

  diagnosis, 283, 283f, 294
  differential diagnosis, 280, 294
Cardiac transplant, ECG and, 182, 192
Cardioembolic event, 136, 150
Cardioembolic stroke, 135, 135f, 150
Cardiogenic shock, 57, 67, 182, 193
Cardiomyopathy
  dilated
    ACE inhibitor use, 181, 192
    beta-blocker use, 183, 193
    biventricular pacing, 186–187, 194
    calcium channel blocker use, 183, 193
    nesiritide use, 182
    systolic heart failure, 180, 192
  hypertrophic
    carotid pulse, 188, 189f, 190f, 195
    diagnosis of, 35, 35f, 49, 49f
    dual-chamber pacing in, 5, 17
    echocardiography, 34–35, 49
    EP study, value of, 187, 194
    ischemic, 183, 193
    peripartum, 186
Cardiovascular risk factor assessment tools, 169–170, 177
Cardioversion. (see also Implantable cardioverter defibrillator (ICD))
  for atrial fibrillation, 10–11, 20
  for post-MI atrial fibrillation, 190, 195
  timing of anticoagulant therapy and, 108, 118
Carotid arteries, 167, 177

Carotid duplex ultrasound, 131, 148, 169, 169f, 177
Carotid intima-media thickness, 177
Carotid pulse, diagnosis of, 125, 188, 189f, 190f, 195
Carotid ultrasound surveillance, 166, 176
Carvedilol, 114, 122, 235, 237
  for heart failure, 114, 122
CASTI/CASTII (Cardiac Arrhythmia Suppression trials), 2, 13
CCBs. (see Calcium channel blockers)
Cell proliferation, 227, 228
Cerebral aneurysm rupture, 128, 146–147
Cervical aortic arch, 135–136, 151
Chemotherapy, 286, 287, 295, 299
Cholestyramine, effect on warfarin, 112, 121
Chronic dissection, 141, 154
Chronic ethanol, 106, 116
Chronic hypertension, 230, 239
Chronic kidney disease (CKD), 231
Chronic obstructive pulmonary disease (COPD), 276
  palpitations, treatment of, 6–7
Chronic thromboembolic pulmonary hypertension (CTEPH), 159, 172
Chronic venous insufficiency, 156, 171
Class I ACC/AHA guidelines, 83, 90–100
Cleft mitral valve, 202, 207, 214, 216, 218t, 305, 323
Clinical disorder, 338
Clinical hyperacute immune response, 159, 172
Clonidine, 113, 122, 231, 232, 235, 236, 238, 239, 247
Clopidogrel, 109, 119
  antiplatelet effects, 110, 119–120
  mechanism of action, 55, 66
  side effects, 110, 119
  ticlopidine versus, 110, 119
Clopidogrel in Addition to Aspirin in Patients with Acute Coronary Syndromes without ST-Segment Elevation (CURE) trial, 119
Coarctation of the aorta, 136, 137, 150–151, 199, 202, 203, 205, 207, 210, 212, 214, 219, 220, 223, 224, 241, 305, 323
Cockett syndrome, 162, 174
Cogan syndrome, 140, 153
Complete blood count (CBC), 157
Complete heart block
  at AV node, 8, 8f, 19
  catheter induced, 6, 17
  at infra-Hision level, 8f, 9, 19
  pacemaker placement for, 6, 17
Compression stockings, 162–164, 163, 174, 175
Computed tomographic angiography (CTA), 129, 147
Computed tomography (CT)
  aortic dissection diagnosis, 27, 45
  pulmonary artery (ALCAPA), 318–319, 318f, 332
Congencital heart disease, common surgical procedures, 213t
Congenital rubella syndrome, 210
Congestive heart failure, 180–195
  carotid pulse in severe decompensation, 188, 189f, 195

characteristics of, 180, 192
exercise limitation, 184
prognosis, 184–185, 194
Conivaptan, 107, 117
Connective tissue disorder, 139–140, 153
Constrictive pericarditis, 277, 278, 292, 293
Continuous infusion, 119
Contralateral popliteal artery, 166–167, 176
Contusion, cardiac, 285–286, 286f, 295
COPD. (see Chronic obstructive pulmonary disease)
Coronary angiogram, 230, 284
Coronary arteriovenous fistula, 207, 208
Coronary artery
anomaly, 207
diagnostic test, 126–127
emergent aortic surgery, 127, 146
management of, 127
Coronary artery bypass graft (CABG)
diagnostic procedure, 129, 147
management, 129, 147
Coronary artery bypass surgery, 163, 175
Coronary artery disease (CAD), 71–101. (see also specific disorders)
arrhythmia treatment in, 3, 14
initial treatment strategy, selection of, 91t
PET scan, 315–316, 316f, 331
sudden cardiac death, association with, 4, 15
Coronary cameral fistula, 208
Coronary sinus ASD, 202, 216, 218t, 219, 220f
Coronary spasm, as myocardial infarction cause, 66
Creatine phosphokinase (CPK) levels, 112, 121
Creatinine, 230, 233, 234, 235, 239, 242, 243, 258, 270, 271, 272, 280, 284, 285
Crouzon syndrome, 210
Cyanosis, 209
Cyclosporine, effect of diltiazem on, 237, 246

Daptomycin, 112, 121
contraindications, 112, 121
Decompression sickness, 205
Deep vein thrombosis, 159, 172
Deep venous thrombosis (DVT) prophylaxis, 157
Defibrillation, for out-of-hospital cardiac arrest, 4, 15
Defibrillator, 3, 15
Dental procedures, antibiotic prophylaxis for, 137–138, 151
Dextrocardia, ECG and, 128, 353
Diabetes
ADA guidelines, 253
CVD events, 254
hypertension, 231, 232, 233, 235, 236, 237, 240
lipid goals therapy, 253
Diabetes mellitus (DM), 111, 121
diagnosis of, 156, 171

ECG in ketoacidosis, 290–291, 290f, 295
myocardial infarction and, 57, 67
Dialysis, for hyperkalemia, 251, 290, 290f, 295, 340f, 351
Diarrhea, 110, 119
Diastolic dysfunction, 181, 233, 237, 280, 281, 294
Digoxin, 113, 122
concentration, 106, 116
converting to IV from PO, 105, 116
effect of flecainide on, 11, 21
increase levels with antiarrhythmic drugs, 1
level, 105, 116
mechanism of action, 107–108, 117
myocardial contractility, 107–108, 117
reduction in hospitalization and, 181, 193
toxicity, 107–108, 117
Digoxin-immune Fab, 117
Dihydropyridines, 240
Diltiazem, 107, 117, 237, 246
overdose, 6, 17
Dipyridamole, adenosine potentiation by, 1, 13
Direct renin inhibitor, 233, 241
Discoloration of hands, 158, 171
antinuclear antibodies, 158, 172
physiologic cold response, 158, 171
schedule for appointment, 158, 172
Diuretics, 107, 117, 209. (see also specific drugs)
effect on left ventricular pressure volume loop, 188, 188f, 189f, 195
loop, 107, 117
Diverticulum of Kommerell, 137, 151
DM. (see Diabetes mellitus)
DNA sequencing, 140, 153
Dofetalide, 110, 120
Dofetilide
contraindications, 1, 13
excretion, 13
indications for, 194, 197
Dopamine, for cardiogenic shock, 182, 193
Down syndrome, 223t
Dronedarone, 110, 120
Drug allergies, 115, 123
Drug-eluting stent (DES) implantation, 91–92
D-transposition of great vessels, 199
Dual-chamber pacemaker, 208
Duplex ultrasonography, 230, 239
Dyslipidemia, 234, 235, 249, 250, 252, 253, 256, 260, 261, 262, 263, 268, 272
management guidelines, 252
secondary causes, 252
Dysphagia, with aortic anomalies, 137, 151
Dyspnea, 209

E:A wave ratio, 185

Ebstein's anomaly, 52, 198–199, 202, 203, 207, 208, 212, 214, 219, 220, 307, 328
ECG. (see Electrocardiography)
Echocardiography
  with amyl nitrate, 35, 48, 49f
  Doppler, indications for, 42, 52
  pericardial disease diagnosis, 276, 292
  with saline contrast, 42, 52
Eclampsia, 230, 239
Ectopic atrial tachycardia, 342f, 351
Ehlers-Danlos syndrome, 134, 143, 149, 153
Eisenmenger physiology, 197, 202
Eisenmenger syndrome, 198, 199, 202, 203, 211, 212, 214, 322
Elective aortic replacement, 127, 144
Elective aortic valve surgery, 138, 152
Electrical alternans, ECG, 340f, 350
Electrocardiogram (ECG), 197
Electrocardiographic interpretation, 334–354. (see also specific disorders)
  abnormalities of QRS voltage, 336
  atrial ventricular interactions in arrhythmias, 336
  atrioventricular conduction abnormalities, 336
  atrioventricular junctional rhythms, 336
  clinical disorder, 337
  general features, 334
  intraventricular conduction disturbances, 337
  p-wave abnormalities, 334
  ST-, T-, and U-wave changes, 337–338
  supraventricular rhythms, 334–335
  transmural myocardial infarction, 337
  ventricular hypertrophy, 336
  ventricular rhythms, 335
Electrocardiography (ECG)
  anterior wall injury, 285–286, 286f, 295
  evaluation of AV conduction, 9, 9f, 18
  hyperkalemia, 290, 290f, 295
  ketoacidosis, 290–291, 290f, 295
  pacemaker evaluation, 6, 6f, 7, 7f, 9, 9f, 18
  pericarditis, 276–277, 292
Elevated serum troponin, 163, 175
Endocarditis, 215, 219, 297, 300, 311, 322, 324
  aortic aneurysm, risk with, 312–313, 313f, 330f
  IV drug use associated, 305, 309f, 324, 324f
  prophylaxis, 114
Endoleaks, 141, 154
Endovascular revascularization, 156–157, 171
Endovascular stent graft (EVAR), 139, 152–153
End-stage renal failure, coronary atherosclerotic lesions and, 81, 99
Enoxaparin, 111, 118, 121, 163, 175
  dose, 111, 121
Episodic burning pain
  diagnosis, 160–161, 173
  laboratory values, 161, 173

Epoprostenol, 159, 172
EP testing
  heart block induced by, 6, 17
  indications for, 9, 19
  tachycardia induced by, 12, 12f, 21
Eptifibatide, loading dose, 109, 110, 111, 120
Erythromelalgia, 161, 173
Eschar formation, 171
Ethacrynic acid, 107, 117
Ethanol alters, 106, 116
Ethanol, effect on warfarin metabolism, 106, 116
EVAR. (see Endovascular stent graft)
E-wave deceleration time, 185, 194
Excitation-contraction coupling, 264, 267
Exercise tolerance
  in heart failure, 184, 193–194
  improvement in, 181, 192
Exercise treadmill stress test, 138, 151

Familial combined hyperlipidemia, 260
Familial hypercholesterolemia (FH)
  American Heart Association (AHA) statistics, 250
  heterozygous, 249
  hyperlipidemia assessment, 249
  lipid management guidelines, 250–251
  phenotypic presentation, 249
Fatal pulmonary embolism, pregnancy, 160, 173
Femoral compression device, 161, 173
FEV1. (see Forced expiratory volume in 1second)
FH. (see Familial hypercholesterolemia)
Fibrate trials, 258, 272
Fibrillin, 146, 231
Fibrinolysis
  for pericarditis in myocardial infarction, 60, 69
  platelet activation, 54, 66
  stroke risk, 55, 65
Flecainide
  for atrial fibrillation, 11, 21
  effect on digoxin level, 11, 21
  elimination, 13
  sodium channel blocking effects, 2, 14
  use dependence, 13
Fondaparinux, 108, 111, 118
Fontan procedure, 199, 210, 213t
Foramen ovale, patent, 150, 205, 212, 215
Forced expiratory volume in 1second (FEV1), 109, 119
Framingham Risk Score (FRS), limitations, 251
Furosemide, 107, 113–114, 117, 122

Gemfibrozil, 112, 121
Gene expression, detection by RT-PCR, 226
Gestational hypertension, 230, 239

Giant cell arteritis, 126, 131, 143–144, 148
Glaucoma, 231
Glenn procedure, 213t
Global Utilization of Streptokinase and tPA for Occluded Coronary Arteries (GUSTO)-III trial, 56, 68
Global Utilization of Streptokinase and tPA for Occluded Coronary Arteries (GUSTO)-I trial, 65
Glucagon
  indications for, 6, 17
  for metoprolol overdose, 185, 195
Glycoprotein IIb/IIIa inhibitors, 110, 120
  acute coronary syndrome, 55, 66
  thrombocytopenia from, 110, 120
Glycoprotein (GP) IIb/IIIa receptor, 227, 228
Gunther Tulip retrievable vena cava filter, 161, 173
GUSTO trial, 112, 121

Half-life of medications, 105, 116
Hands, discoloration of, 158, 171
  antinuclear antibodies, 158, 172
  physiologic cold response, 158, 171
  schedule for appointment, 158, 172
HDL-C management, 252
HDL-C metabolism, 256
Head-upright tilt table testing, 4–5, 16
Heart block
  complete
    at AV node, 8–9, 8f, 19
    catheter induced, 6, 17
    at infra-Hisian level, 8–9, 9f, 19
    pacemaker placement for, 6, 17
  second degree, at infra-Hisian level, 8f, 9, 19
Heart failure. (see also Congestive heart failure)
  treatment, 113–114, 122–123
Heart failure with preserved ejection fraction (HFPEF), 232, 241
Heart rate, abnormal recovery, 185
Heart transplantation
  allograft vasculopathy, 181, 192
  indications for, 184, 194
Hematoma, surgical evacuation of, 161, 173
Hemi-Fontan procedure, 213t
Hemorrhage, subarachnoid or intraventricular, ECG signs of, 107, 117
Hemorrhagic pericardial effusion, 162, 174
Heparin, 159, 172
  for acute coronary syndrome, 55, 65
  anticoagulant activity, 109, 119
  binding to antithrombin, 109, 119
  for mechanical heart valve patients, 37, 50
  for myocardial infarction, 56, 57, 66, 67
Heparin-induced thrombocytopenia (HIT), 159, 172
Hibernating myocardium, 186, 291, 314–315, 315f, 331
Hirudin, 60, 69
HOCM, 305, 325, 330

Holter monitoring, 138, 151
Homocystinuria, 134, 149
Homozygous FH, 250, 260
HTN. (see Hypertension)
Hydralazine, 113, 114, 122, 231, 233, 238, 240, 247
  for heart failure, 114, 122
  for LV function and exercise tolerance improvement, 181, 192
Hydrochlorothiazide, 113, 122
Hypercholesterolemia, 112, 121, 171
Hyperkalemia, diagnosis of, 290, 290f, 295
Hyperlipidemia, 112, 121–122, 235, 236, 237, 249
  American College of Cardiology [ACC]/AHA guidlines, 254
  NCEP ATP III comparison with ACC/AHA guidelines, 254–255
Hyperparathyroidism, 171, 231, 240
Hypertelorism, 210, 223, 224
Hypertension (HTN), 111, 121, 134–135, 150, 207, 230–247
  medications, 113, 122
  rebound, 113, 122
  treatment of, 113, 122
Hypertensive emergency, 235, 243
Hyperthyroidism, 252, 263
Hypertrophic cardiomyopathy, 200, 213
Hyperviscosity syndrome, 197
Hypokalemia, ECG and, 245, 295
Hyponatremia, conivaptan for, 107, 117

IABPs, contraindications, 60, 69
Ibuprofen, 240, 277, 292
ICD. (see Implantable cardioverter defibrillator)
IE. (see Infective endocarditis)
Iliac deep vein thrombosis, 163–164, 175
Iliac vein compression syndrome, 160, 173, 174
Iliocaval compression syndrome, 162, 174
Immunosuppression, 113, 122
Implantable cardioverter defibrillator (ICD)
  implantation procedure, 3, 15
  indications for, 3, 15
  myocardial infarction and, 59, 68–69
Indomethacin, 277, 279, 287, 292
Infective endocarditis (IE), 198
Inferior vena cava filter, 163–164, 173–174
  placement of, 164, 175
Inflammatory aortitis, 143, 144
Initial therapy, 110, 119
Initiate isosorbide dinitrate, 114, 123
Inotropic agents, 107–109, 118. (see also specific drugs)
  antiarrhythmic drug effects, 2, 14
  benefit of long-term IV, 114, 123
Insulin-like growth factor-1β, 227, 228
Intra-atrial reentrant tachycardia (IART), 210
Intracardiac shunts, 205

Intracranial bleed, 127–128, 146–147
Intracranial hemorrhage, risk factor for, 111, 121
Intramural hematoma, 130, 148
Intravenous (IV) drug abuser, 305, 324
Intraventricular conduction disturbances, 337
Ischemia, PET scan of multivessel, 315, 316f, 331
Isosorbide dinitrate, for heart failure, 114, 123

Jatene procedure, 213t
JUPITER trial, 250, 261, 266

Kartagener syndrome, 210
Kawasaki disease, 268
Konno procedure, 213t
Kussmaul's sign, 190, 195

Labetalol, properties of, 106–107, 117
LAD. (see Left anterior descending artery)
LBBB (left bundle branch block), 3, 14–15
LDL. (see Low-density lipoprotein)
LDL-C reduction, pharmacologic therapies, 255–256
LDS. (see Loeys-Dietz syndrome)
Left anterior descending artery (LAD)
  hibernating myocardium, 314–315, 315f, 331
  PET scan, 314–315, 315f, 331
  stenosis, 61, 62f, 70
Left bundle branch block, 3, 14–15
Left femoral vein thrombosis, 159, 172
Left-sided lesions, 207
Left-to-right shunt, management of, 33, 48
Left ventricle
  dilatation
    risk of sudden death, 27, 46
    vasodilator therapy for, 27, 46
  filling pressure, medications effect on, 185, 194
Left ventricular hypertrophy, 348f, 353
LEOPARD syndrome, 210
Lepirudin, 109, 119
Leukopenia, from captopril use, 235, 243
Lidocaine, for myocardial infarction, 59, 69
Lipid management, 250, 255, 264, 273
Lisinopril, 113, 122, 230, 231, 233, 235, 236, 237, 238, 239, 244, 245, 246, 247
  for heart failure, 113, 122
LMWH. (see Low-molecular-weight heparin)
Loeys-Dietz syndrome (LDS), 140, 140f, 153, 210
Lomitapide, 250, 260
Long-QT syndrome, 9, 20
Long-term IV inotropic therapy, 114, 123
Loop diuretics, 107, 117
Losartan, 231, 233, 240
  indications for, 181, 192
Lovastatin, 258

Low-density lipoprotein (LDL)
level, 164, 175
lowering ability, 112, 121
lowering with medication, 113, 116
Lower extremities, 141, 154
Low-molecular-weight heparin (LMWH), 110, 118. (see also Heparin; specific drugs)
diagnosis, 162, 174
management option, 162–163, 174
in pregnant women, 160, 173
Lung disease, chronic, 280, 292, 338
Lupus, hydralazine-induced, 238, 247
LV dysfunction, 221, 276, 292, 305, 332
LV function and exercise tolerance improvement, 181, 192

MADIT (Multicenter Automatic Defibrillator Implantation Trial), 15, 68–69
Magnesium, for myocardial infarction, 57, 67
Magnetic resonance angiography (MRA), 125–126, 143
of great vessels, 125–126, 143
Magnetic resonance imaging (MRI), 131, 148
congenital absence of pericardium, 286–287, 287f, 295
Magnet, use for inappropriate ICD shocks, 4, 15
Marfan syndrome, 126–127, 134, 140, 145–147, 149, 153, 210
aortic disease in, 127, 145–146
May-Thurner syndrome, 162, 173, 174
Mesenteric vein thrombosis, 160
Mesothelioma, 282, 291, 295
Methyldopa, 231, 233, 236, 239, 242, 245
Methylenetetrahydrofolate reductase (MTHFR), 160, 173
Metoprolol, 106, 113, 166, 122, 230, 231, 233, 234, 235, 236, 237, 238, 239, 240, 243, 245, 247
for hypertension, 113–114, 122, 123
overdose, 6, 17
MI. (see Myocardial infarction)
Middle cerebral artery, embolism of, 134–135, 150
Migraine, 205
Milrinone, 108, 118
indications for, 108, 118
for metoprolol overdose, 185, 195
Minoxidil, 237, 246
pericarditis from use of, 237, 240
Mipomersen, 250, 258, 260, 272
Mitral regurgitation
echocardiography, 24, 44f
myocardial infarction and, 60, 69
surgery, indications for, 24, 44
systolic anterior motion, 305–306, 306f, 324–325, 325f–326f
Mitral stenosis, rheumatic, 30, 46
Mitral valve
aspirin therapy, 33, 48
cleft, 304–305, 305f, 311, 312f, 323f
prolapse, 305, 309f, 324, 324f
echocardiography, 38, 50, 50f

prolapse, management of, 33, 48
replacement
ball and cage valve, 36, 50
bioprosthetic valve, 33, 43
evaluation of valve function, 37, 50
prosthetic mitral stenosis, 41, 52
septal myectomy, 312–313, 313f, 330, 330f
Mitral valve prolapse (MVP), 305, 324
Mitral valve replacement (MVR)
abnormal mechanical, 297, 320
bileaflet mechanical, 297, 320
M mode tracing, in mitral valve prolapse, 305, 309f, 324–326, 324f–326f
Monotherapy, 129, 147–148
Motor vehicle accident, cardiac/aortic injuries from, 161
MRI. (see Magnetic resonance imaging)
MTHFR (methylenetetrahydrofolate reductase), 160, 173
Multicenter Automatic Defibrillator Implantation Trial (MADIT), 15, 68–69
Multifocal atrial tachycardia, 341f, 351
Multivessel ischemia, 315, 331, 332
Murmur. (see also specific conditions)
of aortic insufficiency, 322
Muscular pain, 164, 175
Muscular VSD, 197
Mustard procedure, 199, 212, 213t
MVR. (see Mitral valve replacement)
Myocardial contractility, improvement with digoxin, 107, 117, 185
Myocardial infarction (MI), 111, 120
ACE inhibitors, 57, 67
acute, 54–70
age and revascularization benefit, 60, 69, 70
aspirin, 54–58, 55, 65, 66
cardiogenic shock, 57, 67
cocaine abuse and, 66, 70
diabetes and, 57, 67
diagnosis, 73, 92
implantable cardioverter defibrillator (ICD), 59, 68–69
lidocaine, 59, 68–69
magnesium, 57, 67
mechanical complication of, 23, 44
mitral regurgitation and, 60, 69
pain before, 129–131, 148
pericarditis and, 60, 69
plaque rupture, 54, 65
post-MI atrial fibrillation, 190, 195
stent placement, 56, 66
streptokinase, 55, 66
ST-segment elevation (STMI), 56, 57, 65, 66
management of, 111, 120
target vessel revascularization, 56, 66
TIMI, 55, 65, 66
ventricular septal rupture, 57–58, 67

warfarin, 57, 59, 67
Myxedema, 338
Myxomatous mitral valve disease, 305, 309f, 324–326, 324f–326f

Na+/K+-adenosine triphosphatase, inhibition by digoxin, 107, 117
Narrow complex tachycardia, 340f, 341f, 351
adenosine reduction for, 1, 13
National Health and Nutrition Examination Survey (NHANES) data, 250, 260
NCEP ATP III guidelines, Framingham Risk Score (FRS) limitations, 251
Nesiritide
contraindications, 113–114, 122
side effects of, 182, 193
Neutropenia, from ticlopidine use, 110, 119
New York Heart Association class III heart failure, 114, 123
New York Heart Association class III limitations, 197
Nimodipine, for subarachnoid hemorrhage, 107, 117
Nitric oxide, 226, 269
Nitroprusside, 234, 235, 238, 244
for hypertension, 113, 122
indications for, 183, 194
Non-HDL-C goals, cardiovascular event rate, 262
Non-ST-elevation myocardial infarction (NSTEMI), 165, 169, 176, 177
Nonsteroidal anti-inflammatory drug
for pericarditis, 276–278, 292
for post-MI pericarditis, 59, 69
Nonsteroidal anti-inflammatory drugs, 157, 171
Noonan's syndrome, 202, 210, 222–223, 223t, 224
Norwood procedure, 213t
NSAID. (see Nonsteroidal anti-inflammatory drug)
NYHA Class IV heart failure, 110, 120

Obstructive lung disease, differential diagnosis, 280, 292, 293
Obstructive pulmonary disease, 134, 149
Occluded Artery Trial (OAT), 67, 99
Omega-3polyunsaturated fatty acid supplements, 252, 263
Ormond's disease, 141, 153
Oropharynx, 140–141, 140f, 153, 153t, 154
Osteoarthritis, 231
Osteogenesis imperfecta, 134, 149
Overdiuresis, 279, 293

Pacemaker
atrial undersensing, 6, 6f, 17
indications for, 19, 20
mode switch behavior, 8, 18
tachycardia induced by, 6–7, 18
Pacemaker syndrome, 5, 17
Paclitaxel-eluting stent, 91–92
Papillary muscle rupture, 23, 44
Paradoxical embolism, 205
Patent ductus arteriosus (PDA), 136, 150–151, 200, 202, 213
Patent foramen ovale (PFO), 205, 212

Patients with Acute Coronary Syndromes (PLATO) trial, 105, 116
PCI. (see Percutaneous coronary intervention)
PDA. (see Patent ductus arteriosus)
Pelvis, CT venogram of, 163, 175
Penetrating aortic ulcer, 130, 148
Penicillin, 115, 123
Percutaneous coronary intervention (PCI), indications for, 181, 182
Percutaneous coronary revascularization, 74, 93–94
Percutaneous mitral valvuloplasty (PMV), 298, 320
Percutaneous transluminal angioplasty, 157, 171
Pericardial cyst, 282, 283f, 294
Pericardial disease, 276–295. (see also specific conditions)
  cardiac catheterization in, 278, 293
  diagnosis, 292
  restrictive, diagnosis of, 279, 294
Pericardial effusion
  aortic dissection and, 283, 283f, 294–295
  causes of, 287, 295
  diagnosis, 61
  echocardiography, 283
  rheumatoid arthritis and, 287, 288f, 295
Pericardial friction rub, 277, 287, 288f, 295, 297
Pericardial hematoma, 284, 284f, 295
Pericardial tumor, 291, 295
Pericardial valve, bovine, 39, 51
Pericardiectomy, indications for, 277, 287, 288f, 293, 295
Pericardiocentesis, 127, 146, 277, 285, 288, 289, 290, 290f, 295, 323
Pericarditis
  constrictive
    diagnosis, 190, 195
    diagnosis of, 276–277, 292
    ECG findings, 279, 279f, 294
    myocardial infarction and, 60, 69
    uremia-related, 284–285, 285f, 295
  myocardial infarction and, 60, 69
Pericardium, congenital absence of the, 286–287, 287f, 295
Peripheral arterial disease (PAD), 164, 175–176, 232, 241, 267
Peripheral vascular disease, 156–177
Permanent junctional reciprocating tachycardia (PJRT), 2, 14
Peroneal vein, thrombosis of, 162, 174
Persistent left superior vena cava (SVC), 202
PET. (see Positron emission tomography (PET) scan)
PFO (patent foramen ovale), 205, 212
Pharmacodynamics, 105, 116
  defined, 105, 116
Pharmacogenetics, 105, 116
  defined, 105, 116
Pharmacokinetic parameters, 105, 116
Pharmacokinetics, 105, 116
Pharmacology, 105–123. (see also specific drugs)
  defined, 105, 116

disease conditions
acute coronary syndromes, 111–112, 119–120
endocarditis, 114–115, 123
heart failure, 113–114, 122–123
hyperlipidemia, 112–113, 121–122
hypertension, 113, 122
drug classes
angiotensin-converting enzyme (ACE) inhibitors, 106, 116–117
antiarrhythmic agents, 110–111, 120
anticoagulation, 109–110
antiplatelet agents, 110, 119
beta-blockers, 106–107, 116–117
calcium channel blockers (CCBs), 107, 117
diuretics, 107, 117
inotropic agents, 107–108, 117
pharmacokinetics and pharmacodynamics, 105–106, 116–117
Phentolamine, 236
use in hypertension, 236, 246
Pheochromocytoma, 236, 245
Phlebotomy, contraindications for, 197, 211
Physiologic cold response, 158, 171
Physiology, 226–228
Pindolol, properties of, 106–107, 114, 117
PJRT (permanent junctional reciprocating tachycardia), 2, 14
Plaque rupture
arterial thrombosis after, 226, 228
pathogenesis, 54, 65
Platypnea-orthodeoxia, 205
Pneumohydropericardium, 289–290, 289f, 295
Pneumopericardium, 288, 289f, 290, 295
Polygenic hypercholesterolemia, 249, 260
Polysomnography, 237, 247
Popliteal artery aneurysms, 166, 166f, 167, 176
Positron emission tomography (PET) scan
coronary artery disease, 315–316, 316f, 331
hibernating myocardium in LAD territory, 314–315, 315f, 331
indications for, 182, 192
multivessel ischemia, 315, 316f, 331
Postinfarction pericarditis, 282, 294
Potency, 106, 116
Potts procedure, 213t
Prasugrel, for acute myocardial infarction, 55, 67
Pravastatin use with amiodarone, 106, 116
Preeclampsia, 230, 239
Pre-excitation (Wolff-Parkinson-White) syndrome(s), 336, 353
Pregnancy, 160, 173
absolute contraindication, 199
fatal pulmonary embolism, 160, 173
Premature ventricular contractions (PVCs), 335
drugs for suppression of, 13
Procainamide, 105, 116

for atrial fibrillation, 11, 20–21
loading dose, 105, 116
Progressive exertional dyspnea
diagnosis, 159, 172
IV epoprostenol, 159, 172
pulmonary arteriogram, 159, 172
Prolonged QT interval, ECG, 338
Prominent central pulmonary arteries (PAs), 203
Propafenone
for atrial fibrillation, 1, 13
contraindications, 21
hepatic elimination, 13
Prophylaxis, 114, 123
Propranolol, properties of, 106–107, 114, 117
Prosthetic valve abscess, 33, 47
Protamine, antagonism of, 109, 118
Protease inhibitors, 252, 270
Protein-losing enteropathy, 210, 222
Pseudoaneurysm, 167, 167f, 176
Pseudoclaudication, 164, 175
Pseudomonas, 305, 324
Pulmonary arteriovenous fistula, 210, 232
Pulmonary artery hypertension, 159, 172
Pulmonary artery stenosis, 223t, 224t
Pulmonary atresia, 199
Pulmonary embolism, 159, 169–170, 170f, 172, 177
Pulmonary embolus, 303, 322
Pulmonary endarterectomy, 159, 172
Pulmonary hypertension, 208
Pulmonary regurgitation, 209
Pulmonary stenosis, 209, 210, 220, 221, 222, 224, 232
Pulmonary vasodilator, 205
Pulmonary venous drainage, anomalous, 202, 214
Pulmonary venous return, anomalous, 215–216, 216f
Pulmonic stenosis, 200, 209
echocardiography, 42–43, 52, 257f
Noonan syndrome and, 210, 222
percutaneous valvuloplasty, 43, 52
Pulsus paradoxus, 191
PVCs. (see Premature ventricular contractions)
P-wave, 346f, 353
abnormalities, 334

QRS voltage, abnormalities of, 336
Quadricuspid aortic valve, echocardiography, 203, 215
Quinidine, 1, 13
Q waves, 344f, 352

Radial artery, rigid, noncompressible, 97
Ramipril, 231, 232, 241
aspirin use with, 186, 194
Rash, 110, 119

Rashkind procedure, 199, 212, 213t
Rastelli procedure, 213t
Raynaud phenomenon, diagnosis of, 158, 171
RBBB. (see Right bundle branch block)
RCA. (see Right coronary artery)
Regular narrow QRS tachycardia, 3, 14
Relapsing polychondritis, 131, 148
Renal impairment, 171
Renin inhibitor, 233, 241
Respiratory diseases, 109, 119
Resuscitation, out-of-hospital cardiac arrest, 4, 16
Reteplase, 56, 64, 66
Revascularization
  endovascular, 156–157, 171
  procedure, 157, 171
Reverse Allen test, 158
Reverse transcriptase-polymerase chain reaction (RT-PCR), 226, 228
Rhabdomyolysis, 112, 121
  complications of, 112, 121
  risk of, 112, 121
Rheumatic MV disease, 311, 328
Rheumatoid arthritis, pericardial effusion and, 268, 287, 288f, 295
Right atrial (RA) thrombus, 299, 321
Right axis deviation, ECG, 236, 251
Right bundle branch block, 9, 19, 342f, 351
  anterior hemiblock, 342f, 352
Right coronary artery (RCA), 142, 142f, 154
Right foot pain, 156, 171
Right internal carotid artery stenting, 165–166, 176
Right knee swelling, 166, 166f, 176
  dignosis, 166, 176
Right-sided aortic arch, 136–137, 137f, 151
Right-sided lesions, 208
Right upper sternal border (RUSB), 136–137, 137f, 151
Right ventricular hypertrophy (RVH), 341f, 347f, 351, 353
Ross procedure, 199, 212, 213t
RT-PCR (reverse transcriptase-polymerase chain reaction), 226, 228
Rubella, congenital malformations associated with, 212, 224t
RV impairment, 282, 294
RVOT obstruction, 214

Saddle pulmonary embolism, 177
Sagittal delayed enhancement, 126f
Sagittal oblique, 133, 133f, 149
Saphenous vein grafts, prognosis for atherosclerotic progression, 94, 98, 228
Scandinavian Simvastatin Survival Study (4S), 250
Sclerae, blue, 149
Senning procedure, 199, 212, 213t
Septal defects. (see Atrial septal defect; Ventricular septal defect)
Septal myectomy, 312, 330
Serial duplex ultrasound scans, 164, 175

Shone syndrome, 210, 224
Shortness of breath, 163, 175
Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) trial, 68, 70, 76, 95
Sick sinus syndrome (SSS), 5, 7, 9, 17
Simon Broome Register Group, 250, 260
Simvastatin, 106, 112, 116, 181, 183, 187
Single photon emission computed tomographic (SPECT), 100
Sinus arrhythmia, sinus bradycardia with, 349f, 354
Sinus bradycardia, 339f, 345f, 350, 352
  degree of QT prolongation, 340f, 351
  with sinus arrhythmia, 349f, 354
Sinus infection, 114
Sinus rhythm, 110, 111, 120, 339f, 345f, 350, 352
  2:1 AV block, 343f, 352
  with AV dissociation, 350f, 354
  first degree AV block, 342f, 351
  first-degree AV block, 349f, 354
  inferior Q waves, 345f, 353
  lateral T-wave changes, 344f, 352
  lateral T-wave flattening, 348f, 354
  P wave, 346f, 353
  and right axis deviation, 347f, 353
  small Q waves, 344f, 352
  ST elevation, 343f, 352
  T waves, 346f, 353
Sinus tachycardia, 339f, 350
Sirolimus-eluting stent, 92
Skin lesion, 168, 168f, 177
Sleep apnea, 232, 241, 247
  obstructive, 156, 232, 241
Sleep study, overnight, 247
Smooth muscle cell proliferation, inducers of, 227, 228
Sodium
  for amitriptyline overdose, 6, 17
  channel blocker, 2, 14
  depletion, 106, 116–117
Sotalol
  contraindications for, 21
  excretion, 13
  ionotropic effects, 13
Spectral waveform analysis, 161, 173
Spironolactone, benefits of, 184, 195
Splenectomy, pulmonary hypertension and, 158
SSS (sick sinus syndrome), 5, 7, 9, 17
Stable angina, 54, 72, 74
Stable angina, risk stratification, 72, 83, 261
Staphylococcus epidermidis, endocarditis and, 43, 52
Statin, 135, 150
Statin therapy, 255–258
Stenotic lesion, 157, 171
Stent

for acute coronary syndrome, 56, 66
effects of exercise training after, 90
in-stent restenosis, 72, 92
placement, venography for, 162–163, 174
thrombosis, 69
Steroid therapy, 277, 278, 292
Streptococcus viridans, endocarditis and, 43, 52
Streptokinase, for myocardial infarction, 55, 66
Stress echocardiogram, 138, 152
Stress echocardiography, 138, 152
Stress test, aortic regurgitation, 41, 51
ST-segment elevation, 73
ST-segment elevation myocardial infarction (STMI), 56, 57, 66, 67
Subaortic membrane, 208, 215, 312, 330
Subarachnoid hemorrhage, 107, 117
Subclavian artery stenosis, 167, 168f, 168f, 177
Subendocardial ischemia, 72, 92
subvalvular aortic stenosis, 208
Sudden cardiac death
CAD association with, 4, 16
medications for prevention of, 4, 16
Sulfonamide allergy, 107, 117
Superficial vein thrombosis, 157, 171
Superior vena cava, persistent left, 202, 214
Supracristal VSD, 307, 328
Suprasternal notch (SSN), 131, 132f, 149
Supravalvular aortic stenosis, 202, 214
Supravalvular pulmonary stenosis, 136, 150–151
Supravalvular pulmonic stenosis, 202, 214
Supraventricular arrhythmia, aberrant intraventricular, 235, 237f
Supraventricular rhythms, 334–335
Syncope
evaluation of, 4, 5, 16, 19, 20
pacemaker placement for, 6, 17
treatment of vasovagal, 4, 16
Systemic venous pressure, evaluation of elevated, 191, 195, 222

Tachycardia, 163, 175, 346f, 353
atrioventricular nodal reentrant tachycardia (AVNRT), 5, 16, 21
atrioventricular reentrant tachycardia (AVRT), 2–3, 14, 15
induced by EP testing, 12, 12f, 21
narrow complex, adenosine reduction for, 1, 13
pacemaker, 6–7, 18
permanent junctional reciprocating tachycardia (PJRT), 2, 14
regular narrow QRS, 3, 14
supraventricular tachycardia differentiated from, 10, 20
Takayasu's arteritis, 126, 131, 143, 148, 162, 174
Tamponade. (see Cardiac tamponade)
Target vessel revascularization, decrease with stent use, 56, 66
TdP (torsades de pointes), 9, 20
TEE. (see Transesophageal echocardiography)

Terazosin, use in hypertension, 236, 244
Tetralogy of Fallot (TOF), 137, 151, 198, 202, 208, 209, 213, 223t
TEVAR, 141, 154
Theophylline, adenosine antagonism by, 13, 18
Thiazide diuretic, 165, 176, 233, 234–235, 236, 237, 238, 241, 242, 243, 244, 245
Thrombin
  inhibitors of, 110, 120
Thromboangiitis obliterans, 162, 174
Thrombocytopenia, 110, 120
  from glycoprotein IIb/IIIa inhibitors, 110, 120
  heparin-induced, 110, 119
Thrombocytopenic purpura, thrombotic, 110, 120
Thromboembolic events, 210
Thromboembolism, 160, 167, 173, 176
Thrombolysis in Myocardial Infarction (TIMI), 55, 65, 66
Thrombolytic therapy
  contraindications, 112, 121
  risk for intracranial hemorrhage, 111, 121
Thrombosis stent, 69
Thrombotic thrombocytopenic purpura, 110, 120
Thrombus removal, 162–163, 174
  venography for, 162–163, 174
Ticagrelor, 109, 119
Ticlopidine, 110, 120
  antiplatelet effects, 110, 120
  versus clopidogrel, 110, 120
  side effects, 110, 120
TID (transient ischemic dilation), 331
TIMI. (see Thrombolysis in Myocardial Infarction)
Tissue factor, 226, 228
Tissue gangrene, 156–157, 171
Tissue plasminogen activator (tPA)
  mortality and, 67
  for myocardial infarction, 56
Tobacco abuse, 162, 174
Torsades de pointes (TdP), 9, 20
Toxicology screen, 234, 243
TPA. (see Tissue plasminogen activator)
TR. (see Tricuspid regurgitation)
Transesophageal echocardiography (TEE), 304–305, 307f, 323, 323f–324f
  aortic aneurysm, 312–313, 313f, 330, 330f
  left ventricular thrombus, 312–313, 313f, 330, 330f
  mechanical complication of myocardial infarction, 23, 44
  mitral insufficiency, 36, 49
  mitral leaflet perforation, 305–306, 306f, 324–326, 325f–326f
  mitral regurgitation with systolic anterior motion, 305–306, 309f, 324–326, 325f–326
  pericardial hematoma, 284, 284f, 295
  prior to percutaneous valvuloplasty, 25–26, 46
  prosthetic valve abscess, 33, 47
  subaortic membrane, 312, 312f, 330
Transforming growth factor (TGF)-β, 127, 145–146, 153, 227, 228, 254

Transient ischemic dilation (TID), 331
  cleft mitral valve, 304–305, 305f, 311, 312f, 323f
  coarctation of the aorta, 304–305, 305f, 323
Transmural myocardial infarction, 337
Transposition of great vessels, 137, 151
Transthoracic echocardiogram (TTE), 125
Transthoracic echocardiography (TTE), 127, 134–135, 146, 149–150
  aortic dissection, 283, 283f, 294
  cardiac tamponade, 287, 287f, 295
  mitral regurgitation, 44
  pericardial cyst, 282, 293f, 294
  pericardial effusion, 61, 285–286, 286f, 287, 288f, 295
  pericardial hematoma, 284, 284f, 295
Tricuspid atresia, 199
Tricuspid regurgitation (TR), 197, 312, 330
  diagnosis, 191, 195
  pulmonary hypertension as cause of, 43, 52
Tricuspid stenosis
  carcinoid syndrome, 26, 45
  diagnosis, 39, 51
Tricuspid valve, 208
  atresia, surgical procedure for, 199, 210
  regurgitation (see Tricuspid regurgitation)
  replacement with bioprosthetic valves, 43, 52
  stenosis (see Tricuspid stenosis)
Trisomy 21 (Down syndrome), 210, 223
Truncus arteriosus, 137, 151
T-segment-elevation, 112
TTE. (see Transthoracic echocardiography)
Tuberculous pericarditis, 278, 293
Turner syndrome, 131–133, 148–149
T-waves, 346f, 353
  changes, 344f, 352
  flattening, 348f, 354

Ulceration, etiology of, 156, 171
Ulcer, in chronic venous insufficiency, 156, 171
Unfractionated heparin (UFH), 108, 118
United States Preventive Services Task Force (USPSTF), 139, 152
Unroofed coronary sinus, 206
Unstable angina (UA), 54, 71
Urinary catecholamines, 230
Urine metanephrines, 234, 243
U.S. Food and Drug Administration, 206

Valvular aortic stenosis, 208
Valvular calcification, 208, 219
Valvular heart disease, 23–52. (see also specific disorders)
Valvuloplasty
  balloon for aortic stenosis, 39, 51
  percutaneous indications for, 37, 50
  for pulmonic stenosis, 42, 52

transesophageal echocardiogram prior to, 30, 46
Vancomycin, 115, 123
Vasodilator for bicuspid aortic valve and left ventricular dilatation, 27, 45
Vasopressors, 193, 194
Vasovagal syncope
classification of, 6, 17
evaluation of, 6, 17
treatment of, 4, 16
Venography, for thrombus removal and stent placement, 162, 174
Venous duplex, 157, 162, 174
ultrasound, 164, 175
Venous insufficiency, chronic, 156, 171
Venous thromboembolic disease, 160, 173
Venous valvular incompetence, 163
Ventricular fibrillation (VF), 111, 120
amiodarone for, 110–111, 120
in out-of-hospital cardiac arrest, 4–5, 16
Ventricular septal defect (VSD), 128, 147, 197, 199, 200, 206, 209
classification, 218t
Ventricular septal rupture, 57–58, 67
Ventricular tachycardia (VT), 107, 117, 208
supraventricular tachycardia differentiated from, 10, 20
treatment of, 3, 15
Ventriculoarterial discordance
Verapamil, 107, 117, 227, 234, 240, 246, 270
contraindications, 1, 13, 18
effect on digoxin levels, 105, 116
properties of, 117
use in chronic obstructive pulmonary disease, 6–7
for Wolff-Parkinson-White syndrome, 2–3, 14
Veterans' Administration Heart Failure Trial (V-HeFT) II, 106, 116–117, 181, 192
VF. (see Ventricular fibrillation)
Vitamin K, 108, 118
antagonists, 160, 162, 172
VSD. (see Ventricular septal defect)
VT. (see Ventricular tachycardia)
Vulnerable plaque, 226, 228

Warfarin, 108, 118, 160, 173
for atrial fibrillation, 57, 59, 67
drug interactions, 112
ethanol effect on metabolism, 106, 116
indications, 108, 118
metabolism, 106, 116
for myocardial infarction, 57, 59, 67
skin necrosis, 168, 168f, 177
systemic anticoagulation with, 135, 135f, 150
Waterston procedure, 213t
Weber-Osler-Rendu syndrome, 210, 212, 222
West of Scotland Coronary Prevention Study (WOSCOPS) trial, 250–251, 261
Whirlpool therapy, 163, 174

White coat hypertension, 235, 244
Williams syndrome, 136, 150–151, 202, 210, 222
Wolff-Parkinson-White syndrome
  procainamide for atrial fibrillation in, 11, 20–21
  verapamil use, 1, 14
